traits on the basis of preimplantation screening, etc. Some of the critiques argue that science cannot be left to scientists and the general public must be vigilant and reserve the decision-making for itself. Some “scientists” also support this view. The problem with this view is that how can the layperson make decisions without being fully familiar with a particular field of science. A solution appears to be to increase the continuous education on the progress of science. The motives behind the accusations are frequently sensationalism and/or attempts to gain political and financial advantage. ►atomic radiation, ►radiation effects, ►chemicals hazardous, ►environmental mutagens, ►biological containment, ►genetic engineering, ►selection conditions, ►mutation, ►eugenics, ►nuclear transplantation, ►ART, ►GMO, ►bioethics, ►ethics, ►informed consent, ►public opinion; Reilly PR 2000 Annu Rev Genomics Hum Genet 1:485; American Society of Human Genetics, Commentary 2002 Am J Hum Genet 70:1; for a biased negativism see Bowring F 2003 Science, Seeds and Cyborgs: Biotechnology and the Appropriation of Life. Verso Books, New York.

Crk: An adaptor protein in a signal transduction pathway, and containing SH2-SH3-SH3 domains. It requires phosphorylation between the two SH3 domains (by the Abl tyrosine kinase). ►signal transduction, ►SH2, ►SH3, ►abl; Feller SM 2001 Oncogene 20:6348.

CRM: Cross-reacting material is a serologically identifiable protein (generally the product of a gene that fails to display enzyme activity). CRM[−] designates a phenotype without an immunologically detectable protein. ►immune response

CRM (cis-regulatory module): ►cis, ►module, ►cis-regulatory module

CRM1/XPO1 (exportin): A nuclear protein, which mediates the export of polypeptides with Leu-rich sequences of the nuclear export signals (NES). It works in cooperation with RanGTP. ►nuclear pore, ►RAN, ►nuclear export sequences, ►nuclear localization complex, ►snRNA; Fornerod M et al 1997 Cell 90:967; structure: Petosa C et al 2004 Mol Cell 16:761.

CRMP-62 (collapsin response mediator protein): A M_r 62 K protein required for axon extension in chickens and *Xenopus*. ►collapsin, ►UNC-33; Ricard D et al 2001 J Neurosci 21:7203.

crRNA: (complementary RNA): A DNA transcript. ►cDNA

Cro repressor: The *cro* repressor of the λ phage, cooperatively with *cI*, regulates lysogeny. ►lambda phage

Crocodile: ►alligator

Crohn Disease (CD, regional enteritis, 14q11-q12): CD, an autosomal recessive inflammation of the bowel, is a familial condition because 10% of the affected individuals have relatives with the same affliction yet the genetic control is unclear. Ashkenazi Jews have increased (2–4 fold) risk to this disease. It is likely that more than a single genetic factor is involved in Crohn disease. A recessive gene for inflammatory bowel disease (IBD1) is located at 16p12-q13. Within this site, mutations in the NOD2/Apaf gene have been identified. The wild type allele of this gene activates NF-κB that senses the presence of bacterial lipopolysaccharides. Some NOD2 variants may alter thus the susceptibility to bacteria. TNF-α has been implicated in the symptoms. Genetic factors for CIBD and ulcerative colitis (UC) have been located also to human chromosomes 3p26, 7q and 21. The 7q region includes the MDR1 (multidrug resistance locus), besides one form of Crohn disease, and the similar but not identical ulcerative colitis (Brant SR et al 2003 Am J Hum Genet 73:1282). Two new bowel diseases have been mapped to 5q31-q33 (Rioux JD et al 2001 Nat Genet 29:223) and 19p13 (Rioux JD et al 2000 Am J Hum Genet 66:1863). At 1p31, the IL23R gene encodes a subunit of the receptor for proinflammatory interleukin-23 (Duerr RH et al 2006 Science 314:1461). GWA revealed involvements also of an intergenic region on 10q21.1 and a coding variant in ATG16L1, which is expressed in intestinal epithelial cell lines and whose functional knockdown abrogates autophagy of *Salmonella typhimurium*, suggesting that autophagy and host cell responses to intracellular microbes are involved in the pathogenesis of Crohn disease. There were also strong associations in the genomic regions encoding the paired-like homeobox (PHOX2B, 4p12), neutrophil cytosolic factor (NCF4, 22q13.1), and a predicted gene at 16q24.1 (Rioux JD et al 2007 Nat Genet 39:596). Some studies indicate the presence of *Mycobacterium paratuberculosis* RNA sequences in the clinical samples obtained from patients. The drinking water may be the source of infection. The cause of the disease is probably the immune system's aggravated reaction to intestinal bacteria (Cominelli F 2004 New Engl J Med 351:2045). ►Apaf1, ►cadherin, ►TNF, ►CIBD, ►CARD, ►NEMO, ►Blau disease, ►multidrug resistance; Parkes M et al 2000 Am J Hum Genet 67:1605; Ogura Y et al 2001 Nature [Lond] 411:603; Lawrance IC et al 2001 Hum Mol Genet 10:445; Sugimura K et al 2003 Am J Hum Genet 72:509; Schreiber S et al 2005 Nat Rev Genet 6:376;

<http://www.niddk.nih.gov/health/digest/pubs/crohns/crohns.htm>.

Cro-Magnon Men: ►Neanderthal people

Crop Plants: Barley, wheat, potato and pea EST and annotations:

<http://pgrc.ipk-gatersleben.de/crest/>; ►legumes, ►plant genomics database, ►EST, individual plants.

Cross: Mating between individuals of not-identical genetic constitution.

Cross Breeding: ►cross-fertilization

Cross Feeding: ►channeling, ►syntrophic

Cross Fertilization (allogamy): Cross fertilization takes place when the sperm and the egg of two different individuals of different genotypes are combined in the zygote.

Cross Fostering: A procedure to test how much of a behavioral trait is hereditary and how much of it is due to the influence of the postnatal environment. Pups are separated from the natural mother and are given to foster mothers belonging to another inbred strain and then the behavioral differences compared with those individuals, which were reared with the birth mother.

Cross Presentation (cross-presentation, cross-priming): The transfer of antigen from antigen-bearing cell to antigen-presenting cell (dendritic cell). It is called cross presentation because the antigens are not directly transferred to the T cells. The process may involve phagosomes and MHC class I- but also class II-restricted antigens. The phagosomal pH is regulated by NOX2 (NSDPH oxidase). In the absence of NOX2, the dendritic phagosomal lumen is acidified, degradation is increased, and cross-presentation is impaired (Savina A et al 2006 Cell 126:205). The result of cross-presentation may be either cross-priming of the cytotoxic T cells or T cell tolerance (cross tolerance). Cross presentation may involve many types of antigens, e.g., tumors, grafts, viruses, and even self tissues or enzymes and other proteins delivered by cell adsorption. A high dose of the antigen is favored. Cross presentation occurs with a few days delay of the host compared what occurs with professional antigen presenting cells. Cross presentation is different from the mechanism used by professional antigen presenting cells. ►antigen presenting cell, ►MHC, ►T cell, ►phagocytosis; Heath WR, Carbone FR 2001 Annu Rev Immunol 19:47; Houde M et al 2003 Nature [Lond] 425:402.

Cross Protection: ►host-parasite relations

Cross-Sectional Study: The assessment of a condition in pairs of monozygotic and dizygotic twins at a particular time. ►longitudinal study

Cross-Species Color Segmentation: In cross-species color segmentation, FISH stained chromosomes (fragments) of one species are hybridized to another species to reveal a cross-species pattern. ►FISH

Cross Sterility: ►incompatibility alleles

Cross Validation: Cross validation tests whether the results from one population can be generalized for another.

Cross-β Spine: The X-ray diffraction pattern shown by fibrils. The fibril is a set of parallel β sheets (with amino acid sequences GNNQQNY and NNQQNY) of protein that are perpendicular to the axis. Amyloid fibers of prions and other amyloid-like fibrils share this general feature. Such stacks are stabilized by side chains protruding from two β sheets, and contribute to the stability of amyloid fibers as well as to their characteristics of self-replication and to the formation of polymorphic structures. ►prions; Nelson R et al 2005 Nature [Lond] 435:773; Krishnan R, Lindquist SL 2005 Nature [Lond] 435:765; Ritter C et al 2005 Nature [Lond] 435:844.

Crossing: Mating of two parental types of different genetic constitution.

Crossing Barrier: ►incompatibility, ►incompatibility alleles

Crossing Over: The process of reciprocal exchange between chromatids. Genes within a pair of homologous chromosomes may be linked in two fashions, either by coupling or by repulsion (see Fig. C183).

Figure C183. Coupling and repulsion

Independent segregation observed by Mendel has the limitation that the linkage and association of genes within a chromosome is not absolute either, because crossing over and recombination may separate genes depending on their genetic (physical) proximity. Chiasmata during meiotic prophase is the physical basis of crossing over (the exchange between chromatids), and this is then detected in the genetic segregation as recombination. Crossing over takes place at the 4-strand stage, i.e., when each of the bivalents is composed of two chromatids associated at the centromere. This is the tetrad stage of the meocyte. A single crossing over between two genes within a tetrad creates two reciprocally

recombinant chromatids for exceptions ► **gene conversion** whereas the other two chromatids remain unaltered (parental). Since 2/4 chromatids are cross-overs, the frequency of recombination caused by a single crossing over event is 50% for that particular tetrad. Each individual heterozygous for linked genes has numerous meocytes and crossing over does not take place in all of them at the same time, therefore, in a population of meocytes the frequency of crossing over may vary from 0 to 50% depending on the genetic distance between the genes. The maximal frequency of recombination in meiosis is thus 50%. Occasionally, recombination higher than 50% has also been observed in apparent contradiction to the principle described. This higher-than 50% value does violate the principle because it is the result of selection during or after meiosis and gametogenesis or fertilization. 1% recombination is considered, by convention, for 1 genetic map unit (m.u) or 1 c.M. (centiMorgan). More than a single crossing over may take place simultaneously within a single meocyte. A single crossing over, however, always produces 50% recombination. If a second crossing over occurs within the same genetic interval, it may prevent the genetic detection of the first crossing over event because the second crossing over may restore the non-crossover type arrangement of the genes. The third crossing over within the same interval restores again the recombinant arrangement of the genes demarcating that interval (see Fig. C184):

Figure C184. Parental, single crossover, second crossover and third crossover

Figure C185. Two-strand, three-strand and four-strand crossing over. Two-strand, three-strand and four-strand crossing over occur normally in the proportion of 1:2:1 (in the absence of chromatid interference). The frequency of recombination by all four types of double crossing over events combined is 50%

Thus each odd numbered crossover generates detectable recombinants and the even numbered ones restore the original linkage phase of the alleles. Since multiple crossing overs are expected to occur at the product of the frequencies, double crossing within a meocytes does not usually affect the other meocytes.

Therefore, if the frequency of a single crossing over is 0.30, double crossing over occurs by 0.30^2 , and triple crossing over by the frequency of 0.30^3 . Thus, if after the first crossing over the frequency of Ab + aB gametes is 0.30, after the second event it may be $0.30 - 0.30^2 = 0.21$, and after the third event $0.30 - 0.30^2 + 0.30^3 = 0.237$. The incidence of crossing overs may not occur as predicted by probability but the first crossing over may hinder the occurrence of a second one (positive interference) or it may stimulate it (negative interference). Double crossing over may involve two, three, or four strands within a meocyte (see illustration next page). In yeast, each bivalent has at least one crossing over and usually not more than two. The probability of non-crossing over is commonly less than 0.1%. Usually crossing overs are not near each other see Fig. C185).

Recombinational interactions are large but only a few of them progress to develop into crossovers (minimization). Non-crossover interactions exceed actual crossovers by a factor of two in *Neurospora*, four in *Drosophila* and based on the number of early recombination nodules in onions, the excess may be 30–40. It appears that the decision about crossing

over is made before the formation of the synaptonemal complex, but the resolution of the Holliday junctions is delayed by or after pachytene.

Crossing over is generally limited to meiosis when the homologous pairs of chromosomes pair.

The chromosomes of some organisms, or under certain circumstance, may pair also during mitoses, and this may result in somatic recombination. Mitotic crossing over resembles the meiotic event but the mechanism of exchange may not be identical. ▶coefficient of crossing over, ▶cytological evidence for crossing over, ▶oblique crossing over, ▶time of crossing over, ▶models of recombination, ▶recombination frequency, ▶mapping, ▶mapping function, ▶mitotic recombination, ▶coincidence, ▶interference, ▶tetrad analysis, ▶chromosome pairing, ▶synapsis, ▶chiasma, ▶meiosis, ▶mitotic crossing over, ▶crossover, ▶sperm typing, ▶recombinational nodule, ▶association point, ▶pachytene, ▶Holliday juncture, ▶Holliday model, ▶recombination mechanism eukaryotes; review of mechanisms in plants: Mézard C et al 2007 Trends Genet 23:91.

Crossing Over Male: ▶male recombination

Crossing Over Modifiers: ▶the various *Rec* alleles

Crossing Over, Oblique: If the duplicated chromosomal region is obliquely paired, recombination may take place in between the segments in the following way (see Fig. C186):

Figure C186. Oblique crossing over

Such an event may also lead to increase or decrease of the chromatin and cause position effect. ▶*Bar*, ▶position effect, ▶unequal crossing over

Crosslink: Various carcinogens and mutagens (nitrogen mustards, mitomycin C, psoralen dyes, cisplatin, etc.) cause DNA inter- and intrastrand crosslinks. These lesions are repaired by ABC excinucleases, which generate dual incisions and repair DNA synthesis. ▶ABC excinucleases, ▶nitrogen mustards, ▶mitomycin C, ▶psoralen dyes, ▶cisplatin

Cross-Linking: Cross-linking is the establishing of bonds between two molecules or linking together by covalent bond nucleotides in the same DNA or RNA. Chemical cross-linking agents are, e.g., bis-(2-chloroethyl)-methylamine and other mutagens and carcinogens (particularly the alkylating agents). The

resulting quaternary structure leads to disruption of DNA functions. UV light can also produce cross-linking within and between nucleic acids and proteins. ▶alkylating agents, ▶DNA repair, ▶pyrimidine dimers; Kuraoka I et al 2000 J Biol Chem 275:26632; De Silva IU et al 2000 Mol Cell Biol 20:7980; Dronkert ML, Kanaar R 2001 Mutation Res 486:1053.

Crossover: Recombinant chromatids, chromosomes, or individuals, originated by genetic exchange between homologous chromosomes through the process of crossing over. The cross-overs can be single or multiple. ▶crossing over, ▶recombination, ▶mapping function, ▶coincidence, ▶crossover fixation, ▶mapping genetic, ▶noncrossover recombinant

Crossover Connection of a Protein: Structural cores are connected by opposite ends of the cores across the surface of the domain.

Crossover Fixation: A hypothesis that explains the relative homogeneity in repeat units of satellite DNA. According to this model, the repeats can undergo frequent unequal crossing overs during short evolutionary periods and then the same unit may be either propagated or eliminated after the recombinational event. If maintained, it can account for the homology of the sequences because there was not enough time yet to accumulate mutations even in the sequences that are not coding and are exempt of selection pressure. ▶crossing over, ▶crossover, ▶satellite DNA, ▶unequal crossing over; Fletcher HL, Rafferty JA 1993 J Theor Biol 164:507.

Crossover Interference: ▶chromosome interference

Crossover Suppressor: During the early days of *Drosophila* genetics, parental inversions were erroneously considered crossover suppressors in the progeny. Actually, in most of the cases the duplication or deficiency strands (generated by recombination within the inversion strands) of the inversion heterozygotes were not transmitted or caused lethality rather than suppressing crossing over *per se*. In the close vicinity of the inversion breakpoints, chiasmata is usually reduced, however, this is a different phenomenon. ▶inversion

Cross-Pathway Regulation: As per the cross-pathway regulation, the biosynthesis of several different amino acids is coordinately regulated in fungi. ▶tryptophan operon, ▶channeling

Cross-Priming: In cross-priming, antigens are obtained from *donor* cells by bone-marrow-derived antigen presenting cells and delivered to cytotoxic T

C

lymphocytes (CTL) on MHC class I molecules. Most commonly, CTLs recognize antigens which are localized in the cytoplasm of the target cells. Also, GM-CSF transfected cancer cells may recruit a number of tumor antigen presenting cells to T cells.

►cytotoxic T cell, ►antigen presenting cell, ►HLA, ►tumor vaccination

Cross-Reacting Material: ►crm, ►cross-reaction

Cross-Reaction: The binding of an antibody to an antigen; usually in the case when the formation of the antibody was not stimulated by the antigen but by a very similar substance. ►crm, ►antigen, ►antibody, ►nonspecific binding

Cross-Reactivation: ►marker rescue, ►reactivation

Cross-Resistance: As per cross-resistance, resistance against one agent conveys resistance also against others. ►multidrug resistance

Cross-Talk: The transmission of signals from receiver to sensor molecules between signal transduction pathways. ►signal transduction, ►morphogen, ►epistasis, ►microarray hybridization

Crouzon Syndrome (craniofacial dysostosis): An autosomal dominant phenotype of ossified cartilages and various anomalies of the face, particularly protruding eyeballs. It is allelic to the Jackson-Weiss syndrome and to the Pfeiffer syndrome (see Fig. C187). The basic defect appears to be due to the fibroblast growth factor receptor 2 in human chromosome 10q25-q26. ►eye disease fibroblast growth factor, ►receptor tyrosine kinase

Figure C187. Crouzon syndrome with moderate exophthalmos (protrusion of the eyeballs) and malocclusion (improper position of the lower jaw). (From Tessier P 2000 in *Craniosynostosis* p. 228, Cohen MM, MacLean RE eds., Oxford Univ. Press. By permission)

Crowding, Molecular: Molecular crowding indicates the concentration of diverse molecules within a (cellular) environment, where it may differently affect molecular functions (Sasaki Y et al 2007 *Nucleic Acids Res* 35:4086).

Crown Gall: A tumorous disease (mainly) of dicotyledonous plants caused by the soil-borne *Agrobacterium tumefaciens* (see Fig. C188). (photo courtesy of Dr. A.C. Brown). The tumor development is initiated by the large (200-kb), Ti (tumor-inducing) plasmid containing oncogenes responsible for the production of auxins and cytokinin plant hormones. Removal of the bacteria about two days after infection does not stop the disease, because the genes in the T-DNA part of the plasmids by that time have integrated into the plant genome and are expressed in the plant cells. The infection activates the *Tmr* gene in the plant plastid that encodes an adenosine-phosphate isopen-tenyl transferase and increases cytokine production (Sakakibara H et al 2005 *Proc Natl Acad Sci USA* 102:9972). ►*Agrobacterium*, ►T-DNA; Burr TJ, Otten L 1999 *Annu Rev Phytopath* 37:53.

Figure C188. Crown gall

Crozier: A crozier is a fungal structure formed when the ascogenous dikaryotic hyphae of ascomycetes form a three-cell hook-type growth and in the cell at the tip the two nuclei fuse (karyogamy) to become diploid (see Fig. C189). After that an ascus is formed where meiosis takes place. ►ascus, ►fungal life cycle, ►*Neurospora*

Figure C189. Crozier

7CRP: cAMP receptor protein. ▶cAMP

CRP: Proteins with LIM, LMO domains. ▶LIM, ▶LMO

CRP (catabolite response protein): ▶catabolite repression

CRSP: A transcriptional co-factor complex required for activation of Sp1-TFIID ($M_r \sim 700K$). It has nine subunits with MWs of 30K to 200K. ▶Sp1, ▶transcription factors

Cruciform DNA: Cruciform DNA may be formed as a recombination intermediate between single strands of double-strand DNA (see Fig. C190) ▶Holliday model, and when inverted repeats and palindromes occur in both strands in a double-stranded DNA, and within each strands these palindromes fold back and pair. ▶Holliday model, ▶palindrome, ▶repeat inverted, ▶transposition sites; photo is courtesy of Drs. H. Potter and D. Dressler.

Figure C190. Cruciform recombination intermediate of DNA

Cruzigard: The cruzigard technology is based on a similar principle as in the use of the paratransgenic method. Insect vectors are exposed to different bacterial strains transformed by anti-trypanosomal genes as bait. The insect nymphs feeding on them will release the antibiotic within the insect gut and debilitate the protozoon. ▶paratransgenic, ▶Trypanosoma

crwydryn: A centromere-specific retrotransposon family in grasses. ▶retrotransposon

CRX: Transcription factor regulating photoreceptor outer segment proteins. ▶photoreceptor

Cry9C: A bacterial crystal protein with insecticidal property, used in genetically modified maize (corn). The protein belongs to the family of proteins (Bt) present in *Bacillus thuringiensis*, but it is apparently more effective. Other insecticidal proteins of this family are Cry5A, Cry5B, and Cry6A. According to some claims, it is an allergen for humans. ▶Bacillus

thuringiensis, ▶GMO, Crickmore N et al 1998 Microbiol Mol Biol Rev 62:807.

Cryo-Electron Crystallography: Cryo-electron crystallography permits the analysis of fine structure small biological systems by using electron diffraction. (See Craig T et al 2006 Mol Cell 23:651.)

Cryo-EM (cryo-electron microscopy): Quick-frozen samples obtained by CRYO-EM may permit viewing 3-dimensional structures below a resolution of 10 Å. It may reach beyond nuclear magnetic resonance or X-ray crystallography. ▶X-ray diffraction analysis, ▶nuclear magnetic resonance spectroscopy; reconstruction of single particles: Tao Y, Zhang W 2000 Curr Opin Struct Biol 10:616.

Cryopreservation: Cryopreservation is the maintaining of biological tissues, enzymes, etc. at very low temperatures, below -80°C , or in liquid nitrogen (-195.8°C). Frozen mouse embryos sperm, and ovaries can be now stored, distributed, reconstituted and used for reproduction. Mouse spermatids and spermatozoa kept frozen at -80°C up to a year were found to remain functional in fertilization. Testicular spermatozoa of dead mice kept continuously frozen at -20°C for up to 15 years produced normal offspring after microinjection into oocytes. This technology may make possible the extraction of functional spermatozoa from species preserved in permafrost and that after fertilization of oocytes of extant relatives, the extinct species be revived (Ogonuki N et al 2006 Proc Natl Acad Sci USA 103:13098). ▶sperm bank, ▶artificial insemination, ▶vitrification, ▶stem cells; Ludwig M et al 1999 Hum Reprod 14(Suppl):162; Rall WF 1992 Animal Reprod Sci 28:237; Watson PF, Holt WV (eds) 2001 Cryobanking the genetic resource. Wildlife conservation for the future? Taylor & Francis, London, New York.

Crypsis: The evolutionarily determined ability of animals to evade predators by concealing their through mimicking e.g., a certain shape or color. ▶Batesian mimicry, ▶Müllerian mimicry, ▶mimicry

Cryptic Chromosomal Aberration: A cryptic chromosomal aberration is too small to be detected without special staining techniques, e.g., FISH. ▶chromosomal aberrations, ▶FISH

Cryptic Dominance: A particular situation when recessive alleles of different loci fail to display complementation because of interaction of the gene products. ▶epistasis

Cryptic Element: A cryptic element, such as a plasmid or transposon does not express a particular phenotype.

Cryptic Promoter: An epigenetically silenced and normally inactive promoter. Genetic or extraneous

C

alterations may activate it and can lead to the transcription and translation of aberrant peptides. Some cases of carcinogenesis are attributed to activation of cryptic promoters. Cryptic promoters may be responsible for antisense RNA and interfering RNAs. ▶[promoter](#)

Cryptic Plasmids: Do not have a known phenotype; they contain genes only for their maintenance and transmission. ▶[plasmid](#); Burian J et al 1999 J Mol Biol 294:49.

Cryptic Prophage: Can no longer exit from the chromosome of the bacterium and develop into a virion although some its genes are still transcribed. ▶[prophage](#)

Cryptic Satellite: The satellite DNA is not displayed by ultracentrifugation as a separate (band) peak but it is masked within the main band of the DNA. ▶[satellite DNA](#), ▶[buoyant density](#), ▶[ultracentrifuge](#)

Cryptic Simplicity: Cryptic simplicity is found in originally microsatellite regions where many point mutations occur and the repetitiveness breaks down or a few intermixed states are found. These are most common in non-coding regions but may occur in coding sequences too. ▶[microsatellite](#)

Cryptic Splice Site: An unusual juncture where splicing of exons may take place in case the usual site is changed by mutation. ▶[splicing](#), ▶[introns](#)

Cryptobiosis: Suspended life or reversible death.

Cryptochromes: Cryptochromes are linked to plant developmental (photoperiodism, circadian clock) processes under high intensity blue light. Cryptochromes are the blue light photoreceptors of the animal eye and also are modifiers of the circadian rhythm. They display similarities to photolyases. The mammalian cryptochrome genes (CRY) may have light-independent regulatory role. In plant morphogenic responses, cryptochromes cooperate with phytochromes through the Ca^{2+} -binding protein SUB1. Cryptochromes are relevant to various human health problems such as seasonal depression, sleep disorders, jet lag, and even breast cancer. ▶[circadian rhythm](#), ▶[photoperiodism](#), ▶[phytochromes](#), ▶[photolyase](#); Yang H-Q et al 2000 Cell 103:815; Sancar A 2000 Annu Rev Biochem 69:31; Lin C 2002 Plant Cell 14:S207; Liscum E et al 2003 Plant Physiol 133:1429; Lin C, Shalitin D 2003 Annu Rev Plant Biol 54:469; Chen M et al 2004 Annu Rev Genet 38:87; Partch CL et al 2006 Proc Natl Acad Sci USA 103:10467.

Cryptococcus: Several species of the basidiomycete fungus, an opportunistic human and animal pathogen posing a particular risk to immunocompromised populations. The ~20-megabase genomes containing

about 6,600 intron-rich genes of *C. neoformans* (n = 14) have been sequenced. About 5% of the genomes are transposons, accounting for the frequent variations. ▶[basidiomycetes](#); Loftus BJ et al 2005 Science 307:1321.

Cryptogamic Plants: Cryptogamic flowers develop no flowers or seeds and multiply by spores such as ferns, mosses, and algae. ▶[spermatophytes](#)

Cryptogene: Mitochondrial DNA gene with primary transcript subject to pan editing that almost hides the original RNA sequences. ▶[kinetoplast](#), ▶[pan editing](#), ▶[Trypanosoma](#), ▶[RNA editing](#)

Cryptogenic Species: Acryptogenic species is not clearly native in an environment nor is it an introduced one.

Cryptophthalmos: In cryptthalmos, instead of eyelids, the skin of the face covers both of the eyes, or one of the eyes (see Fig. C191). The extent of this developmental anomaly may vary. ▶[Fraser syndrome](#)

Figure C191. Cryptophthalmos

Cryptopolyploidy: Increase in nuclear DNA content among related families with the same chromosome number. ▶[polyploid](#); Sparrow AH, Nauman AF 1976 Science 192:524.

Cryptorchidism: Failure of the testes to descend from the abdominal cavity into the scrotum. This anomaly affects 2% of human births. Mutation in the insulin-like hormone (Insl3) may regulate the growth and differentiation of the gubernaculum (ligament of transient existence connecting the testis and epididymis to the scrotum) and testis descent. In females it may result in sterility. ▶[scrotum](#), ▶[epididymis](#); Kumagai J et al 2002 J Biol Chem 277:31283.

Cryptosporidium: The cryptosporidium protist species are responsible for some types of gastroenteritis and diarrhea and have host specialization. *C. hominis* has ~9.2 million bp genome in eight chromosomes and it has been sequenced (Xu P et al 2004 Nature [Lond] 431:1107). Membrane protrusions are used for entry

sites in infection (Chen X-M et al 2005 Proc Natl Acad Sci USA 102:6338, database: <http://cryptodb.org/cryptodb/>).

Crystal Cells: Hematoidin (hemoglobin-derived bilirubin-like) bodies in the blood.

Crystal Lattice: ▶semiconductor

Crystallins, α -, β -, γ -: Small heat shock proteins occurring in large (700–800 kDa) heteropolymers where they fend off protein denaturation. They are implicated in neuro- and muscle-degenerations and cataracts (opacity of the eye lens). ▶sHsp, ▶eye diseases, ▶desmin; Wang K 2001 Biochem Biophys Res Commun 287:642.

Crystallization: Formation of crystals; a procedure preparatory to X-ray crystallographic analysis of macromolecular structures. ▶X-ray diffraction analysis

Crystals of Protein: Protein crystals have a three-dimensional molecular arrangement (crystal lattice). The components hold a definite position in the lattice by attractive forces yet they may vibrate and assume different characteristic arrangements. Some proteins may not be directly amenable to crystallization due to structural causes. In such instances, appropriate variants can be produced that are more liable to the procedure (Keenan RJ et al 2005 Proc Natl Acad Sci USA 102:8887; Molscript).

Cs (crossovers): Recombinational events

¹³⁷**Cs:** A Cesium isotope emitting β and γ radiation; has a half-life of 33 years. ▶isotopes

CSA: Compartmentalized shotgun assembly. ▶shotgun sequencing

CSAID (cytokine-suppressive anti-inflammatory drug): An inhibitor of cytokine biosynthesis. ▶cytokines, ▶CSBP

CSBP (CSAID-binding protein): Mitogen-activated protein kinases. ▶CSAID, p38.

CSE: A negative regulator element of chromosome segregation in yeast that belongs to the Mediator family. ▶Mediator

CSF: The cytosstatic stability factor (probably the product of c-mos proto-oncogene) stabilizes MPF and thus prevents the exiting of the cell from M phase of mitosis. RSK mediates the activity of CSF. Calcium triggers the exit from meiosis II by targeting the inhibitor, Erp1 of the anaphase-promoting complex (APC). ▶MOS, ▶MPF, ▶proto-oncogenes, ▶mitosis, ▶meiosis, ▶cell cycle, ▶RSK; Shibuya EK, Masui K 1988 Dev Biol 129:253; Rauh NR et al 2005 Nature [Lond] 437:1048.

CSF (CSF-1 at human chromosome 1p21-p13, CSF-2 at 5q31.1, CSF-3 at 17q11.2-q12): The colony stimulating factor, involved in autophosphorylation. The CSF receptor (product of the FMS oncogene) is homologous to the product of the KIT oncogene, a protein tyrosine kinase. ▶KIT oncogene, ▶FMS oncogene, ▶protein tyrosine kinases, ▶colony stimulating factor

CSF1R: The colony stimulating factor receptor, product of the FMS oncogene. ▶FMS oncogene, ▶CSF, ▶KIT oncogene, ▶colony stimulating factor

CSGE (conformation-sensitive gel electrophoresis): CSGE uses gel electrophoresis of PCR fragments for the detection of variations in (mitochondrial) DNA, in order to provide data for evolutionary analyses. ▶gel electrophoresis, ▶PCR; Finnilä S et al 2000 Am J Hum Genet 66:1017.

Csk: A cytoplasmic protein tyrosine kinase; it has two amino-terminal protein-protein interaction domains (Src homology 2 and 3) and a carboxy-terminal catalytic domain. It is necessary for the development of the mouse. In csk⁻ cells, Src, Fyn, and Lyn phosphotyrosine kinase activity is decreased. Csk mediates the selection of T cells and regulates antigen receptors. ▶Src, ▶B lymphocytes, ▶Pyk, ▶Fyn, ▶Lck, ▶protein-tyrosine kinase, ▶SFK; Wang D, Cole PA 2001 J Am Chem Soc 123:8883.

CSL (C-promoter binding factor-1/Suppressor of hairless/LAG-1): A family of transcription factors that mediate transcriptional activation through the Notch receptor (see Fig. C192). Activation of Hes1 and Hes5 may inhibit neurite extension. The Numb, Numb-like and Deltex proteins inhibit Notch signaling and facilitate neurite extension. ▶Notch

Figure C192. Notched wings of *Drosophila*

cSNP (coding SNP): A single nucleotide polymorphism coding for a different amino acid. ▶SNIPs

Csr: A family of RNAs mimicking mRNAs in glycogen biosynthesis, flagellar motility, and biofilm formation in bacteria and blocking their function (Romeo T 1998 Mol Microbiol 29:1321). ▶RNA regulatory, ▶biofilm

CstF: A cleavage-polyadenylation protein factor; may be associated with RNA polymerase II CTD. ▶poll II, ▶transcription factors, ▶CPSF, ▶CTD; Calvo O, Manley JL 2001 Mol Cell 7:1013.

CTAB ($[\text{CH}_3(\text{CH}_2)_{15}\text{N}^+(\text{CH}_3)_3\text{Br}^-]$): ►cetyl trimethylammonium bromide

CtBP: A C-terminal binding protein, a translational co-repressor that interacts with E1A. It modifies histones and may participate in oncogenesis. Ctbp 1 is encoded at 4p16 and Ctbp2 at 21q21.3. ►E1A, ►co-repressor; Chinnadurai G 2002 Mol Cell 9:213; Shi Y et al 2003 Nature [Lond] 422:723.

CTC: ►cytotoxic T cell

CTCF (CCCTC-binding factor, NeP1): A histone deacetylase and repressor of transcription. A CTCF-dependent enhancer-binding element acts as a chromatin insulator and it may regulate imprinting (Filippova, G et al 2005 Dev Cell 8:31). In mouse, CTCF mediates an interchromosomal interaction, perhaps by directing a distant DNA segment of chromosome 7 to a common transcription factory in chromosome 11. These two sites are involved in imprinting in mouse (Ling JQ et al 2006 Science 312: L269). In the human genome, 13,804 CTCF-binding insulator sites have been revealed (Kim TH et al 2007 Cell 128:1231). ►imprinting, ►insulator, ►boundary element, ►imprinting, ►transcription factories, ►non-coding sequences; Hark AT et al 2000 Nature 405:486; Filippova GN et al 2001 Nature Genet 28:335; Chao W et al 2002 Science 295:345.

CTD (carboxy terminal domain): An example of a CTD is the repeat unit of the largest subunit of RNA polymerases (RNAP), which can substitute for the TATA box in genes that lack TATA sequences. This CTD of the α subunits is the contact site for transcription activator proteins and the upstream promoter element (UP) in *E. coli*. The CTDK kinase, TFIIF, and FCP (yeast) phosphorylate the CTD of the transcriptase. The CTD domains of various proteins have structural and functional specificities. ►RNA polymerase, ►TATA box, ►transcription factors, ►RNA polymerase

ctDNA: Same as cpDNA or chloroplast DNA (see Fig. C193).

Figure C193. ctDNA. See ctDNA threads at arrow

C-Terminus: The COOH end of the last amino acid in the primary structure of a protein.

CTF: A CCAA motif binding proteins. ►binding proteins, ►cohesion

CTL (cytotoxic lymphocyte): ►T cell

CTLA-4 (cytotoxic T lymphocyte antigen, 2q33): A T cell regulatory molecule along with antigens bound to the major histocompatibility complex (MHC) on antigen presenting cells. CTLA-4 inhibits TCR signaling by binding to its ζ chain and interferes with tyrosine phosphorylation after T cell activation. The autoimmunity Graves disease, hypothyroidism, and type I diabetes are controlled by a non-coding 6.1 kb 3' region of CTLA-4, which displays an alternative splice form (Ueda H et al 2003 Nature [Lond] 423:506). CTLA-4 has signals opposite to the stimulatory proteins CD28, CD80, CD86, and ICOS. CTLA-4 overrides the T cell receptor-induced stop signal required for stable conjugation between T cell and antigen-presenting cell, and thus modulates the threshold for T cell activation and protects against autoimmune disease (Schneider H et al 2006 Science 313:1972). ►T cell, ►autoimmune disease, ►antigen presenting cell, ►MHC, ►CD28, ►CD80, ►CD86, ►ICOS, ►TCR, ►ITAM, ►ITIM, ►goiter, ►diabetes; Chambers CA et al 2001 Annu Rev Immunol 19:565; Egen JG et al 2002 Nat Immunol 3:611.

CTN-RNA (cationic amino acid transporter 2 RNA): CTN-RNA is transcribed from mouse *CAT2* gene using an alternative promoter. In addition to the transporter protein, it encodes a regulatory RNA, which is retained in the nucleus. (Prasanth KV et al 2005 Cell 123:249).

CTR: ►constitutive triple response

Cubitus interruptus (*ci*, 4.0): *Drosophila* gene locus with many different alleles. The cubital vein is interrupted at various lengths in the mutants (see Fig. C194). (See Aza-Blanc P, Kornberg TB 1999 Trends Genet 15:458).

Figure C194. The *cubitus interruptus* phenotype (wild type, left; mutant at right). (Redrawn after Stern C, Kodani M 1955 Genetics 40:343)

Cucurbits: (Cucurbitaceae): *Cucumis sativus* (cucumber) $2n = 14$; *Cucumis melo* (muskmelon) $2n = 24$; *Citrullus lanatus* (water melon) $2n = 22$; *Cucurbita pepo* (summer squash) and other squashes $2n = 40$. ▶crop pants

CUE: A signal or stimulus that initiates or specifies a developmental fate. The *extrinsic signals* may be diffusible molecules (exocrine or paracrine hormones), cell membrane attached proteins, extracellular matrix factors, morphogens, pheromones, or environmental, i.e., light, temperature-related, or other signals. The *intrinsic cues* can be transcription factors, activators, transactivators, signal transducing adaptor molecules, G proteins, etc. The intrinsic cues are considered to be cell autonomous if they are able to affect cell fates irrespective of the surrounding tissue. ▶exocrine, ▶paracrine, ▶transcription factors, ▶activators, ▶transactivation, ▶morphogens, ▶morphogenesis, ▶signal transduction, ▶G proteins, ▶pheromones, ▶chaperone

Cullin (CUL1): A family of proteins involved in ubiquitination of G_1 phase cyclins and cyclin-dependent kinase inhibitors and other proteins. ▶CDC53, ▶cyclin, ▶ubiquitin, ▶cell cycle, ▶DDB1; Schwechheimer C, Deng X 2001 Trends Cell Biol 11:420.

Cultigens: Forms of cultivated plants. ▶cultivar, ▶variety

Cultivar: A genetically distinct variety of crop plants, generally adapted to a region and with some agronomic value for the grower and the consumer. ▶cultigens, ▶variety

Cultural Transmission of Fitness (CTF): A nongenetic transmission of any kind of behavior that affects reproductive success (Heyer E et al 2005 Trends Genet 21:234). When effective family size (EFS) is correlated from one generation to the next (i.e., the number of children per family who reproduce in their native population), there is a measure for the intensity of CTF. Akin to selection, CTF produces an increase in allele frequencies and like drift it has an impact on the whole genome. There are many examples for CTF when cultural or traditional customs affect the population. The general population may be divided into two groups of families: stable families with greater local reproductive success and migrants with lower local reproductive success. This social structure, transmitted from one generation to the next, may lead to the maintenance of a genetic disorder at increased frequency despite a high level of gene inflow from surrounding populations.

A particular Y chromosomal variant in 16 populations throughout a large region of Asia, stretching from the Pacific to the Caspian Sea, was present in very high proportions, in about 8% of the men in this region when its frequency worldwide appeared to be only 0.5%. The pattern of variation within the lineage suggested that it originated in Mongolia <1,000 years ago. Such a rapid spread cannot have occurred by chance. The lineage is attributed to male-line descendants of Genghis Khan, and it appears that to have spread by a novel form selection resulting from their behavior (Zerjal T et al 2003 Am J Hum Genet). ▶fitness, ▶linkage disequilibrium

Culture Collections: Culture collections maintain the cell lines of microbial, viral, and higher organisms and make available specimens for a fee. (See <http://www.ukncc.co.uk>).

Culture Media: For bacteria see Sambrook J et al 2006 Molecular Cloning, Cold Spring Harbor Lab. Press; for plants Murashige & Skoog medium, Gamborg medium; animal cells Butler M 1996 Animal Cell Culture and Technology, IRL/Oxford Univ. Press, New York.

Cumulus Ovaricus: A group of diploid follicular cells surrounding the mammalian egg. Such cells have been successfully used for nuclear transplantation after removal of the resident nucleus, resulting in cloning. ▶nuclear transplantation

Curare: ▶toxins

Curated: A database, which is generated/maintained by human supervision and not merely by mechanical/electronic means. ▶LC, ▶supervised learning

Curcumin (Natural Yellow, diferuloylmethane): A phenolic compound with antioxidant, anti-inflammatory and apoptosis-promoting properties.

Curie: The basic unit of radioactivity contained in 1 g of radium, i.e., 3.7×10^{10} disintegrations per second (dps). Most commonly, 1/1,000th, the millicurie (mCi) or the 1/1,000,000th the microcurie (μ Ci, 2.2×10^6 disintegrations per minute [dpm]) are used in laboratory work. In most equipment only about half of the disintegrations are detectable and thus 1 μ C corresponds to 1,000,000 counts per minute (cpm). Since the Ci unit defines the rate of disintegrations/time unit and the half-life of the different isotope may vary greatly depending on the species, the shorter half-life isotopes lose their isotopic atoms faster. 1 Becquerel = 2.7027×10^{-11} Curie (≈ 27 picocuries). ▶isotopes

Curing: A process of hardening by chemical or physical agents. It also refers to successful medication.

C

Curing of Plasmids: The removal of a plasmid or prophage from a bacterium, e.g., by the use of chemicals (acridine dye, Novobiocin, Coumeromycin) or irradiation. The $[PSI^+]$ form of the yeast prion can be “cured”, i.e., converted into $[psi^-]$ form by treatment with guanidine hydrochloride or methanol, in a reversible process. ▶prion, ▶acridine dye

Currants (*Ribes* spp): All are $2n = 2x = 16$.

Curarino Syndrome (HAS, 7q36): A dominant hereditary sacral agenesis (defect in the formation of the bone just above the hip). The homeobox gene HLXB9 responsible encodes a 403-amino acid protein. (Ross AJ et al 1998 Nat Genet 20:358).

Curvans: ▶rigens

Curvature of DNA: The curvature of the DNA involves deflection(s) of the local helical axis. It causes retardation of movement in the electrophoretic field. (Hardwidge PR, Maher LJ 2001 Nucleic Acids Res 29:2619).

Curvilinear Relationship: A curvilinear relationship indicates that the variations of two variables vary together but not in constant increments.

Cushing Syndrome (mixoma): also called by the acronym NAME (nevi, atrial mixoma, mixoid neurofibromata, endocrine overactivity). Critical features of the disease are adrenal, hypothalamic, pituitary, and lung tumors and hippocampal atrophy as a consequence of overproduction of glucocorticoids (hydrocortisone). ▶nevus, ▶neurofibromatosis, ▶glucocorticoids, ▶adrenal, ▶pituitary, ▶hippocampus, ▶atrophy; Yano H et al 1998 Mol Endocrinol 12:1708.

Cusp: ▶tooth

Custom Testing: Custom testing aims to detect specific mutation or chromosomal aberration, in case family history indicates the potential of the occurrence of a particular anomaly.

Cut-and-Paste: A mechanism of conservative transposition (see Fig. C195). Transposase (e.g., Tn5) and host proteins bind the transposable element and target double-strand DNA breaks at junction in a staggered manner. Insertion follows and the gaps are filled with complementary nucleotides. and (e.g., 9-bp [depending of the nature of the target cuts]). Duplications are generated at the end of the “simple insert”. Cut-and-paste mechanism may be also used in nucleotide exchange repair. ▶transposons, ▶transposable elements, ▶excision repair

Figure C195. Cut-and-paste model. The catalytically transposon with the aid of an activated water molecule hydrolyzes one strand of the target and liberates a 3'-OH group at the end of the transposon. The 3'-OH end makes a nucleophilic attack on the target and manages transfer of the transposon into a new location. Cut-and-paste model Modified after Davis DR et al 2000 Science 289:77

Cuticle: A layer of substance (collagen) over the surface of epidermal or epithelial cells. ▶collagen

Cutin: A waxy material on the surface of plant cells, slightly permeable to water or gaseous substances.

Cutis Gyrate: ▶Beare-Stevenson syndrome

Cutis Laxa: Cutis Laxa includes autosomal dominant, recessive or X-linked forms. The hereditary forms appear early in life and show loose skin and joints and folding skin. The recessive I form involves, in addition, lung, heart, and digestive tract anomalies. Type II shows bone malformation (dystrophy) and retarded development. Some other forms have the signs of early aging of the skin or emphysema and anemia. The X-linked (Xq12-q13) form causes the formation of bony horns on the foramen magnum (the opening of the cranium to the vertebral canal), deficiency of lysyl oxidase, and disturbance in copper metabolism. ▶skin diseases, ▶elastic fiber diseases, ▶collagen, ▶Ehlers-Danlos syndrome, ▶pseudoxanthoma elasticum, ▶Menkes syndrome, ▶Williams syndrome

CW: Clockwise, ccw (see Fig. C196).

Figure C196. Clockwise

CXCR: Chemokine co-receptor of the CD4 T cells, a member of the serpentine receptor family. CXCR4 and its ligand, SDF-1 (a member of a chemokine family), are involved in hematopoiesis, lymphocyte migration and activation, differentiation of the vascular system, development of neuronal patterning, and acquired immunodeficiency symptoms. CXCR is a seven-transmembrane-spanning G-protein-coupled receptor. ▶CCR, ▶chemokine, ▶CD34, ▶acquired immunodeficiency, ▶SDF, ▶PBSF, ▶serpines, ▶angiogenesis, ▶neuron, ▶seven membrane proteins, ▶G protein, ▶cyclam, ▶metastasis, ▶ZAP-70, ▶gametogenesis, ▶WHIM syndrome; Blanco J et al 2000 FEBS Lett 477:123.

CXR: Chemokine receptor. ▶chemokines

Cxs: Gene conversions accompanied by crossing over. ▶gene conversion, ▶crossing over

Cy (Cy3 [green], Cy5 [red]): Monofunctional cyanine fluorescent labels of different absorption specificities for macromolecules.

Cyanide (HCN): A very powerful inhibitor of cellular oxidation that works by forming a complex with cytochrome oxidase and is thus an extremely dangerous poison. Sodiumthiosulfate and sodium nitrate are antidotes. Cyanides may be present in various foods (almond) and feed (Sudan grass, white clover).

Cyanidine: ▶anthocyanin

Cyanobacteria (blue-green algae): Photosynthetic prokaryotes that contain phycobiliproteins and chlorophyll a. Their genetic material is DNA and can be manipulated in a way similar to that in other prokaryotes. Cyanobacteria harbor phages that exchange genes with the host bacteria. Some phage genes are apparently functional in bacterial photosynthesis (Lindell D et al 2005 Nature [Lond] 438:86). The cyanobacterial circadian clock is different from that of other organisms. A two-component bacterial regulatory system kind mechanism feeds the signals to the clock (Ditty JL et al 2003 Annu Rev Genet 37:513). Cyanobacteria can produce various hazardous toxins (microcystin, nodularin), depending on the species. All known groups seem to produce β -N-methylamino-L-alanine, which upon ingestion may be responsible for neurological disease (amyotrophic lateral sclerosis/parkinsonism-dementia complex) of increased incidence in Guam and other parts of the world where it may enter the human food chain (Cox PA et al 2005 Proc Natl Acad Sci USA 102:5074). ▶phycobilins, ▶phycocyanins, ▶organelle sequence transfer, ▶chlorophyll; genome of *Synechococcus*: Palenik B et al 2003 Nature

[Lond] 424:1037; genome of *Prochlorococcus*: Rocap G et al 2003 Nature [Lond] 424:1042.

Cyanogen Bromide (BrCN): A very toxic, lacrimant gas. It has been used to cleave polypeptides and fusion proteins (at the C-terminal side of methionine) and also as ligand for activated chromatography matrices for Western blotting. ▶ligand, ▶Western blotting

Cyanogenic Glucosides: ▶Insect resistance in plants, ▶lotaustralin

Cyanosis: Bluish discoloration in body areas caused by the accumulation of reduced hemoglobin and methemoglobin resulting from mutation or caused by other factors. ▶methemoglobin

Cy Base: ▶cyclic proteins

Cybernetics: The theory of control and communication such as exists in the nervous system and also in mechanical devices such as the computer. ▶cyborg, ▶genetics digital

Cyborg (cybernetic organism): A futuristic human body modified by substitution of artificial structures for the natural ones, e.g., electronics for the nervous system. Such a system may permit better understanding of the working of an organic system. Also it may correct natural defects in hearing, vision, or muscle control, etc. by the use of microchips (silicon or germanium pieces used in computer circuits, Sequiera S 2001 Trends Neurosci 24:834).

Cybrid: A cybrid contains two different cytoplasm in fused cells. ▶cell genetics, ▶cell fusion

Cyclam: The macrocyclic xylyl-bicyclam (see Fig. C197) blocks HIV entry into the cell by targeting the CXCR4 co-receptor, a seven-helix transmembrane receptor. Several metal ions enhance binding. The Cu-cyclam specifically interacts with tryptophan residues 62, 63, and 123. ▶acquired immunodeficiency, ▶CXXR; Hunter TM et al 2005 Proc Natl Acad Sci USA 102:2288.

Figure C197. Xylyl-bicyclam

Cycle Cloning: In cyclone cloning, mammalian cell cultures are subjected to multiple rounds of phenotypic

selection in order to isolate cells of certain biological properties. ►MaRX

C

Cyclic ADP-Ribose: Cyclic ADP-Ribose is apparently synthesized from NAD⁺ by ADP-cyclase or by CD38 and serves as a (abscisic acid) signaling molecule when activated by Ca²⁺. The ryanodine receptor, regulating calcium ion channels, may be its receptor. It also regulates calcium signaling in T lymphocytes. ►ABA, ►NAD, ►c-AMP, ►ryanodine, ►CD38, ►T cell

Cyclic AMP: cAMP (see Fig. C198).

Figure C198. cAMP

Cyclic GMP: ►cGMP

Cyclic Electron Flow: Electrons emanating from *photosystem I* in light returning to their origin. ►photosynthesis, ►Z scheme

Cyclic Nucleotide-Gated Ion Channels: ►ion channels

Cyclic Permutation: ►permuted redundancy

Cyclic Photophosphorylation: In cyclic photophosphorylation, cyclic electron flow drives ATP synthesis. (See cyclic nucleotide phosphorylase: Conti M, Beavo J 2007 Annu Rev Biochem 76:481).

Cyclic Proteins (macrocytic proteins): Natural products with post-translational cyclization such as sex-pilin of bacteria, some bacteriocins, trypsin inhibitors of plants (cyclotides), and θ -defensins of monkeys. These proteins are resistant to proteolysis. See <http://research1t.imb.uq.edu.au/cybase/html/index.php>.

Cyclin (CLN): CLN proteins, synthesized during cell divisional cycles, are responsible players in the process by activating protein kinases (CDKs) and control the cyclic sequence of divisional steps. In *Saccharomyces* yeast cells, there are 22 cyclins that are associated with one of the five CDKs. ►cell cycle, ►CDK, ►CLB; Stein GS et al (eds) 1999 The molecular basis of cell cycle and growth control. Wiley, New York; Loog M, Morgan DO 2005 Nature [Lond] 434:104.

Cyclin A: Cyclin A is similar to cyclin B but appears earlier in the cell cycle. Cyclin A1 is expressed primarily in the germline, in the testes, and in myeloid leukemia cells. Cyclin A1 deficient males are sterile. Cyclin A2 deficiency results in embryo lethality. ►cell cycle, ►CDK, ►CDF, ►LATS; Coverly D et al 2002 Nature Cell Biol 4:523.

Cyclin B: Cyclin B has no known enzymatic activity; it is a part of MPF and has a role accessory to the protein kinase (*cdc2*) subunit. It seems to determine the substrate specificity of MPF. ►cell cycle, ►MPF, ►cdc2, ►CDK, ►CAK; Groisman I et al 2002 Cell 109:473.

Cyclin C: Cyclin C is involved in mRNA processing (Barette C et al 2001 Oncogene 20:551).

Cyclin D (CCND1, 11q13; CCND2, 12p13; CCND3, 6p21): Proteins involved in the G1 phase of the cell cycle. They are of over 50% homology. Cyclin Ds are also oncogenic proteins. CCND1-deficient mice are somewhat resistant to breast cancer mediated by the NEU/ERBB2 and RAS oncogene loci. CCND1 deficiency, however, does not affect the pathway to breast cancer mediated by c-Myc or Wnt-1 oncogenes. ►cell cycle, ►CDK, ►CAK, ►catenins, ►ERBB1, ►RAS, ►c-Myc, ►Wnt, ►breast cancer; Yu Q et al 2001 Nature [Lond] 411:1017.

Cyclin E: A subunit of CDK2. Under normal conditions, it accumulates between G₁ and S phase and is degraded after the S phase. In cancer cells, its level is maintained or increased and may lead to chromosomal instability common in cancer cells. Cyclin E^{T393A} mutation and loss of the p53 pathway associates with increased kinase activity and chromosomal instability, although the mutation itself increased the cyclin stability and had no phenotypic consequences. Ras oncogene was more active in Cyclin E^{T393A} p53^{-/-} cells than in the absence of p53 alone (Loeb KR et al 2005 Cancer Cell 8:35). When Cyclin E is localized to the centrosomes, it can control entry into S phase in the absence of CDK2 (Matsumoto Y, Maller JL 2004 Science 306:885). Coactivator-associated arginine methyltransferase is a positive regulator of *Cyclin E1* gene in mouse fibroblasts (El Messaudi S et al 2006 Proc Natl Acad Sci USA 103:13351). ►CDK2; Moberg KH et al 2001 Nature [Lond] 413:311; Strohmaier H et al 2001 Nature [Lond] 413:316; Payton M, Coats S 2002 Int J Biochem Cell Biol 34:315.

Cyclin F: Cyclin F displays in various protein-protein combinations the F-box motif that recognizes proteins for proteolytic degradation. It also promotes mitosis. ►SCF, ►F-box; Kong M et al 2000 EMBO J 19:1378.

Cyclin G: Cyclin G forms quaternary complex with the B' subunit of phosphatase PP2A, and also binds Mdm2 resulting in the dephosphorylation of the latter. ►PP2A, ►MDM2; Okamoto K et al 2002 Mol Cell 9:761.

Cyclin K: Cyclin K phosphorylates with cdk9, the carboxyterminal of RNA polymerase II (Edwards MC et al 1998 Mol Cell Biol 18:4291).

7Cyclin L: Cyclin L and an associated kinase are involved in the processing of pre-mRNA (Dickinson LA et al 2002 J Biol Chem 277:25465).

Cyclin T: A part of the Cdk9 complex that assists in binding Cdk9 to the Tat lentiviral RNA polymerase cofactor at the 5'-TAR site. ►acquired immunodeficiency, ►PITALRE, ►TEFb, ►CDK; Yang Z et al 2001 Nature [Lond] 414:317.

Cyclin-Dependent Protein Kinases (CDK): CDK, in association with cyclin, phosphorylate proteins and thus promote cell divisional events. In yeast cells, there are five types of CDK enzymes: Cdc28/Cdk1, Pho85, Kin28, Srb10, and Ctk1. The inhibitors of kinase activity may inhibit cell divisions and can be used for therapeutic purposes. ►cell cycle, ►CDK, ►CDK2; Francis D et al (eds) 1998 Plant Cell Division, Portland Press, London, UK.

Cycling Genes: Cycling genes display oscillating expression during embryogenesis.

5',8-Cycloadenosine: 5',8-cycloadenosine (see Fig. C199) and other cyclopurine deoxynucleosides may be generated in the DNA when under hypoxic conditions it is exposed to reactive oxygen. 5',8-cycloadenosine may be formed in stereoisomeric forms as well, and both of them block the 3' to 5' exonuclease function of the DNase III repair enzyme. DNA polymerase η may use them as templates for translesion synthesis, although this enzyme prefers the normal deoxypurine. ►DNA repair, ►translesion; Kuraoka I et al 2001 J Biol Chem 276:49283.

Figure C199. Cycloadenosine

Cyclobutane Dimer: Cyclobutanes have 4 C atoms in a ring. Such a structure may also be formed by cross-linking adjacent pyrimidines in the DNA upon

exposure to UV light. The most common, genetically effective, alteration in ultraviolet light-exposed DNA is the formation of thymine dimers (see Fig. C200).

Figure C200. Cyclobutane pyrimidine dimer

The formation of cyclobutane dimers is dependent on the wavelength of the radiation. At 280 nm it is induced almost five times as efficiently as at 240 nm. At 272 nm the mutagen is formed after ~ 1 picosecond following excitation (Schreier WJ et al 2007 Science 315:625). The dimer physically distorts the DNA and interferes with normal DNA replication and incorporation of nucleotides at wrong sites. Substitutions may lead to mutation. Visible light-activated enzymes may split the dimers by light repair. Adenine phosphoribosyltransferase may also repair the damage at both strands of the DNA. ►DNA repair, ►photolyase, ►pyrimidine dimer, ►pyrimidine-pyrimidinone photoproduct, ►glycosylases, ►5',8-purine cyclodeoxynucleosides, ►cis-syn dimer, ►adenine phosphoribosyltransferase; Zheng Y et al 2001 J Biol Chem 276:15786; You Y-H et al 2001 J Biol Chem 276:44688; electrochemistry of the photolyase repair: DeRosa MC et al 2005 Proc Natl Acad Sci USA 102:10788.

Cyclodeoxynucleosides: 5',8-purine cyclodeoxynucleosides.

Cycloheximide: An antibiotic, which blocks the peptidyl transferase on the 80S ribosomes but does not affect protein synthesis on the 70S ribosomes (see Fig. C201). ►antibiotics, ►protein synthesis, ►peptidyl transferase, ►signaling to translation, ►ribosome

Figure C201. Cycloheximide

Cycloidea Alleles (*radialis*, *rad*): Cycloidea alleles determine the radial symmetry of the flowers of *Antirrhinum* (see Fig. C202). Four genes control

dorsoventral asymmetry (*cyc*, *dich*, *rad* and *div*). *CYC* and *DICH* promote dorsal identity and encode a TCP family transcription factor, which activates *RAD*. The Rad protein contains 93 amino acids and has one MYB domain. *CYC* and *DICH* repress the expression of *DIV*. The three genes also affect posttranscriptional development. Mutation in *CYC* and *DICH* results in radial symmetry of the flowers. *DIV* encodes a MYB family transcription factor and promotes ventral identity (Corley SB et al 2005 Proc Natl Acad Sci USA 102:5068). ▶*peloric*, ▶*snapdragon*, ▶TCP, ▶MYB

Figure C202. Cycloidea alleles

Cyclooxygenase (COX): An enzyme involved in the synthesis of nitric oxide, eicosanoids, prostaglandins, prostacyclins and thromboxanes from arachidonic acid. This enzyme thus plays an important role in inflammation, pain, fever, and embryo implantation, suppresses immunosurveillance, and stimulates tumorous growth. Inducible nitric oxide synthase specifically binds COX2, S-nitrosylates it, and enhances its catalytic activity. This system is important for inflammation responses (Kim SF et al 2005 Science 310:1966). Resveratrol, a product of grapes and the legume *Cassia quinqueangulata*, acts as a chemopreventive of the tumorigenic effect of cyclooxygenases. The common drug aspirin acetylates both COX-1 (prostaglandin-endoperoxide synthase 1; 9q32-q33.3) and COX-2 (prostaglandin-endoperoxide synthase 2; 1q25.2-q25.3) and irreversibly inactivates COX-2. Acetylated COX-1 has antithrombotic (protection against heart diseases) as well as inflammatory effects (causing heartburn, etc.), whereas shutting off COX-2 is beneficial for immunological and neoplastic diseases. For COX-2 inhibitors, are a new class of nonsteroidal anti-inflammatory drugs (NSAIDs) that provide effective treatment in arthritis but often lead to complications that include cardiovascular disease, myocardial infarction, stroke, and life-threatening skin reactions (Topol EJ 2005 J Am Med Assoc 293:366). Thus, they are no longer marketed. ▶*arachidonic acid*, ▶*lipoxigenase*, ▶*nitric oxide*, ▶*inflammation*, ▶*prostaglandins*, ▶*thromboxanes*, ▶*aspirin*, ▶*IKK*, ▶*thrombosis*, ▶*polyposis adenomatous intestinal*, ▶*MET oncogene*, ▶*implantation*; Smith WL et al

2000 Annu Rev Biochem 69:145; Turini ME, DuBois RN 2002 Annu Rev Med 53:35.

Cyclophilins (Cpr, Cyp, rotamase): Evolutionarily highly conserved peptidyl-prolyl isomerases that catalyze cis-trans isomerization of X-Pro peptide bonds. Peptidyl-prolyl isomerases are encoded at several human chromosomal locations. The cytoplasmic cyclophilin A (18-kDa, 7p13) is bound to and may be inhibited by the immunosuppressive antibiotic, cyclosporine. Cyclosporine bound to cyclophilin inactivates calcineurin. Cyclophilin B and cyclophilin C (each 23 kDa) are found in the secretory pathway. Cyclophilin D (20-kDa, 4q31.3) is mitochondrial and regulates mitochondrial permeability and some necrotic lesions, but not apoptosis (Nakagawa T et al 2005 Nature [Lond] 434:652). Overproduction of cyclophilin D leads to mitochondrial swelling and death, whereas in its absence mice are protected from Ca^{2+} overload and oxidative-stress-induced death (Baines CP et al 2005 Nature [Lond] 434:658). Cyclophilin 40 (40-kDa) is cytoplasmic and usually heat-inducible and seems to participate in heat shock protein-90 and heat shock protein-70 dependent signal transduction. ▶*cyclosporine*, ▶*calcineurin*, ▶*acquired immunodeficiency*, ▶*immunosuppressant*, ▶*mitochondrial import*, ▶*heat shock proteins*, ▶*signal transduction*, ▶*immunophilins*, ▶*PPI*, ▶*peptidyl-prolyl isomerases*, ▶*SCC*, ▶*nina*; Schiene-Fischer C, Yu C 2001 FEBS Lett 495:1.

Cyclophosphamide (cytoxan, endoxan, $\text{C}_7\text{H}_{15}\text{Cl}_2\text{N}_2\text{O}_2\text{P}$): An alkylating carcinogen, clastogen, anti-neoplastic agent, and immunosuppressive drug (see Fig. C203). Preconceptual exposure of male rats to this drug caused embryo loss, malformation, and behavioral deficits in the offspring. Early postfertilization zygotic male pronuclei exposed to cytoxan are hyperacetylated at histones. Male pronuclei are hypomethylated by midzygotic development but female pronuclei are hypermethylated.

Figure C203. Cyclophosphamide

Thus this anticancer agent disturbs the epigenetic balance and its risks in chemotherapy must be considered (Barton TS et al 2005 Proc Natl Acad Sci USA 102:7865). ▶*aldehyde dehydrogenase*, ▶*oncolytic viruses*

Cyclopia: A developmental anomaly resulting in the formation of only a single eye. The build-up of cholesterol and defective signaling through the sonic hedgehog protein appear to be causative factors.

► [sonic hedgehog](#), ► [holoprosencephaly](#)

Cyclosome: Same as APC, ► [cell cycle](#)

Cyclosporine: A peptide antibiotic. It inhibits the activation of T lymphocytes by blocking the synthesis of IL-2, and it is thus an immunosuppressant (see Fig. C204). Cyclosporine may also become carcinogenic, not only by its immunosuppressive effects but also by boosting the synthesis of TGF- β . ► [immunosuppressant](#), ► [FK506](#), ► [antibiotics](#), ► [calcineurin](#), ► [cyclophilin](#), ► [cyclophosphamide](#), ► [immunophilins](#), ► [TGF](#), ► [immunological surveillance](#), ► [immunosuppression](#)

Cyclosporine-Binding Protein: ► [cyclophilins](#)

Cyclotides: Naturally synthesized circular plant peptides of ~30 or fewer amino acids occurring in *Rubiacea*, *Viola odorata*, and some other plants. The molecules form a distorted triple-stranded β -sheet and a cystine-knot motif. They are antibiotics and protect against insects. ► [cystine-knot](#); Craik DJ et al 1999 J Mol Biol 294:1327; Jennings C et al 2001 Proc Natl Acad Sci USA 98:10614.

Cyclotron: An accelerator of electrically charged particles and atomic nuclei. It is used to cause transmutations in atomic nuclei, e.g., a normal magnesium into radioactive sodium.

Cylindromatosis (CYLD, turban tumor): A (benign) skin tumor (primarily on hairy areas) caused by rare inactivation of a dominant gene in human chromosome 16q12-q13. The gene encodes a cytoskeleton-associated protein of 107 kDa. The CYLD gene mediates signaling from tumor necrosis factor α

through NF- κ B (NEMO) and I κ B. CYLD is a tumor suppressor and it blocks NF- κ B signaling through BCL-3 (Massoumi R et al 2006 Cell 125:665). As a consequence of reduction in CYLD, deubiquitination of TRAF2—a tumor associated factor—results and apoptosis is inhibited and tumor formation is promoted. ► [NF- \$\kappa\$ B](#), ► [NEMO](#), ► [I \$\kappa\$ B](#), ► [TNF](#), ► [TRAF](#), ► [deubiquitinating enzymes](#); Wilkinson KD 2003 Nature [Lond] 424:738.

Cyme: An inflorescence where the growth of the apex ceases early to the benefit of the branches (see Fig. C205).

Figure C205. Cyme

Cynomolgus: Cynomolgus most commonly means the *Macaca irus* laboratory monkey. ► [Rhesus](#), ► [Cercopithecidae](#)

CYP: ► [cytochromes](#)

Cyp: ► [cyclophilins](#)

Cyritestin: An ADAM family protein regulating the binding and fusion of the membranes of the sperm and the egg. ► [ADAM](#), ► [fertilization](#); Grzmil P et al 2001 Biochem J 357[pt 2]:551.

Cys₄ Receptor: Cys₄ receptor contains four cysteines—zinc domains in eukaryotic transcriptional regulators of α -helix-loop motif. The N-termini of the α helix contacts the nucleotide base, the N-terminal loop binds to the phosphate backbone, and the C-end is the dimerization interface. ► [zinc finger](#), ► [binding proteins](#)

Cyst: In general, bridges (ring canals) connecting a closed cavity in the body or the cluster of germline-derived cells that have undergone only a limited cytokinesis in the cells (see Fig. C206). Spermatogenesis in most animals (except nematodes) takes place in cysts. The oocyte develops within ovarian cysts. ► [fusome](#), ► [gametogenesis](#), ► [morphogenesis in *Drosophila*](#), ► [maternal effect genes](#); de Cuevas MA et al 1997 Annu Rev Genet 31:405.

C

Cystathionine β -Synthetase (21q22.3): The excessive expression of cystathionine β -synthetase seems to be linked to decreased atherosclerosis and higher survival rates, if stricken by acute myeloblastic leukemia (AML) in Down syndrome (see Fig. C207). Its anomalies may cause homocystinuria. ▶homocystinuria, ▶AML; Ge Y et al 2001 J Biol Chem 276:43570.

Figure C207. Cystathionine

Cystathioninuria: A recessive (human chromosome 16) deficiency of γ -cystathionase. Consequently, cystathionine cannot be cleaved into cysteine and homoserine, resulting in benign defects. ▶cystinosis, ▶cystinuria, ▶cystin-lysineuria, ▶homocystinuria, ▶amino acid metabolism, ▶aminoacidurias

Cystatine (cysteineprotease inhibitor): The loss of the gene *Cstb* causes myoclonous epilepsy of the Unverricht-Lundborg type and an increase in cathepsin S, C1qB chain of the complement, microglobulin β_2 , glial fibrillary acidic protein, apolipoprotein D, fibronectin 1, and metallothionein II. Cystatin level is an indication of renal function and high cystatin content predicts death by cardiovascular events in older patients (Shlipak MG et al 2005 New England J Med 352:2049). Neurosphere-derived cystatin C promotes growth and differentiation of embryonic stem cells into neurons, astrocytes, and oligodendrocytes (Kato T et al 2006 Proc Natl Acad Sci USA 103:60129). See terms under separate entries; ▶latexin; Lieuallen K et al 2001 Hum Mol Genet 10:1867.

Cysteamine: A decarboxylation product of cysteine. It is a radioprotective compound.

Cysteine ($\text{HSCH}_2\text{CH}[\text{NH}_2]\text{COOH}$): Upon hydrolysis of proteins in air, cysteine is converted to cystine. It is a radio-protective molecule.

Cystein-Histidine Finger: ▶DNA-binding protein domains, ▶zinc finger

Cysteine Knot: The cysteine-rich inhibitory motif of proteins, held together by disulfide bonds.

Cysteine Proteases: ICE, ICH1, NEDD2, ICH2/TX, CPP32/YAMA/apopain, and MHC2 are implicated in apoptosis. ▶apoptosis, ▶caspase

Cysteine-Scanning Mutagenesis: In cysteine-scanning mutagenesis, single amino acid residues in a protein domain are replaced by cysteine and modified by sulfhydryl-specific iodoacetamide derivatives of 7-nitrobenz-2-oxa-1,3-diazolyl dye. The activity of the 'mutated' protein is then determined. ▶site-directed mutagenesis; Kunkel TA 1985 Proc Natl Acad Sci USA 82:488.

Cysteine String Proteins (CSP): CSP contain palmitoylated cysteines on the peripheral membranes involved with the nerve synaptic vessels. ▶fatty acids, ▶synapse

Cystic Fibrosis: Cystic fibrosis is apparently one of the most common serious recessive hereditary defects in humans (human chromosome 7q31-q32), involving fibrous degeneration of the pancreas, bile ducts, the respiratory system, intestinal glands, sweat glands, male genital system, etc. The primary defect is apparently in chloride transport due to alteration of the gene regulating transmembrane conductance, which is caused by membrane lipid imbalance. The electrolyte transport is mediated by syntaxin, and the Munc18 protein blocks the latter. Several genetic modifiers (tissue necrosis factor, transforming growth factor, nitric oxide synthase, glutathione transferase, angiotensin convertase, mannose-binding lectin, etc.) affect the severity of the disease. It afflicts $\sim 1/2,000$ white newborns (the frequency of the responsible alleles may exceed 0.02). In American blacks the prevalence is more than an order of magnitude less and it is even much less common among Orientals. The large CF gene (27 exons) has been cloned (250 kbp). Hundreds of different mutations, including several deletions, have been identified. The manifestation of the disease varies a great deal especially in the lung. Prenatal diagnosis is 98% effective on the basis of determining the high level of immunoreactive trypsin in the serum, characteristic for CF. Sweat test and DNA test can also be used for diagnosis. Inhaling DNase solutions and avoiding respiratory infections may provide pulmonary relief by the use of antibiotics. Replacement and proper diet may alleviate pancreatic symptoms. The intestinal mucilage may be removed by surgery. Cystic fibrosis can be detected on the basis of the pattern of heat inactivation of the enzymes acid phosphatase and α -mannosidase. Homozygotes display practically no activity, heterozygotes 40–60%, and the absence of the defective allele is indicated by 80–100% activity. The testing of γ -glutamyltranspeptidase, aminopeptidase M, and alkaline phosphatase from the second trimester amniotic fluid permits prenatal diagnosis. Genetic screening can be carried out in newborns on the basis of immunoreactive trypsin. The normal allele of the cystic fibrosis gene is involved in the

regulation of sodium and chloride absorption and therefore it has been called cystic fibrosis transmembrane conductance regulator (CFTR, 27 exons), a protein kinase A and ATP regulated Cl^- ion channel. CFTR also affects HCO_3^- transport. A large deletion in the CFTR gene ($\Delta F508$) conditions the deficiency of internalization of *Pseudomonas aeruginosa* bacteria—to which cystic fibrosis patients are hypersusceptible—and because of this, the epithelial cells are unable to clear from the lungs the mucosa by desquamation. *Pseudomonas* infection particularly leads to the production of measurable amount of carbonyl sulfide in the breath and the presence of these bacteria may be revealed by a noninvasive measure of the infection (Kamboures MA et al 2005 Proc Natl Acad Sci USA 102:15762). *P. aeruginosa* infection causes apoptosis by activation of the CD95/CD95-ligand system. The *P. aeruginosa* strains in the CF patients generally carry mutator genes that facilitate the bacterial adaptation to antibiotic treatment. *Salmonella typhi* (the human pathogen) enters the intestinal mucosa through wild type CFTR. The human CFTR⁺ gene, equipped with the rat intestinal fatty acid-binding protein promoter, when transfected into a mouse corrected a lethal intestinal defect. Mice heterozygous for the cystic fibrosis gene secreted 50% of the normal fluid and chloride ions in response to cholera toxin, and thus CF may convey heterozygote advantage in natural selection. It has been suggested that the relatively high prevalence of cystic fibrosis in humans is due to a selective advantage in cases of *Vibrio cholerae* and *Escherichia coli* infection causing diarrhea by their toxin, which stimulates intestinal chloride secretion (Högenauer C et al 2000 Am J Hum Genet 67:1422). Many different mutations exist in the CF genes ranging from nil to only reduced synthesis of CFTR to various types of defects in regulation, in processing, and in altered conductance. CFTR is a member of the multidrug resistance protein family. Defects in CF may be associated with defects in the excretory channel of the testis (congenital bilateral aplasia of the vas deferens), azoospermia, asthma (breathing difficulties), nasal polyposis, and hypertyrosinemia. CFTR protein is also essential for normal sperm function (Xu WM et al 2007 Proc Natl Acad Sci USA 104:9816). Experiments indicate that gene therapy for cystic fibrosis is possible using primarily adenoviral, adeno-associated, and retroviral vectors but the efficiency of local transformation is low <0.1%. 10% efficiency may be required for effective remedy. Liposomal transfers and receptor-mediated gene transfers have also been attempted. The target should be the columnar cells lining the airways. Unfortunately, these cells are rather refractory to gene transfer. It has been shown that DNase I treatment has beneficial

effect on the removal of mucosa from the respiratory channel. Unfortunately, DNase is inhibited by F-actin secreted by the leukocytes that infiltrate the airways in response to infections. Actin-resistant DNase has been engineered that alleviates this problem. ▶cystic fibrosis antigens, ▶syntaxin, ▶munc, ▶genetic screening, ▶gene therapy, ▶infertility, ▶cholera toxin, ▶CD95, ▶azoospermia, ▶polyp, ▶tyrosinemia, ▶CBAVD, ▶multidrug resistance, ▶biofilm, ▶ABC transporters, ▶endoplasmic reticulum, ▶adenovirus, ▶adeno-associated virus, ▶retroviral vectors, ▶liposomes, ▶receptor-mediated gene transfer; Zielenski J, Tsui L-C 1995 Annu Rev Genet 29:777; Sheppard DN, Welsh MJ 1999 Physiol Rev 79: S[1] 23; Mateu E et al 2001 Am J Hum Genet 68:103; Bobadilla JL et al 2002 Hum Mut 19:575; Cutting GR 2005 Annu Rev Genomics Hum Genet 6:237, <http://www.genet.sickkids.on.ca/cftr/>.

Cystic Fibrosis Antigens (calgranulin A and B): Cystic fibrosis antigens are determined by dominant genes in human chromosome 1q12-q22. Homozygosity for the cystic fibrosis gene (7q31-q32) is accompanied by absence of these proteins whereas the symptom-less carriers have an intermediate level. It appears that these independent proteins track the basic defect in cystic fibrosis. Antigen A (also called calgranulin A because it is most abundant in the granulocytes) has a M_r 11,000 and antigen B (calgranulin B) has M_r 14,000. These two proteins are virtually identical with calcium-binding proteins in other sources. ▶cystic fibrosis

Cystine-Knot: A cystine knot is formed when two disulphide bridges link adjacent antiparallel strands of a peptide chain and form a ring that is penetrated by the third. Such cystine knots are found in NGF, TGF- β and PDGF-BB growth factors. ▶TGF- β , ▶platelet derived growth factor; Hymowitz SG et al 2001 EMBO J 20:5332.

Cystine-Lysinuria (diaminopentanuria): An autosomal recessive increase of diamines (cadaverin) in the urine, causing ataxia and mental degeneration. ▶amino acid metabolism, ▶cystinuria, ▶cystinosis

Cystinosis (CTNS): A semi-recessive autosomal hereditary disorder (see Fig. C208) under the control of more than one locus involving up to 100-fold amounts of cystine in the cells (lysosomes). Although it may not involve phenotypically obvious symptoms, it may eventually cause kidney failure, eye defects, growth arrest, and rickets. The heterozygotes can be identified by an increase in cystin in their cells. A cystinosis gene has been assigned to the short arm of human chromosome 17p13. The onset may be early or late.

C

Figure C208. Cystinosis. (Photograph is the courtesy of Dr. D.L. Rimoin, Harbor General Hospital, Los Angeles, CA)

Cystinosis is actually a lysosomal membrane protein (cystinosin) disease. The symptoms may be relieved by cysteamine. Renal transplantation may provide only a transient cure because the metabolic root is not localized to the kidney; kidneys only accumulate cystine. ▶[Fanconi renotubular syndrome](#), ▶[amino acid metabolism](#), ▶[cystinuria](#), ▶[cystin-lysinuria](#), ▶[homocystinuria](#); Touchman JW et al 2000 Genome Res 10:165.

Cystinuria: A recessive disease in several allelic forms, causing variable degrees of cystin deposits in the kidney cysts and in the bladder. Besides the increase of cysteine in the urine, larger than normal amounts of other amino acids (lysine, arginine and ornithine) may also be excreted. High fluid intake may prevent or alleviate the amino acid deposits. Type I is encoded at human chromosome 2p16.3, at the same site as the rBAT transporter protein. Another cystinuria gene was revealed at 19q12-q13.1. ▶[amino acid metabolism](#), ▶[cystinosis](#), ▶[cystine-lysinuria](#), ▶[homocystinuria](#), ▶[rBAT/4F2hc](#); Font M et al 2001 Hum Mol Genet 10:305.

Cystoblast: In the *Drosophila* germarium, the cystoblast divides four times and produces 16 cells (cystocytes), of which one becomes the oocyte, while the remaining 15 become nurse cells. The oocyte develops from one of the two, which are connected to four others. ▶[germarium](#), ▶[maternal effect genes](#)

Cystocarp: A spore-bearing structure formed in red algae after fertilization.

Cystocytes: ▶[cystoblast](#)

Cytidine: A pyrimidine base, cytosine, is associated with ribose or deoxyribose (see Fig. C209).

Figure C209. Cytidine

Cytidine 5'-Triphosphate Synthetase (CTPS, 1p34.1):

CTPS mediates the conversion of uridine triphosphate into cytidine triphosphate. Its deficiency may result in mutator effects and multidrug resistance.

▶[multidrug resistance](#)

Cytidylate: The salt of cytidylic acid.

Cytidylic Acid: Cytidine plus phosphate (a DNA or RNA nucleotide).

Cytoblast: The mitotic cell of the germarium in insects.

▶[germarium](#)

Cytochalasins: Toxins that break cellular actin microfilaments, inhibit glucose transport, thyroid secretion, growth hormone release, phagocytosis, and platelet aggregation and are used to evict nuclei from animal cells to produce cytoplasts and karyoplasts (see Fig. C210). ▶[toxins](#), ▶[cytoplast](#), ▶[karyoplast](#), ▶[actin](#), ▶[phagocytosis](#), ▶[nuclear transplantation](#)

Figure C210. Cytochalasins

Cytochemistry: The chemical analysis of isolated subcellular components, it also employs histochemical techniques for in situ tracing their action.

Cytochromes (CYP): Electron carrier heme proteins with important roles in respiration, photosynthesis, and other oxidation-reduction processes, including the activation of promutagens and procarcinogens. Human mitochondria encode three subunits of

cytochrome oxidase (COX), and 10 are coded by the nucleus. The nuclear SCO genes (22q13, 17p13.1) assist the assembly. In the mitochondria, cytochromes c_1 and c oxidize quinols, and in the chloroplasts, reduce a terminal oxidase, while photosynthetic bacteria cytochromes f and c_6 oxidize quinols and reduce a photo-oxidized reaction center. The cytochrome-b—cytochrome- c_1 complex including heme c_1 , and the Rieske [2Fe-2S] protein and ubiquinol/ubiquinon sites within the mitochondrial inner membrane, play essential roles in electron transfer along with cytochrome oxidase and NADH-dehydrogenase. Cytochrome c nitrite reductase plays an essential role in the nitrogen cycle. Many other roles of cytochromes are also known. When the permeability of the mitochondrial membrane is altered, cytochrome c may be released into the cytoplasm and apoptosis may follow. CYP2D6 (22q13.1) CYP2E1 (10q24.3-qter), CYP3A4, and CYP4A10 are responsible for the metabolism of ~30 drugs used to control debrisoquine-4-hydroxylase activity in the treatment of hypertension. There are hereditary variations among humans in cyclophilin activity and this may seriously affect the response to some drugs. ▶ **promutagens**, ▶ **procarcinogen**, ▶ **activation of mutagens**, ▶ **NADH**, ▶ **dehydrogenase**, ▶ **P450**, ▶ **cyclophilin**, ▶ **porin**, ▶ **carotene**, ▶ **insecticide resistance**, ▶ **Leigh's encephalopathy**, ▶ **SXR**, ▶ **pharmacogenetics**; Berry EA et al 2000 Annu Rev Biochem 69:1005; cytochrome b-transmembrane traffic: Cramer WA et al 2006 Annu Rev Biochem 75:769.

Cytodifferentiation: ▶ **differentiation**, ▶ **morphogenesis**

Cytoduction: The dominant cytoplasmic transmission of a particular hereditary state, such as introduction, e.g., mitochondria into a cell and heterokaryosis in yeast. ▶ **heterokaryon**

Cytofectin GS2888 (dioleophosphosphatidylethanolamine): A transfecting agent for mammalian cells. It is coupled with a fusogenic compound and a cationic lipid (GS2888). It carries plasmids, AS ODNs, etc. into cells efficiently and its toxicity is low. Histidine-rich amphipatic peptide antibiotics also facilitate gene delivery into mammalian cells. ▶ **liposome**, ▶ **fusogenic liposome**, ▶ **AS ODN**, ▶ **transfection**; Axel DI et al 2000 J Vasc Res 37:224; Kichler A et al 2003 Proc Natl Acad Sci USA 100:1564.

Cytogenes: Cytogenes are located in the cellular organelles (plastids, mitochondria) and not in the nucleus. ▶ **mitochondrial genetics**, ▶ **chloroplast genetics**

Cytogenetics: A branch of genetics involving the study of chromosomal structure and behavior in connection with inheritance. It also involves the study of chromosomal anomalies and accompanied pathological conditions, as well as cytological analysis of the

evolution of chromosomes. Integrated cytogenetic and physical maps are available, Trask BJ 2002 Nat Rev Genet 3:769. (See human cytogenetics: <http://www.ncbi.nlm.nih.gov/genemap>).

C

Cytohesins: Brefeldin A-resistant guanine exchange factors (GEF) for ADP-ribosylation factors (ARF) involved in cytoskeletal organization through integrin activation or signaling. Their inhibition by the relatively small molecule SecinH3 causes insulin resistance in the liver (Hafner M et al 2006 Nature [Lond] 444:941; Fuss B et al 2006 Nature [Lond] 444:945). ▶ **brefeldin**, ▶ **GEF**, ▶ **ARF**, ▶ **cytoskeleton**, ▶ **integrin**, ▶ **insulin**

Cytohet: Heterozygosity in cytoplasmic genes (in plastids and mitochondria) when the zygotes receive cytoplasmic material biparentally. ▶ **chloroplast genetics**, ▶ **mtDNA**

Cytokines: Peptides secreted in response to mitogenic stimulation, they participate in intercellular communication and cellular activation. Most of the cytokine receptors invoke tyrosine phosphorylation of cellular proteins. The various cytokine receptors permit the action of different protein tyrosine kinases (PTK) in different cell types. They are instrumental in the induction and regulation of the immune system, cellular differentiation, blood cell formation, apoptosis, and tumor inhibition, and may facilitate cancer metastasis, cell migration, DNA synthesis, etc. The cytokine receptors belong to several superfamilies with some common features within the groups: (1) hematopoietin receptors, (2) interferon receptors, (3) TNF receptors, (4) interleukin-1 receptors and (5) TGF- β receptors, (6) immunoglobulin receptors [M-CSF-R, EGF-R, PDGF-R, etc.], and (7) chemokine receptors. Generally (one of) the α -chains provides the cytokine specificity, whereas a β -chain exerts a boosting effect. Different cytokine receptors may share functions and more than one kind may be involved in the same process. The cytokines may have pleiotropic effects in the signal transduction paths. Different cytokines may recruit various docking proteins and utilize different Janus (JAK) kinases and Tyk2 to increase specificity. Cytokine therapies are hindered by the short half-life of cytokines. A remedy is to fuse the latency-associated protein (LAP) of the transforming growth factor- β 1 (TGF) to interferon- β (IFN) through matrix metalloproteinase (MMP). This fusion product resembles transforming growth factor but stays inert until it is cleaved by metalloproteinase. Cerebrospinal or synovial fluid can activate the construct and the latent construct is more effective in therapy of inflammatory disease because of its prolonged half-life (Adams G et al 2003 Nature Biotechnol 21:1314). ▶ **interleukins**,

►interferons, ►colony stimulating factor, ►PTK, ►TGF, ►M-CSF, ►EGF, ►PDGF, ►signal transduction, ►aminoacyl-tRNA synthetase, ►chemokines, ►lymphokines, ►CIS, ►SOCS-box, ►CSAID; Thompson AW ed. 1998 *The Cytokine Handbook*. Acad. Press, San Diego, CA, USA; Dranoff G 2004 *Nature Rev Cancer* 4:11, www.copewithcytokines.de; <http://csp.medic.kumamoto-u.ac.jp>, cytokine-receptor interactions: <http://bioinf.xmu.edu.cn/software/cytosvm/cytosvm.php>.

Cytokine Storm: The sudden release of cytokines, it may result in strong inflammatory response due to activation of T cells.

Cytokinesis: The division of the cytoplasm after nuclear division leading to the formation of two cells from one (see Fig. C211). In animal cells, a contractile ring composed of actin and myosin and attached to the cell membrane generates a furrow, which separates the mother cell into two daughter cells after the completion of mitotic anaphase. In the mid-zone of the spindle PRC1, a microtubule-associated protein moves to the plus ends of the microtubules during the metaphase–anaphase transition with the assistance of Kif4 motor protein. Phosphorylation of PRC1 by a cyclin-dependent kinase determines the timing of Kif4 action on PRC1 and the eventual formation of the midzone (Zhu C, Jiang W 2005 *Proc Natl Acad Sci USA* 102:343). *Centralspindlin complex* composed of MKLP1 kinesin-like protein (among others) and the Rho guanosine triphosphatase activating protein (GAP) aided by CYK-4 facilitates GTP hydrolysis (Jantsch-Plunger V et al 2000 *J Cell Biol* 149:1391). Cdc5 activates Rho1 (Yoshida S et al 2006 *Science* 313:108). Cytokinesis requires that spindle checkpoint and Aurora B protein are functional. Chromosome segregation is then mediated through microtubule elongation. In the midzone protein “nocut” and anilin-related proteins Boi1 and Boi2 are inhibitors of abscission of the microtubules. When “nocut” senses that the chromosomes are cleared from the midzone and migrated to the opposite cells, cytokinesis (separation) is completed. If the spindle is damaged or “nocut” is inactivated, abscission may take place prematurely and chromosome breakage may ensue (Norden C et al 2006 *Cell* 125:85). ►mitosis, ►cell cycle, ►cell plate, ►midzone, ►cleavage furrow, ►Cdc5; Nan-ninga N 2001 *Microbiol Mol Biol Rev* 65:319; Zeitlin SG, Sullivan KF 2001 *Curr Biol* 11:R514; Heese M et al 2001 *J Cell Biol* 155:239; Glotzer M 2001 *Annu Rev Cell Dev Biol* 17:351; Guertin DA et al 2002 *Microbiol Mol Biol Rev* 66:155; Balasubramanian MK et al 2004 *Curr Biol* 14:R806; proteins mediating animal cytokinesis: Eggert US et al 2006 *Annu Rev Biochem* 75:543.

Figure C211. Cytokinesis. (Courtesy Kevin Sullivan and DW Cleveland)

Cytokinins: Cytokinins and auxins are the most important plant hormones regulating plant development. ►plant hormones; Werner T et al 2001 *Proc Natl Acad Sci USA* 98:10487; Hwang I, Sheen J 2001 *Nature [Lond]* 413:383; Mok DW, Mok MC 2001 *Annu Rev Plant Physiol Plant Mol Biol* 52:89; Hutchison CE, Kieber JJ 2002 *Plant Cell* 14:S47.

Cytoline: Cytoplasm replacement (by several backcrosses) generates a new line that is characterized by the identity of the cytoplasm (Allen JO 2005 *Genetics* 169:863).

Cytological Evidence for Crossing Over: The first cytological evidence for crossing over was collected in 1931 in maize by using a line heterozygous for chromosome 9 bearing a large terminal knob and the *C/c* and *Wx/wx* genes. Creighton HB and McClintock

Figure C212. Cytological evidence for crossing over. An outline of one of the *Drosophila* experiments on correspondence between genetic and physical exchange of chromosomes. (After Stern C 1931 *Biol Zbl* 51:547)

B in 1931 (Proc Natl Acad Sci USA 17:492) found that the cytologically detected knob followed the syntenic genetic markers and corresponded to the expectation in the recombinants.

Around the same time, Curt Stern used in *Drosophila* a fragmented X-chromosome marked with *carnation eye* (*cr*) and *Bar eye* (*B*) and another X-chromosome with the wild type alleles and also a fragment of the Y-chromosome attached. Again, the genetically observed recombination was associated with the physical exchange of the cytologically marked chromosomes. (See crossing over, diagram).

Cytological Map: A cytological map shows genetic sites in relation to microscopically visible structures such as chromosome bands, knobs, centromeres, and satellite(s). ▶genetic map, ▶physical map, ▶RFLP, ▶RAPD

Cytological Marker: A unique feature of the chromosome, e.g., knob and satellite, the number of nucleoli in the nucleus, defective plastids, etc., visible by cytological analysis. ▶salivary gland chromosomes, ▶pachytene analysis, ▶knob, ▶satellite

Cytology: The study of structure and related functions of the cell and subcellular elements. See www.cellnucleus.org.

Cytolysin: Cytolysin is secreted by cells to dissolve other cells, e.g., during the immune reaction, during quorum sensing, and during pore-formation by bacteria. ▶streptolysin; Haas W et al 2002 Nature [Lond] 415:84.

Cytolysis: The dissolving of the cells into its chemical components.

Cytomegalovirus (CMV): CMV include the herpes viruses, Epstein-Barr virus, varicella-zoster virus, and the Kaposi sarcoma associated virus. CMV has an icosahedral capsid that is assembled after an internal protein scaffold is cleaved proteolytically (see Fig. C213). Interference with this encapsidation step reduces infectivity by four orders of magnitude (Yu X et al 2005 Proc Natl Acad Sci USA 102:7103). These potentially tumorigenic viruses have double-stranded DNA genetic material and great and diverse mammalian host specificity. US28 chemokine receptor, coupled with G protein and encoded by human CMV, facilitates angiogenesis and contributes to tumor onset and progression (Maussang D et al 2006 Proc Natl Acad Sci USA 103:13068). The name (megalo) comes from the observation that the infection enlarges the host cells. The epidermal growth factor receptor is essential for CMV infection of humans (Wang X et al 2003 Nature [Lond] 424:456). The human cytomegalovirus can produce about 200 potentially antigenic polypeptides, however, the CMV early-expressed gene (gpUL40) may

Figure C213. Cytomegalovirus

block antigen presentation by class I MHC molecules (HLA-E), and thus the defense function of CD8⁺ cytotoxic T lymphocytes. In the mouse mutations in proteins, m157 enables the virus to evade natural killer cells of the host (Voigt V et al 2003 Proc Natl Acad Sci USA 100:13483). Phosphorylation of the immediate early (IE) proteins may prevent the interference with antigen presentation and the CTL defense system. The human CMV may cause serious disease in congenitally infected infants and adults with defective immune system. Homosexual males and female prostitutes may frequently (up to 90%) be infected with CMV, depending on the number of sexual partners. The opportunistic CMV disease (most commonly expressed as inflammation and necrosis of the retina) may surface after latent infections in case of AIDS. The latent virus resides in myeloid dendritic progenitor cells and chromatin remodeling leads to reactivation of the virus and pathogenesis (Reeves MB et al 2005 Proc Natl Acad Sci USA 102:4140). Treatment may employ the antisense oligodeoxynucleotide fomivirsen. The human cytomegalovirus may cause site-specific (human chromosome 1q42 and 1q21) breakage due to viral adsorption/penetration but not by expression of CMV genes. It is a common cause of virus-induced birth defects. Several variants have been (~230,000 bp) sequenced. The human virus has ~192 open reading frames (Murphy E et al 2003 Proc Natl Acad Sci USA 100:13585). ▶herpes, ▶Epstein-Barr virus, ▶MHC, ▶antigen presenting cell, ▶T cells, ▶CTL, ▶AIDS, ▶fomivirsen, ▶chemokines; Murphy E et al 2003 Proc Natl Acad Sci USA 100:14976.

Cytoneme: The projection toward the signaling center of the imaginal disk. Cytonemes may transmit signals between the organizing centers and outlying cells. ▶imaginal disks, ▶organizer, ▶signal transduction

C

Cytonuclear Disequilibria Analysis: A method of evolutionary (population genetics) study of the association between nuclear and markers to detect non-random mating, gene flow, population subdivision, mutation, and genetic drift. (See Latta RG et al 2001 Genetics 158:843).

Cytopathic: A cytopathic agent causes pathological changes in the cell.

Cytopenia: The reduction in the number of blood cells. It may occur as a consequence of chemotherapy or disease. ►IVIG

Cytophotometry: Spectrophotometric chemical study of the content(s) of single cells. ►spectrophotometry, ►microscopy

Cytoplasm: All materials enclosed by the cell membrane, including cellular organelles, but excluding the nucleus. ►cell, ►protoplasm

Cytoplasmic Drive: The cytoplasmic drive promotes maternal inheritance by cytoplasmic factors.

Cytoplasmic Incompatibility: Cytoplasmic instability involves the disruption of fertilization or embryogenesis because of bacterial infection in insect species. ►infectious heredity, ►incompatibility, ►*Wolbachia*; Charlat S et al 2001 In Symbiosis: Mechanisms and Model Systems, Seckbach J (ed) Kluwer Academic, Dordrecht, the Netherlands.

Cytoplasmic Inheritance: Cytoplasmic inheritance is determined by non-nuclear genetic factors. Some organelles (plastids, mitochondria) are endowed with independent genetic material, but organelles like the endoplasmic reticulum and the Golgi apparatus do not have independent genetic material. Their transmission to daughter cells requires attachment to the cytoskeleton or actin filaments or they may be also *de novo* synthesized. Their transmission, unlike that mediated by the mitotic spindle, may be asymmetric. ►chloroplast genetics, ►mtDNA, ►mitochondrial genetics; Barr FA 2002 Curr Opin Cell Biol 14:496.

Cytoplasmic Male Sterility (*cms*): In maize, five different mitochondrial genomes have been identified and three of them (*T*, *Texas*; *S*, USDA and *C*, Charrua) control cytoplasmically inherited male sterility. The *Rf* restorer genes restore fertility.

Fertility restoration requires specific nuclear genes or the loss of the *T-urf13* site caused by an intramolecular mtDNA recombination between two 4.6-kb repeats, followed by an intermolecular recombination of a 127-bp repeat, and resulting in a 0.4-kb deletion involving *T-urf13*.

The joint action of *Rf1* and *Rf2* restorer genes is sporophytic, i.e., approximately all (95%) the pollen produced is fertile in the plants heterozygous for these dominant nuclear genes. In the *S* cytoplasm, *Rf3* conveys gametophytic restoration, i.e., in the heterozygotes approximately half of the pollen is fully functional and half is aborted. *Rf4* acts sporophytically also in *S* cytoplasm. Although *cms* has been identified in over 100 maize stocks, all of them fall into the three groups.

The various circular mtDNAs have been physically mapped and their sizes differ (*T* is 540-kb). The male sterility in the *Tcms* stock was attributed to a mitochondrial locus, *T-urf13*, near a 4.7-kb repeat absent from normal mtDNA. Maize mitochondria contain several smaller DNAs besides the main genome.

The loss of mitochondrial linear double-stranded DNA plasmids *S-1* (6,397-bp) and *S-2* (5,453-bp) from the *S* cytoplasm may or may not be required for the restoration of fertility, depending on the nuclear genome (see Fig. C214). In the *cms-S* mitochondrial DNA there are 2-kb recombinational repeats (*R*) at the junctions σ - σ' and Ψ - Ψ' . These repeats may become the sites of recombination between the integrated and the episomal *R* sequences, thus resulting in rearrangements of the mtDNA genomes. The *R* elements carry 210-bp sequences, which are highly homologous (~90%) with the terminal inverted repeats (TIR) of the *S* plasmids. These TIR sequences are sites of frequent recombinations, resulting in complex rearrangements of the mtDNA. The size of the *R* elements varies in different maize stocks. Their homologs in some teosinte lines are named M1 and M2. Some of the nuclear fertility restorer genes (called *Rf* or *Fr* in different species) control the transcription and translation of the *cms* mtDNA. The "reversion" usually represents loss of parts of the *R* sequences and thus it is a permanent, irreversible change. The cytoplasmic male sterility of the *T* type is associated with susceptibility to *Helminthosporium maydis* (*Cochliobolus heterostrophus* Drechsler) blight and to other factors. The *T* cytoplasm conveys susceptibility also to the systemic insecticide methomyl (acetylcholinesterase inhibitor) and the toxin of the fungus *Phyllosticta maydis* (yellow corn leaf blight). The URF13 protein contains 115 amino acids residing in the inner membrane of the mitochondria. URF13 is a receptor of the toxin of the blight pathogens and also for methomyl. When URF13 binds the toxin it forms a mitochondrial pore and uncouples oxidative phosphorylation. *Rf1* restorer gene alters the transcript of the *T-urf13* gene but *Rf2* does not do this although it too inhibits male sterility. The RF2 protein

C

Figure C214. Cytoplasmic male sterility. An outline of the procedure for obtaining double-cross hybrid seed by the use of cytoplasmic male sterile lines of maize. *R* stands for a dominant fertility restorer gene; *r* does not affect cytoplasmic male sterility. The inner circles represent the cell nucleus and a band around it symbolizes the cytoplasm. Shading in the cytoplasm stand for determinants of mitochondrial male sterility. Plants with shaded cytoplasm can produce seed only when fertilized by *R* pollen

is very similar to mammalian mitochondrial aldehyde dehydrogenase. Restoration of fertility does not abolish the susceptibility to the fungal toxins. The elements of these systems are influenced also by the genetic background. In cultured cells *Helminthosporium*-resistant mitochondrial mutations occur that are also male fertile. Cytoplasmic male sterility systems were observed also in several other plant species. The 3.7-kb *pvs* mtDNA sequence in common bean plants is associated with cytoplasmic male sterility. This sequence includes two open reading frames, *orf239* and *orf98*. The 27-kDa protein product of *orf239* localizes in the callose layer and the primary cell wall of the pollen. The mitochondrial *pcf* gene of *Petunia* encodes a 25-kDa protein in the CMS plants, but it is unknown how it affects sterility. Transforming *orf239* into tobacco (*N. plumbaginifolia*) without targeting it into the mitochondria causes pollen disruption. Cytoplasmic male sterility is not based on a single nucleotide change in the mtDNA although nuclear encoded male sterility may be due to point mutations. The majority of the cytoplasmic

male sterility cases are not the direct consequence of deletions.

Transformation of the β -ketothiolase gene (*phaA*) driven by the light-sensitivity promoter (*psbA*) into tobacco chloroplasts was seen to result in male sterility without affecting other functions. Under continuous illumination, the male sterility (caused by collapsed pollen) was entirely reversed and the plants became normally fertile. This procedure, if employed in plant breeding, may facilitate the production of heterotic hybrids. The physiological basis of the ketothiolase action is that it successfully outcompetes acetylcoenzyme-A carboxylase for mediating the conversion of acetyl-CoA into malonyl-coA (required for fatty acid synthesis and normal pollen); instead, acetyl-coA is converted into acetoacetyl-coA, resulting in pollen defects (Ruiz ON, Daniell H 2005 Plant Physiol 138:1232; Khan MS 2005 Nature [Lond] 436:738).

Mitochondrial respiration defects caused by the accumulation of mtDNA induce oligospermia and asthenozoospermia in the mito-mice (Nakada K et al

2006 Proc Natl Acad Sci USA 103:15148). ▶male sterility, ▶mtDNA, ▶mitochondrial abnormalities in plants, ▶symbionts hereditary, ▶heterosis, ▶hybrid vigor, ▶mitochondrial plasmids, ▶mitochondrial genetics, ▶fertility restorer genes, ▶RU maize, ▶cholinesterase, ▶oligospermia, ▶mito-mice; Duvick DN 1965 Adv Genet 13:1; Williams ME, Levings CS III 1992 Plant Breeding Revs 10:23; Budar F, Pelletier G 2001 CR Acad Sci III 324:543; Bentolia S et al 2002 Proc Natl Acad Sci USA 99:10887; general review of methods: Daniell H et al 2005 Methods Mol Biol 286:111; review of plant CMS: Chase CD 2007 Trends Genet 23:81.

Cytoplasmic Transfer: ▶conjugation *Paramecia*

Cytoplasm: An enucleated cell (cell that has lost its nucleus). ▶transplantation of organelles, ▶karyoplast

Cytosine (C): A pyrimidine base in RNA or DNA. ▶pyrimidines

Cytosine Deaminase (CD): Bacterial (gene 1.3-kb) and fungal enzymes transform cytidine into uracil or deoxycytidine into deoxyuridine. Mammalian cells may lack this function. Activation-induced cytosine deaminase (AID) appears to be an RNA-editing enzyme and is however required for somatic hypermutation, class switch recombination, and gene conversion of immunoglobulin genes (Yoshikawa K et al 2002 Science 296:2033). CD also deaminates cytosine arabinoside, an antileukemic drug, into inactive uracil derivatives. CD converts 5-fluorocytosine (5-FC) into 5-fluorouracil (5-FU), a more effective anti-cancer drug, by suicidal action. Transformation within the CA gene itself does not affect mammalian cells, but it may increase the sensitivity to 5-FC by 10^2 to 10^4 -fold depending on the type of cancer. The effectiveness of CA gene therapy is determined by the effectiveness of delivering the vector to all cells of the tumor. The cancer cells, which do not incorporate the vector, may reinitiate new tumor growth after an initial regression. The targeting of the vectors is also a problem even when it is equipped with tumor-specific monoclonal antibody. On the other hand, the CA therapy may have a bystander effect. ▶fluorouracil, ▶suicide vector, ▶cancer gene therapy, ▶bystander effect, ▶immunoglobulins, ▶somatic hypermutation; Ueda K et al 2001 Cancer Res 61:6158.

Cytosine-Repressor (CytR): CytR regulates the transcription of at least eight genes of *E. coli* involved in nucleoside uptake and catabolism. All CytR-repressed promoters have a catabolite repressor (CRP) binding site and repression is the outcome of the cooperation between the CytR and the CRP-cAMP complex. ▶catabolite repression, ▶cAMP

Cytoskeleton: The bracing and scaffolding fibers (actin, microtubule and other filaments) in the cytoplasm (see Fig. C215). The cytoskeleton may affect different cellular functions, the progression of the cell cycle, differentiation, diseases, cirrhosis of the liver, highways for intracellular vehicles moved by motor proteins, etc. ▶filaments, ▶intermediate filaments, ▶ARP2/3 complex, ▶cirrhosis of the liver, ▶motor proteins, ▶actin, ▶ankyrin, ▶pollen; Fuchs E 1996 Annu Rev Genet 30:197; Gachet Y et al 2001 Nature [Lond] 412:352; Kost B, Chua N-H 2002 Cell 108:9; bacterial cytoskeleton: Michie KA, Löwe J 2006 Annu Rev Biochem 75:467.

Figure C215. Cytoskeleton

Cytosol: The soluble, non-particulate material of the cell that suspends all cellular structures within the plasma membrane.

Cytostatic: A cytostatic substance hinders cell division.

Cytostatic Factor: ▶CSF

Cytostatic Stability Factor: The cytostatic stability factor maintains MPF at high level during metaphase II and prevents exit from metaphase. ▶MPF, ▶mitosis

Cytotactin: The extracellular matrix protein affecting cell movement.

Cytotaxonomy: Evolutionary studies based on the analysis of the cells and chromosomes.

Cytotoxic: A cytotoxic substance poisons or kills cells, primarily by inhibition of mitosis.

Cytotoxic Ribonuclease: ▶colicins

Cytotoxic T Cell (CTL, CTC): A type of T lymphocytes that destroys infection-carrying cells or foreign antigens. CTLs recognize their targets by the antigenic peptides presented on dendritic cells. CTLs require activation mediated by $CD4^+$ T helper cells (T_H), which have on their surface CD40 or the CD40L (ligand) proteins. CD40 and CD40L alone may be sufficient for activation of CTLs and their presence on the antigen presenting cells (dendritic cells, macrophages and B lymphocytes) enhances the

activation of CTLs. The natural killer cells (NK) lyse various types of cells without the cooperation of the MHC system. CTL and NK cells, however, may cooperate and induce the formation of cytolytic granules and lytic pores. Perforin expression on CD8⁺ T cells and sometimes on CD4⁺ cells plays an important role in this process. The cytolytic granules may contain granulysin, a saposin-like glycoprotein. Saposins are generated by cleavage of the 511-amino acid presaposin and the four types of saposins stimulate the hydrolysis of ceramides by stimulating the particular enzymes. Various leukodystrophies and Gaucher disease are attributed to saposin deficiencies. Another mechanism of action was suggested to rely on the Fas-dependent apoptosis. Actually, these two routes may be used simultaneously. CD8⁺ T cells recognize cytopathic and noncytopathic viruses by presentation of their peptide antigens on MHC I molecules. The killing may also involve the secretion of antiviral lymphokines. Bacterial infections are handled also by activated macrophages, NK cells, T cell receptors, granulocytes, and CD4⁺ and CD8⁺ T cells. IFN γ and perforin

are the fighting molecules. Perforin-dependent destruction of insulin-producing cells seems to be involved in autoimmunity diseases and diabetes mellitus. Graft rejection is caused by the infiltration into the added tissue NK cells, macrophages, and CD4⁺ and CD8⁺ T cells. The latter two recognize MHC II or MHC I differences, respectively. ▶lymphocytes, ▶T cell, ▶T cell receptor, ▶perforin, ▶granzyme, ▶killer cells, ▶apoptosis, ▶CD4, ▶CD8, ▶CD40, ▶antigen presenting cell, ▶dendritic cell, ▶MHC, ▶Fas, ▶macrophages, ▶diabetes, ▶graft rejection, ▶cytomegaloviruses, ▶Gaucher disease, ▶leukodystrophy; Kägi D et al 1996 Annu Rev Immunol 14:297; Raulet DH et al 2001 Annu Rev Immunol 19:291; Moretta A et al 2001 Annu Rev Immunol 19:197; Russell JH Ley TJ 2002 Annu Rev Immunol 20:323.

Cytotoxicity: The ability of any agent to harm, destroy or poison cells.

CytR: ▶cAMP receptor protein

Historical vignettes

Sturtevant AH 1967 Reminiscences of Morgan TH Genetics 159:1 [2001]:

“...if you mix eggs and sperm from the same individual [*Ciona*, an ascidian]. Normally nothing happens. But sometimes self-fertilization does occur. And one of the questions was, Why? What brings this about? How does this happen? And Morgan had a nice hypothesis: maybe the acidity of the water is responsible. And let's see what pH changes will do. But being Morgan he didn't set up measured amounts or concentrations. What he did was to take a dish in which eggs and sperm were present and squeeze a lemon over it. And it worked. Then he studied it in more detail after that. This was one of the most successful experiments in the field.”

Curt Stern recalled his discovery of the cytological and genetical proof of crossing over at the 1st Stadler Genetics Symposium in 1969 and published in vol. 1, p. 24:

“In the context of reminiscences as well as for the benefit of sociologists of science who perhaps may find food for their thoughts, let me recount some aspects of my first report on the cytological proof of crossing over. By the summer of 1931 I had completed the work, had written the paper, which was accepted for publication and had then gone on vacation. At the end of this period I went to Munich to attend the September meeting of the German Genetics Society and to present my results. With me came my fiancée who on the day of my speech presented me with a set of beautifully arranged attached and translocated peppermint canes. I gave my paper with the enthusiasm of a successful youth. Soon after, one of my colleagues from the Kaiser Wilhelm Institut came to me and said: “I didn't want to spoil your fun but while you were on vacation a paper came out written by Harriet Creighton and Barbara McClintock who did experiments in maize equivalent to what you just announced as unique.” May I confess that I am still grateful to my colleague for permitting me the, feeling of triumph for half an hour longer than I would have had it if he had told me about the Creighton-McClintock paper before my talk.”

DAF: ▶decay accelerating factor

DAF: dauer larva formation. ▶dauer larva

DAG: ▶diacylglycerol

DAI: DAI is an interferon-induced protein and a double-strand RNA activated inhibitor that is involved in kinase function regulating translation. When 25–30% of the factor is phosphorylated protein synthesis is severely inhibited. ▶interferon, ▶kinase, ▶translation

DALA: δ-aminolevulinic acid.

DALI: A three-dimensional protein query program. <http://www.ebi.ac.uk/dali/>.

Dalton (Da): Measurement unit of molecular mass (M_r), generally used to estimate the size of macromolecules, 1 Da = 1.661×10^{-24} g (1/12 of the MW of the C^{12} isotope). 1 MDa is 10^6 Da. 1 pg of DNA is

about 0.60205×10^{12} Da; the M_r of a nucleotide pair is about 650 Da; 1 kbp DNA (Na salt) is about 6.5×10^5 Da. The “average” molecular weight of an amino acid residue in a protein is about 110–120 Da.

DALY (disability-adjusted life year): DALY is the sum of life years lost due to premature mortality and years of life with disabilities adjusted for the severity of the disability. On this basis, congenital anomalies occupy the 10th rank among 17 leading disabilities in the world. ▶ [genetic diseases](#)

Dam: Female mammal. ▶ [sire](#)

dam: The deoxyadenine methylation factor in a GATC sequence. ▶ [methylation of DNA](#)

DAM Methylase: These enzymes are several main groups of methyl transferases (Hha I C5-cytosine methyltransferase, Taq I N6-adenine methyltransferase and the catechol *O*-methyl transferase). The majority of these enzymes use *S*-adenosyl-L-methionine (SAM) as a methyl donor. Their catalytic domain is rather well conserved and the various methylases can transfer methyl groups to DNA, RNA, proteins and other molecules. ▶ [methylguanine-O⁶-methyltransferase](#), ▶ [methyltransferase](#), ▶ [methylation of DNA](#); Cheng X 1995 Annu Rev Biophys Biomol Struct 24:293; Malygin EG et al 2001 Nucleic Acids Res 29:2361.

DAMD (directed amplification of minisatellite DNA): DAMD uses PCR to produce probes for the determination of homologous variations among different species or genetic stocks for DNA fingerprinting, generally by RFLP. ▶ [PCR](#), ▶ [RFLP](#), ▶ [minisatellite](#), ▶ [DNA fingerprinting](#); Heath DD et al 1993 Nucleic Acids Res 21:5782.

D-Amino Acids: Enantiomorphs of the natural L-amino acids. The D and L, respectively, are related to the optical rotation of the molecule, however D or L molecules may have either [+] or [−] optical rotation (see Fig. D3). According to the original Fischer’s model, a D and L amino acid can be represented as shown but other representations are also used. The D forms frequently have inhibitory or antimicrobial effects. The genetic codons of both forms are the same and they are the products by post-translational enzymatic reaction. The inclusion of D-amino acids into vaccines against infectious agents or autoimmune diseases may be advantageous because they last longer and resist enzymatic degradation (Seala M, Zisman E 1997 FASEB J 11:449). An epitope of the mucin2 glycoprotein containing ¹⁵TPTPTGTQTPT²⁵ retained full function after substitution of two D-amino acids at its N-terminal flank and up to three at its C-terminal flank (Tugyi R et al 2005 Proc Natl Acad Sci USA 102:413).

D-amino acids occur naturally in some hemolytic peptides of the skin of frogs, snails, spider venom and in some crustaceans. The D-amino acids are coded by the L form codons and enzymatically converted to the D enantiomorph (Jilek A et al 2005 Proc Natl Acad Sci USA 102:4235). ▶ [amino acids](#), ▶ [mucins](#), ▶ [enantiomorph](#), ▶ [epitope](#)

darwin: A measure of the rate of evolution = $(\ln[x_2] - \ln[x_1])/n$, where x_1 and x_2 indicate population sizes as they change during n million years (Myr), \ln is the natural logarithm.

Darwinian Fitness: ▶[fitness](#), ▶[neutral mutation](#), ▶[beneficial mutation](#)

Darwinism: The interpretation of evolution as the outcome of natural selection; and survival of the fittest. Charles Darwin published his theory in 1859, in his *Origin of Species*, two decades after he expounded it. The cause of the delay is still unclear; he might have either worried about public response to his revolutionary theory or wanted to accumulate additional data to make it unassailable. On molecular basis, non-synonymous amino acid replacement versus synonymous replacement may be an indication of selective or random events.

“Darwin’s greatest accomplishment is to show that the complex organization and functionality of living beings can be explained as the result of a natural process—natural selection—without any need to resort to a Creator or other external agent. The origin and adaptations of organisms in their profusion and wondrous variations were thus brought into the realm of science” (Ayala FJ 2007 Proc Natl Acad Sci USA 104 Suppl. 1:8563). ▶[natural selection](#), ▶[neo-darwinian evolution](#), ▶[social darwinism](#), ▶[synonymous codons](#), ▶[non-synonymous codons](#), ▶[algorithm genetic](#), ▶[creationism](#), ▶[intelligent design](#); Gould SJ, Lloyd EA 1999 Proc Natl Acad Sci USA 96:11904; complete works of Darwin: <http://darwin-online.org.uk/>; Darwin library, publications on darwinism: <http://darwinlibrary.amnh.org/>; Charles Darwin’s correspondence: <http://www.lib.cam.ac.uk/Departments/Darwin/index.html>.

Data Model: A set of bioinformatics constructs (sets, relations, objects) suitable to build databases. ►bioinformatics, ►databases

Data Sharing Principles (Fort Lauderdale Agreement): <http://www.genome.gov/10506537>.

Database Management System (DBMS): DBMS interprets the structure of data (schema) for generation of databases in a specified form, e.g., Oracle and Sybase. ►sybase

Databases: (for some addresses and additional information see under **special entries**) Databases provide information of different subjects by electronic means. Addresses frequently change and many have overlapping information, but they can be very helpful. Internet addresses hundreds of databases that are listed each year in the first issue of *Nucleic Acids Research* and accessible through the Internet without charge: <http://nar.oupjournals.org>. Links to several databases follow:

<http://www.biologie.uni-hamburg.de/b-online/e00/links.htm>. Much more information is now available under separate entries in the alphabetical lists. Data management hardware, software and service providers are listed in *Nature* 428:778 (2004)

or <http://www.ajb.dni.us/>.

Cautionary note: Many symbols have multiple synonyms or single symbols standing for different genes or spelling and capitalization may vary for the same word and various errors may be encountered. Some databases cannot be entered without permission; the conditions for access can usually be obtained from the URL addresses. Addresses frequently change or are decommissioned (http://www-class.unl.edu/biochem/url/broken_links/html). Despite the problems, the databases provide invaluable information on details that could not be included in this book. The information must be critically read just as well as any publication coming from other sources. The addresses given above have been updated shortly before the completion of this book. (See, however, Nature [Lond] 402:722). According to Dellavalle RP et al 2003 Science 302:787 lost Internet site may be recovered through www.google.com; <http://www.altavista.com> or other search engines.

Data Mining: Searching for the biological meaning of nucleotide acid or amino acid sequences. ► [dredging data](#); Baxter SM, Fetrow JS 2001 Curr Opin Drug Discov Devel. 4(3):291; Smyth P 2000 Stat Methods

Med 9[4]:309; Perez-Iratxeta C et al 2002 Nature Genet 31:316; for drug development: Loging W et al 2007 Nature Rev Drug Discov 2007:220.

Data Submission Standards: Provide information on the forms of submission or correction of data as suggested on nucleic acid sequences and proteins by the European Molecular Biology Organization. (<http://www.ebi.ac.uk/Submissions/index.html>)

Date Palm (*Phoenix dactylifera*): One of the 12 species; dioecious, $2n = 2x = 36$.

dATP: deoxyadenosine triphosphate.

Datura: Members of the *Solanaceae* family ($2n = 24$), they have been primarily used for genetic studies involving cytological (trisomics) and cell culture methods. These species are the sources of the alkaloids atropin, hyoscyne, hyoscyamine and scopolamine (see Fig. D5). ► [henbane](#), ► *Atropa*, <http://www.b-and-t-world-seeds.com/Datura.htm>.

Figure D5. *Datura stramonium*

Daubert Rule: A 1993 modification of the principle of the Frye test, it allows the judge in the court to decide whether a scientific method is acceptable and recognized as an effective means to draw valid conclusions. The test in question must have been peer-reviewed and a have demonstrable accuracy. ► [Frye test](#); Klee CH, Friedman HJ 2001 NeuroRehabilitation 16[2]:79.

Dauer Larva: Represents an alternative form of larval development. It becomes semi-dormant at an early stage (e.g., after the second molt the larva of *Caenorhabditis*), if feeding is inadequate or the culture is overcrowded. Under such conditions, daumone (a fatty acid derivative) (see Fig. D6) is synthesized and it controls both development and aging (Jeong P-Y et al 2005 Nature [Lond] 433:541). It is a safety option for survival. Such a larva does not feed and responds only to touch and may stay alive for 30 to 70 days. Normal life cycle may be resumed with new food supply. Dauer larvae do not age

because when they resume the normal life the dauer stage does not affect the post-dauer longevity. Autophagy has an essential role in dauer larva formation (Meléndez A et al 2003 Science 301:1387). Dauer larva formation is under the control of bone morphogenetic (BMP)-like protein, a transforming growth factor (TGF- β) analog, cyclic GMP signals to sensory neurons responding to pheromones and insulin receptor signaling. The orphan nuclear receptor DAF-12 regulates dauer larvae, fat metabolism and longevity of the worms. DAF-9, a cytochrome P450 involved in hormone production, generates two 3-keto-cholestenic acid metabolites (dafachronic acids) (see Fig. D7), which represent DAF-12 activating steroidal ligands. DAF-9 is similar to the CYP27A1 steroidal regulator of humans (Motola DL et al 2006 Cell 124:1209). [▶Caenorhabditis](#), [▶TGF](#), [▶longevity](#), [▶autophagy](#), [▶bone morphogenetic protein](#); Inoue T, Thomas JH 2000 Genetics 156:1035; Houthoofd K et al 2002 Exp Geront 37:1015; Ailion M, Thomas JH 2003 Genetics 165:127.

Figure D6. Daumone

Figure D7. Δ^4 -Dafachronic acid (3-Keto-4-cholestenic acid) and Δ^7 -Dafachronic acid (3-Keto-7, (5 α)-cholestenic acid)

Dauermodification: Induced modification of the phenotype that may be transmitted to the progeny but persists only for a few generations (therefore, it is not a mutation).

Daughter Cells: These are formed after division from the parental one. [▶cell division](#)

Daughter Chromosome: A replicated chromosome has two chromatids. When the chromatids are separated at the centromere during mitotic anaphase they become two single-stranded daughter chromosomes (see Fig. D8). [▶chromatid](#), [▶centromere](#), [▶mitosis](#)

Figure D8. Daughter chromosome formation

D

Daughter of Sevenless (DOS): The sevenless (SEV receptor tyrosine kinase) is a protein in the eye developmental pathway. Corcscrew (CSW) is a phosphotyrosine phosphatase in the signaling path and its substrate is DOS, a pleckstrin homology domain protein transmitting light signals for the eye between sevenless and RAS1 in *Drosophila*. In this pathway, Grb2 is an adaptor molecule with the son of sevenless (SOS) guanine exchange factor. The receptor sevenless tyrosine kinase (RTK) triggers neuronal differentiation in the single R7 cells of the ommatidia in response to the BOSS (bride of sevenless) ligand on the neighboring R8 photoreceptor cell. [▶sevenless](#), [▶son of sevenless](#), [▶boss](#), [▶ommatidia](#), [▶RTK](#), [▶pleckstrin domain](#), [▶rhodopsin](#); Bausenwein BS et al 2000 Mech Dev 90[2]:205.

DAX: [▶adrenal hypoplasia](#)

Day Blindness (hemeralopia): Autosomal recessive, defective vision in bright light and total colorblindness. It is the result of defective cone-like bodies of the retina. [▶night blindness](#), [▶colorblindness](#)

Day Neutral: Not responding to photoperiodic treatments. [▶photoperiodism](#)

Days Post Coitum: [▶dpc](#)

Dazla: [▶azoospermia](#)

DBA: Old inbred, grey mouse; it is frequently used for coat color analysis, heart, nerve and autoimmune diseases.

dbEST: A database for expressed sequence tags. [▶expressed sequence tag](#); Boguski MS et al 1993 Nature Genet 4:332.

DBF4: A Cdc7 binding and activating protein and may be required for the initiation of DNA re-plication. [▶Cdc7](#); Ogino K et al 2001 J Biol Chem 276:31376; Jares P et al 2000 EMBO Rep 1[4]:319.

DBL Oncogene: same as MCF2.

DBM Paper: [▶diazotized paper](#)

DBP (DNA binding proteins): These are histones, suppressors, activators, silencers and DNA and

RNA polymerases, transcription factors. separate entries.

DBMS: ►database management system

dbSNP: A single nucleotide polymorphism database.
►SNIPs; <http://www.ncbi.nlm.nih.gov/SNP>.

D

DCC: Deleted colon carcinoma gene involved in cancerous growth. DCC also drives an apoptotic pathway by interacting with caspases 3 and 9. DCC encodes also the main receptor of netrin-1 (Furne C et al 2006 Proc Natl Acad Sci USA 103:4128). ►colorectal cancer, ►tumor suppressor genes, ►pancreatic adenocarcinoma, ►p16, ►caspases, ►apoptosis, ►netrin; Graziano F et al 2001 BMC Cancer 1:9.

dCF (deoxycyformicin): ►ADA; Jehn U, Heinemann V 1991 Anticancer Res 11:705.

dcm: ►methylation of DNA

DCMU (3[3,4-dichlorophenyl]-1,1-dimethylurea): DCMU is an inhibitor of photosystem II. ►photo-synthesis, ►Z scheme

DCP1 (dipeptidyl carboxy peptidase): An angiotensin-converting enzyme. When it is active it may protect against Alzheimer's disease. ►angiotensin, ►Alzheimer disease

Dcp1p: A mRNA decapping nuclease. ►cap

DcR (death decoy receptor): ►FAS

DC-SIGN (dendritic cell-specific ICAM-3 grabbing non-integrin): A protein on the surface of dendritic cells and communicates to the T lymphocytes. It also transfers HIV-1 virus from the mucosa of the cervix or rectum to the lymphnodes where HIV infects the CD4⁺ T cells and eventually by the destruction of the immune system causes AIDS. DC-SIGN responds to different types of pathogens such as Hepatitis C virus, *Helicobacter pylori*, *Mycobacterium tuberculosis*, etc. ►acquired immunodeficiency, ►ICAM, ►acquired immunity, ►integrin, ►dendritic cell, ►Dengue fever; Steinman RM 2000 Cell 100:491.

DCT1 (divalent cation transporter): DCT1 are transporters of metal ions into the cells. ►ion channels

DctB: Bacterial kinase, acting by phosphorylating protein DctD.

dCTP: deoxycytidine triphosphate (di-Na salt, MW 511.13) (see Fig. D9)

Figure D9. dCTP

DDB (aspartic, aspartic, glutamic acids): DDB appears to be the core motif in various transposases. ►amino acid symbols in protein sequences

DDB (damaged DNA-binding protein): A heterodimer of p127 and p48. Mutations at the xeroderma pigmentosum gene E results in loss of it p48 activity and deficiency in global cyclobutane pyrimidine repair. ►DNA repair, ►cyclobutane dimer, ►xeroderma pigmentosum; Wakasugi M et al 2002 J Biol Chem 277:1637.

DDB1: A core subunit of the Cul4A-based ubiquitin complex. ►Cul; Li T et al 2006 Cell 124:1095.

DDBJ (<http://www.ddbj.nig.ac.jp>): Data Submissions, Laboratory of Genetic Information Analysis, Center for Genetic Information Research, National Institute of Genetics, 111 Yata, Mishima Shizuoka 411, Japan. General inquiries about nucleotide sequence database, e-mail: ddjb@niguts.nig.junet, submission forms: ddjbsub@niguts.nig.junet, telephone: 559 75 0771, <http://gib.genes.nig.ac.jp>.

DD(35)E: Insertion elements characterized by this motif (D = aspartic acid, E = glutamic acid. ►insertion elements; Mahillon J, Chandler M 1998 Microbiol Mol Biol Rev 62:725.

DDT: ►dichlorodiphenyltrichloroethane

De Lange Syndrome (Cornelia de Lange, Brachmann-de Lange syndrome): De Lange syndrome is most likely caused by new autosomal dominant mutations (see Fig. D10). The afflicted individuals do not reproduce. According to a Danish study, its frequency appeared to be 6×10^{-6} . The gene is situated in the area 3q21-qter.

About 30% of the cases are associated with various chromosomal anomalies, including duplication (and possibly deficiency) of the long arm of human chromosome 3. Some of the chromosomal anomalies may be unrelated to the syndrome characterized by the two eyebrows growing across the nose, hairy forehead and neck, long eyelashes, depressed nose bridge and uptilted nose tip, wide spacing of teeth, flat fingers and hands, altered palm print, mental

retardation, etc. The physical anomalies are evident by the end of the second trimester.

Mutations at Xp11.2 involving a cohesin subunit (SMC1L1) affect about half of the De Lange cases (Musio A et al 2006 *Nature Genet* 38:528). ►[mental retardation](#), ►[limb defects in humans](#), ►[head/face/brain defects](#), ►[hypertrichosis](#), ►[cohesin](#)

Figure D10. De Lange syndrome. Note deformed ear, long eyelashes and flat nasal bridge. (Modified from Bergsma, D., ed. 1973 *Birth Defects. Atlas and Compendium*). By permission of the National Foundation of the March of Dimes

De Novo: To start anew (from “scratch”).

De Sanctis–Cacchione Syndrome (xerodermic idiocy): A neurological defect frequently associated with xeroderma pigmentosum; it is due to a deficiency of repair caused by mutation in ERCC6. ►[xeroderma pigmentosum](#), ►[excision repair](#)

Dead-Box Proteins: A family of ATP-dependent helicases, present in prokaryotes and eukaryotes, they can stabilize mRNA and facilitate translation with the involvement of the 43S complex containing eIF4A, eIF4B, eIF4F. The 4Fs have three subunits: eIF4A, eIF4E, and eIF4G. 4B and 4F form a helicase that binds the 5'-end of the untranslated RNA through the 4E subunit. The name DEAD comes from the single letter amino acid symbols of proteins: Asp (D)-Glu (E)-Ala (A)-Asp (D) identifying a sequence present in eIF4A. The Vasa DEAD-box protein of *Drosophila* sharply bends the bound RNA to avoid a clash with the conserved α -helix in the N-terminal domain. This “wedge” helix may disrupt base pairs when an RNA duplex is bound. This mechanism potentiates targeted modulation of intricate RNA structures (Sengoku T et al 2006 *Cell* 125:287). ►[helicases](#), ►[eIF-4A](#), ►[DEAD-box proteins](#), ►[amino acid symbols in protein sequences](#), ►[translation initiation](#), ►[degradosome](#), ►[RNA surveillance](#), ►[ataxia](#), ►[P body](#); de la Cruz J et al 1999 *Trends Biochem Sci* 24:192.

Dead-End Complex: If the required nucleotides are not available for transcription the action of the polymerase is halted and may not be resumed after supplying the needed building blocks, presumably because of

changes in the proper configuration at the 3' end. Transcription may be resumed, however, if RNA hydrolytic proteins are supplied and that leads to redirection of the transcription complex. (Erie DA et al 1993 *Science* 262:867.)

De-Adenylation Pathway: The degradation of mRNA by removal of the poly(A) tail. ►[polyA tail](#); Caponigro G, Parker R 1996 *Microbiol Rev* 60:233; Tucker M et al 2001 *Cell* 104:377.

DEAE-Cellulose: As a membrane, DEAE-cellulose is used for trapping DNA from agarose gels. ►[gel electrophoresis](#)

DEAE-Dextran: A polycationic diethylaminoethyl ether of dextran (a polysaccharide) that stimulates the uptake of proteins and polynucleotides into cells, promotes the infection of cells by viral RNA and DNA, may inhibit tumors in animals, and stimulates reactions to antibody. ►[dextran](#), ►[transformation genetic animal cells](#)

DEAE-Sephacel: DEAE-Sephadex, DEAE Sepharose are ion exchangers used for gel filtration, as ion exchangers and chromatographic media. ►[sephadex](#), ►[sepharose](#), ►[ion-exchange resins](#), ►[gel filtration](#)

Deafmutism: The hereditary loss of hearing and speech with a prevalence of about 0.03–0.04%, and with a recurrence risk of about 12% among afflicted sibs. There are an estimated number of 35 loci capable of causing this anomaly. The spontaneous rate of mutation was estimated to be about 4.5×10^{-4} . The incidence of deafness has a rather large environmental component. ►[Usher syndrome](#), ►[deafness](#)

Deafness: A hearing deficit within a broad range from slight hearing difficulties to complete loss and this may be a progressive phenomenon. By age 90, about half of the human population experiences some degree of hearing loss. It has been estimated that about 1% of all human genes are involved in the control of hearing. About 68 loci are involved with non-syndromic hearing deficit. The sensation of balance and hearing is mediated by the stereocilia (epithelial appendages) of the inner ear hair cells via electrical signals to the brain. Transient receptor potential (TRP) ion channels at the tip of the sensory hair cell bundle initiates perception of sound (Corey DP et al 2004 *Nature [Lond]* 432:723).

About 3/4 of the hearing problems have complete or partial genetic determination and the rest may be environmentally induced. About 5–10% of the population develops hearing problems with advancing age and about 0.001 fraction of newborns are deaf or develop some kind of hearing loss by school age. The first indication of an infant's hearing loss is inability to articulate. About 87% of congenital

D

deafmutism is caused by recessive factors. Dominant inheritance determines deafness to some low, middle and high tone sounds, while at other frequencies the hearing may be normal. The Michel syndrome is responsible for a complete lack of the internal ear formation. The hearing problems may have a wide range of organic bases but usually, they are classified as *conductive* (transmission) *hearing deficit* that is caused by defects in the hearing canal or the middle ear. *Sensorineural* defects involve the inner ear and the associated nervous system. This type *non-syndromic* (single phenotype is only deafness) is based on a mutation of the connexin gene (DFNA3) in chromosome 13q11-q12. DFNA2 (1p34) is due to mutations at a complex locus encoding the potassium ion channel KCNQ4 and possibly connexin 31. DFNA5 (7q15) is caused by deletion in intron 7 and premature termination of transcription. Deafness (DFNA15) in human chromosome 5q31 involves mutation in transcription factor POU4F3. The non-syndromic DFNA17 (22q12.2-q13.3) is a mutation in the non-muscle myosin gene, MYH9. DNFA23 (14q21) and DNFA25 (12q21-q24) encode non-syndromic deafness. DFNB1 encodes connexin-26. The Myo7a mutation (DFNB2) is non-syndromic myosin VIIa defect. DFNB3 in human chromosome 17p11.2 (homologous with mutation shaker-2 in mouse) involves a defect in an unusual myosin molecule (Myo15), resulting in short stereocilia ([singular stereocilium] protoplasmic filaments on the ca. 100 hair cells of the inner ear). DFNB4 encodes pendrin. DFNB9 is a mutation in otoferin and DFNB21 involves α -tectorin. DFNB29 gene (21q22.1) encodes the tight junction protein, Claudin-14, DFNB31 is a defect in the protein whirlin of the stereocilia. The non-syndromic DFNA13 (human chromosome 6) is due to mutation in a collagen gene, COL11A2. DFNA1 appears to affect the cytoskeleton through connexin 32. DFNA16 is a dominant non-syndromic deafness is encoded at 2q23-q24.3. Mutation in human chromosome 11q22-q24 (DFNA8, DFNA12) involves α -tectorin, an extracellular matrix protein over the inner ear hair cells. The latter mutation is synonymous with *shaker-1* of mouse chromosome 9. DFNB26 was assigned to 4q31. DFNB37 (6q13) is based on recessive defect(s) in myosin-6 (Ahmed ZM et al 2003 Am J Hum Genet 72:1315). DFNM1 at 1q24 is recessive deafness suppressor. Congenital deafness in some instances in humans has been remedied by cochlear implants at early stage of development. Also in cats auditory nerve synapses have been improved by some and stimulation after cochlear implants (Ryugo DK et al 2005 Science 310:1490).

The classifications may not be absolute because the types may overlap and further complicated in a

number of syndromes. Conductive hearing problems occur in otopalatodigital syndrome, Treacher Collins syndrome, osteogenesis imperfecta, Crouzon syndrome, Turner syndrome. Sensorineural hearing defects are found in Alport syndrome, Jervell and Lange-Nielsen syndrome, Pendred syndrome, Usher syndrome, Stickler syndrome, Refsum syndrome, Wildervanck syndrome, Norrie's disease, albinism (cutaneous), Waardenburg syndrome, LEOPARD syndrome and the Ménière disease. Both conductive and sensorineural defects may be present in the Klippel-Feil syndrome and some other cases. Deletions or mutations in the Xq21 region may also cause deafness (DFN1, Charcot-Marie-Tooth disease, Mohr-Tranebjaerg syndrome, DFN3) in case of (surgical) injuries to the stapes (the stirrup-like bones in the ear) resulting in leakage of the fluid (perilymph) of the inner ear (gusher deafness). The molecular basis of this hearing impairment is in gene Brain Protein 4 (BRN-4/RHS2/POU3F4), encoding a transcription factor with a pou domain. Approximately 6% of the hereditary deafnesses are X-linked and are brought about by different mechanisms such as defects in the iris, cornea or by ocular albinism or other types of albinisms. Thyroid hormone receptor β is essential for the normal development of the auditory function. Maternally determined high sensitivity to aminoglycosides (streptomycin, neomycin, and paromomycin) may result in non-syndromic hearing loss due C1494T mutation in the 12S mitochondrial RNA gene (Zhao H et al 2004 Am J Hum Genet 74:139). A non-syndromic recessive deafness was located to human chromosomes 2p22-p23 and to 21q22. Hereditary deafness occurs among children at a frequency of 5×10^{-4} . Some deaf children may be helped by stimulation of the auditory cortex through implants. The Ames waltzer mouse's deafness is caused by mutation in a protocadherin gene. Genetic testing is feasible for connexin based defects in hearing deficits. By 2001, 77 human gene loci have been identified for non-syndromic deafness (40 autosomal dominant, 30 autosomal recessive and 7 X-linked and defects in mitochondrial RNA). Additional genes are known to affect hearing (15 autosomal dominant, 9 autosomal recessive, 2 X-linked, 5 mitochondrial and more than 32 genes control syndromic hearing deficits). the named syndromes under separate entries, ►mitochondrial diseases in humans, ►stereocilia, ►connexin, ►Charcot-Marie-Tooth disease, ►mucopolysaccharidosis [Hunter and Hurler syndromes], ►Wolfram syndrome, ►Usher syndrome, ►Lange-Nielsen syndrome, ►pou, ►connexin, ►tight junction, ►cadherin, ►otosclerosis, ►mitochondrial diseases in humans; Steel KP 1995 Annu Rev Genet 29:675; Scott HS et al 2001 Nature Genet 27:59; Kelsell DP

et al 2001 *Am J Hum Genet* 68:559; Petit C et al 2001 *Annu Rev Genet* 35:589; Resendes BL et al 2001 *Am J Hum Genet* 69:923; Call LM, Morton CC 2002 *Current Op Genet Dev* 12:343; anatomy, genes, function: Friedman TB, Griffith AJ 2003 *Annu Rev Genomics Hum Genet* 4:341, <http://www.uia.ac.be/dnalab/hhh/>; <http://webhost.ua.ac.be/hhh/>; <http://www.medicality.org.uk/diseases/hereditary-deafness.php>.

Deah-Box Proteins: These are involved in the processing of precursor RNA and may be responsible for silencing of transgenes and transposons. ▶**DEAD-box**; Wu-Scharf D et al 2000 *Science* 290:1159.

Deamidation: The removal of an amide group (NH₂) from a protein introduces a negative charge and may affect the tertiary structure, as well as the biological activity of the molecule. Deamidation of amino acids 52 and 66 of Bcl-X_L antiapoptotic protein disables its attachment to the BH3 domain proteins (PUMA, NOXA) and opens the path to cell death. Thus, it may result in the death of cancer cells. Damage to DNA generally activates the transcription of p53 tumor suppressor resulting in the upregulation of protein p21 and other proapoptotic proteins. Proteins Bax and Bak then mediate the mitochondrial release of cytochrome c and caspases, which cause the tumor cell death by proteolysis. Deamidation may be involved in other regulatory functions too. ▶**Bcl**, ▶**p53**, ▶**p21**, ▶**Bax**, ▶**Bak**, ▶**apoptosis caspase**; Li C, Thompson CB 2002 *Science* 298:1346.

Deamination: The removal of amino group(s) from a molecule. Cytosine is deaminated to uracil at the rate $3 \text{ to } 7 \times 10^{-13} \text{ sec}^{-1}$ in double-stranded DNA, i.e., about 40 to 100 deaminations of this type occur daily in the human genome. Thus C≡G transitions to T=A are apparently of major significance for mutation and evolution. The deamination of 5-methyl-cytosine is 2 to 4 times higher than that of cytosine. In single-strand DNA the rate of deamination is about 140 times higher than in double strands. Mismatched Cs are deaminated 8 to 26 times the rate of normally paired ones. Transcribed strands are about 4 times more likely to show deamination than the non-template strands. Some of the deaminated nucleotides are, however, removed by uracil-DNA glycosylases. ▶**nitrous acid**, ▶**transition**, ▶**DNA repair**

Death: An irreversible stop to vital functions, especially that of the brain and the genetic material (see Fig. D11). The *genetic death* is a population genetics term for lack of reproduction. Lack of reproduction may be due to the presence of deleterious or lethal genes. The probability of survival depends on the number of recessive lethal factors (n), according to e^{-n} , e.g., in case of $n = 2$, $e^{-2} \approx 0.135 = \text{survival}$.

Figure D11. Death

Death Domain: 60–80 amino acids in the cytoplasmic regions of cytokine receptors that engage the apoptosis path. ▶**cytokine**, ▶**apoptosis**, ▶**TNFR**, ▶**scaffold-mediated activation**, ▶**death receptor**

Death Rates: ▶**age-specific birth and death rates**, ▶**apoptosis**, ▶**Hayflick's limit**

Death Receptors: They transduce the apoptotic signals with the aid of cysteine-rich extracellular domains to the intracellular death domains. ▶**FADD/Mort**, ▶**DED**, ▶**death domain**, ▶**FAS**, ▶**FASL**, ▶**PLAD**, ▶**TRAIL**, ▶**mannose-6-phosphate**; Ashkenazi A, Dixit VM 1998 *Science* 281:1305.

Death Signaling: (i) ligands bind death receptors, (ii) trimerization of receptor and initiation of DISC, (iii) recruitment of FADD to DISC, (iv) recruitment of procaspase 8, (v) formation of active heterotetrameric caspase 8, (vi) activation of caspase cascades, (vii) truncation of Bcl/2 molecules, (viii) release of *cytochrome c* and Smac/DIABLO, (ix) cleavage of the death substrates leading to apoptosis. ▶**apoptosis**, ▶**death receptors**, ▶**FADD**, ▶**DISC**, ▶**caspases**, ▶**Bcl**, ▶**cytochromes**, ▶**Smac**, ▶**DIABLO**

Deazanucleotides: Analogs of nucleotides, antiviral agents and used for compression of sequencing gels (see Fig. D12). ▶**compression in gels**, ▶**DNA sequencing**

Figure D12. 7-Deazaadenosine

DEB: Diepoxybutane is an alkylating mutagen and carcinogen. ▶**mutagens**

Debranching Enzyme: It converts a nucleic acid loops (lariat) into a linear molecule. ▶**lariat RNA**; Khalid MF et al 2005 *Nucleic Acids Res* 33:6349.

Debrisoquine: An adrenergic-blocking drug used for treatment of hypertension. The response to the drug (human chromosome 22, dominant) depends on

cytochrome P450IID family of proteins. About 1–30% of the populations, depending on ethnicity, may be poor hydroxylators of this and other similar drugs, and may suffer serious side effects upon treatment. ▶cytochromes

D

DEC-205: An integral membrane protein, homologous to the macrophage mannose receptor. It appears to have important role in antigen presentation and processing in antigen-capturing (dendritic) T cells. ▶antigen presenting cell; Mahnke K et al 2000 J Cell Biol 151:673.

Decapentaplegic (DPP): DPP is a complex gene/protein involved in dorsoventral and anterior/posterior (wing) differentiation in insects. Its vertebrate homolog is the bone morphogenetic protein (Bmp). An active dpp/Bmp favors ventral differentiation. DPP interacts with a large number of proteins. ▶morphogenesis of *Drosophila*, ▶organizer, ▶bone morphogenetic protein, ▶*Mothers against decapentaplegic*; Hsiung F et al 2005 Nature [Lond] 437:560; Affolter M, Basler K 2007 Nature Rev Genet 8:663.

Decapping: Process of removal of the mRNA cap (encoded by *DCP1* in yeast) and degradation by enzymatic decay in the 5'→3' direction (by exonuclease Xrn1p). It is usually triggered by shortening of the poly(A) tail (←3') but it may be brought about also by other means (Badis G et al 2004 Mol Cell 15:5). Mutation in the 7 *LSM* genes of yeast inhibit decapping and the decapping activator proteins Pat1/Mrt1. Decapping represses translation. The non-translated mRNA accumulates in processing bodies (P bodies). Decapping activators Dhh1p and Pat1p mediate the process; both the deficiency and overexpression of these proteins result in inhibition of translation (Coller J, Parker R 2005 Cell 122:875). ▶mRNA, ▶cap, ▶polyA mRNA, ▶polyadenylation signal, ▶Translation, ▶P body; Tucker M, Parker R 2000 Annu Rev Biochem 69:571; Dunckley T et al 2001 Genetics 157:27; decapping factors: Fenger-Gran M et al 2005 Mol Cell 20:905.

Decarboxylation: The removal of COOH group(s) from a molecule.

Decatenation: The disentangling of the catenated sister chromatids formed during DNA replication with the aid of topoisomerase II. This is a requisite for chromatid condensation during the ensuing phases. Decatenation inhibitors—without DNA damage—arrest cell cycle at mitosis (Skoufias; DA et al 2004 Mol Cell 15:977). ▶catenane, ▶sister chromatid; Downes CS et al 1994 Nature [Lond] 372:467; Deming PB et al 2001 Proc Natl Acad Sci USA 98:12044.

Decay-Accelerating Factor: (DAF, CD55, 1q32): DAF is an erythrocyte membrane glycoprotein along with

MCP and other members of the group control convertase activity. DAF may regulate translation without affecting mRNA in transgenic animals. ▶erythrocyte, ▶MCP, ▶complement, ▶convertase, ▶SMGT; Miyagawa S et al 2001 J Biochem 129:795; Uhrinova S et al 2003 Proc Natl Acad Sci USA 100:4718; Lukacik P et al 2004 Proc Natl Acad Sci USA 101:1279.

Decidua: A membrane lining the uterus during pregnancy that is shed around delivery. ▶embryo-genesis in animals

Decision Tree: A decision tree can assist in exploring conditional probabilities among several possible actions and outcomes (see Fig. D13). It starts out at the left square and connects to new decisions (squares) or uncertainties (circle), which are also called nodes. On the connecting lines (edges) the estimated probabilities can be represented. One may use a large number of branches if necessary. Each probability can be multiplied by a numerical value (percentage or fraction) and at the end the most rewarding or harmful decision can be evaluated. Such a procedure has merits in business or in medicine when different treatments are contemplated. Several software tools are available on the Internet. (Chen HY et al 2007 New England J Med 356:11)

Figure D13. Decision tree

deCODE: genetics research, Reykjavik, Iceland, <http://www.decode.com/>.

Decoding: Although the genetic code intrigued biologists before the nature of the genetic material was firmly determined, the complete genetic code was deciphered between 1961 and 1966. From frameshift mutations, Crick's laboratory concluded that the code is written most likely in triplets of nucleotides. Since 1961 random copolymers of RNA were used. E.g., in a 5A: 1 C copolymer the AAA triplet are expected to be more common the CCC triplets. By chance alone the AAA sequence is expected to have a frequency of $(5/6)^3 = 0.579$ (125/216). ACA is expected to have the frequency of $5/6 \times 1/6 \times 5/6 = 25/216$ (0.116) and CCC is expected in a frequency of $(1/6)^3 = 0.0046$ (1/216). Thus, the 3 triplets' proportions were expected to be 125:25:1. In an in vitro protein synthesis assay, this copolymer promoted the incorporation of lysine the most abundantly. Therefore, the codon of AAA was expected for lysine. The 2A:1C codons could be

AAC, ACA, CAA, therefore additional copolymers were needed for determining their meanings. Repetitive ordered copolymers UUCUUCUUC permitted the incorporation of phenylalanine (UUC), serine (UCU) and leucine (CUU), depending in what register the sequence was read. The sequences GAUAGAUAG directed the incorporation Asp (GAU), Arg (AGA) and then the translation was stopped. Thus UAG was identified as the amber stop codon. The most precise method used ribosome binding. A collection of charged tRNAs were allowed to bind single known sequence triplets. Then tRNAs were charged with radioactively labeled amino acids. Cognate anticodons of a specific charged tRNAs bound only one triplet and thus the codons were identified. The validity of the code was then confirmed also by recombination. At amino acid site 211 in the wild type tryptophan synthetase glycine was identified. One mutation at this site resulted in a replacement by arginine and in another mutant by valine. A transduction experiment between the mutants restored glycine at site 211. This could be achieved if in the wild type there was CCT, and in the mutants GCT and CAT, respectively.

Recombination between the first bases $\frac{GCT}{CGA}$ could produce CCT (glycine), and thus verified the codons for glycine, arginine and valine. In the living cells the tRNAs in association with proteins recognize the amino acid codons on the surface of the ribosomes. ►genetic code, ►code genetic, ►ribosome binding assay, ►synthetic polynucleotides, ►wobble, ►overlapping genes, ►isoacceptor tRNA; Yčas M 1969 The Biological Code, North-Holland, Amsterdam, The Netherlands.

Decoding, Non-Standard: The use of the standard codon or a stop codon for specifying an amino acid other than usual for the majority of living systems. For e.g., some yeasts (*Candida*) use the leucine codon CUG for serine and in this case the special tRNA^{Ser} has a modified G (N1-methylguanosine) at position 37. ►decoding, ►genetic code; Santos MA et al 1997 Mol Microbiol 26:423.

Decoding, Ribosomal: The recognition of the proper mRNA triplet by the charged aminoacyl tRNA on the 30S ribosomal subunit and GTPase activation center on the 50S subunit. This step is called *accommodation* and it involves the moving of the aminoacyl-tRNA inside the ribosome (Sanbonmatsu KY et al 2005 Proc Natl Acad Sci USA 102:15854). Single nucleoside replacement in the tRNA may substantially alter the conformation of the tRNA and its control of the reading frame (Stuart JW et al 2003 J Mol Biol 334:901). Chloroplasts use only 31 anticodons for translation. Mitochondria may employ only as few as

22 anticodons, however, in some organisms the mitochondria use nuclear encoded tRNAs. Note also that the genetic code dictionary in mitochondria varies among different organisms and may be different from the 'universal' code. ►genetic code, ►tRNA, ►isoaccepting tRNA; Agris PF 2004 Nucleic Acids Res 32:223.

Deconvolution: A computer algorithm to remove haze from optical microscopy; a section for clarifying and sharpening images. Deconvolution microscopy provides high-resolution images by computer-assisted reconstruction of cross-sectional images of several planes.

Decoration: Minor protein fold(s) upon the basic structure that allow differences in function.

Decorrelation: Recombination frequencies vary along the length of a chromosome therefore average linkage disequilibrium does not accurately reflect the age of a chromosome during evolution.

Decoy Receptors: Decoy receptors bind various activator ligands, detract them from their normal receptors and may suppress inflammation. Some members of TNF family receptors such as lymphotoxin-β, osteoprotegerin, TNFR2 may alleviate bowel inflammation, arthritis, autoimmune disease, etc. ►TNF, ►autoimmune disease, ►arthritis, ►receptor, ►dumbbell oligonucleotides; Mantovani A et al 2001 Trends Immunol 22[6]:328.

Decoy RNA: It may be used to decrease gene expression by sequestering viral RNA-binding regulatory proteins. ►sequester, ►transdominant molecules; Jayan GC et al 2001 Gene Ther 8:1033.

Decussate: Consecutive leaf nodes in alternating rectangle arrangement (see Fig. D14). ►phyllotaxy

Figure D14. Decussate leaves of mint

DED (death-effector domain): DED of apoptosis proteins like FLICE. ►apoptosis, ►FLICE

Dedifferentiation: The loss of cellular differentiation frequently followed by new cell divisions. It has been generally assumed that terminally differentiated

mammalian cells (in contrast to that of lower animals and plants) are incapable of dedifferentiation. Cancerous transformation is, however, a type of dedifferentiation. Mammalian *msx1* gene can stimulate myotubes to dedifferentiate (in the presence of growth factors), and undergo transdetermination.

►redifferentiation, ►transdetermination, ►myotube, ►redifferentiation, ►regeneration

D

Deep Sequencing: An extensive coverage of the DNA sequence; indicating the number of times a tract is sequenced. It may be extended to methylation of histones in the chromatin that affects expression of genes.

Deer: Chromosomally, a very diverse group of Cervidae yet, the American whitetail deer (*Odocoileus virginianus*) is $2n = 70$ and the reindeer (*Rangifer tarandus*) is also $2n = 70$. (Slate J et al 2002 Genetics 160:1587, <http://www.thearkdb.org/browser?species=deer>).

De-Etiolation: Plants grown in the dark usually elongate and fail to synthesize leaf pigments and thus show etiolation. Some mutations, however, show short hypocotyls and green pigment in the dark, i.e., they are deetiolated. The *Arabidopsis* AtDET1 gene homologs are also conserved in animals and encode a c-Jun ubiquitin ligase (Wertz IE et al 2004 Science 303:1371). ►Jun, ►ubiquitin, ►brassinosteroids

Default: A preset instruction followed until new instruction is given.

Defective Interfering Particle (DI): Subgenome-size mutants due to deletion(s) that require homologous virus for replication. They may have advantage in replication over the helper virus and thus secure their maintenance. ►helper virus

Defensin: ►Antimicrobial peptides, ►Paneth's cell. (Salzman NH et al 2003 Nature [Lond] 422:522)

Deficiency, Chromosomal: The (terminal) loss of a piece of the chromosomes ►deletion. Terminal losses of chromosomes can be readily induced by ionizing radiation at first order kinetics ►kinetics and they frequently behave as null alleles. If in a heterozygote the wild type allele is destroyed or removed the remaining recessive may be expressed (pseudodominance). An interstitial loss—if it is of substantial size—may be detected cytologically at meiotic pachytene because the wild type strand bulges out across the lost tract as shown by the diagram. Nutritional or metabolic deficiency may be due to a mutant gene (see Fig. D15) ►deletion, ►deletion mapping, ►duplication, ►duplication – deficiency

Figure D15. Deficiency, chromosomal

Defined Medium: Contains chemically identified and characterized nutrients.

DeFinetti Diagram: The genotype frequencies are represented as perpendicular lines from a point within an equilateral triangle in such a way as the length of the lines or the area correspond to the frequencies (see Fig. D16). (Li CC 1976 First Course in Population Genetics, Boxwood Press, Pacific Grove, CA.

Figure D16. DeFinetti diagram

Deformation: Abnormal development caused by mechanical or physiological restriction(s).

Degeneracy of Lymphocytes: An ability of T cells to recognize and respond to different peptides (epitopes) carried by different MHC complexes despite the renowned specificity for molecules. Some degeneracy may also exist with B cells, which have Igs of low affinity. ►T cell, ►epitope, ►major histocompatibility complex, ►Ig

Degenerate Code: The same amino acid is coded for by more than one type of nucleic acid triplet, e.g., the RNA code word for phenylalanine can be either UUU or UUC; other amino acids may have a single or up to six codons (i.e., 6 codons degenerate [go down] into 1 amino acid). ►code genetic, ►genetic code; Crick FHC 1959 Brookhaven Symp Biol 12:35.

Degenerate Oligonucleotide-Directed Mutagenesis: A degenerate oligo-nucleotide (with several A residues is self-annealed) at the 3' end with an 8-nucleotide palindrome (see Fig. D17). The 3' sequence includes an EcoRI (G↓AATTC) restriction enzyme recognition site. The 5'-end should also encompass another restriction enzyme site (see diagram, Dde I. [C↓TNAD]). The central region is mutagenized (as shown by larger letters and a dot above the new base).

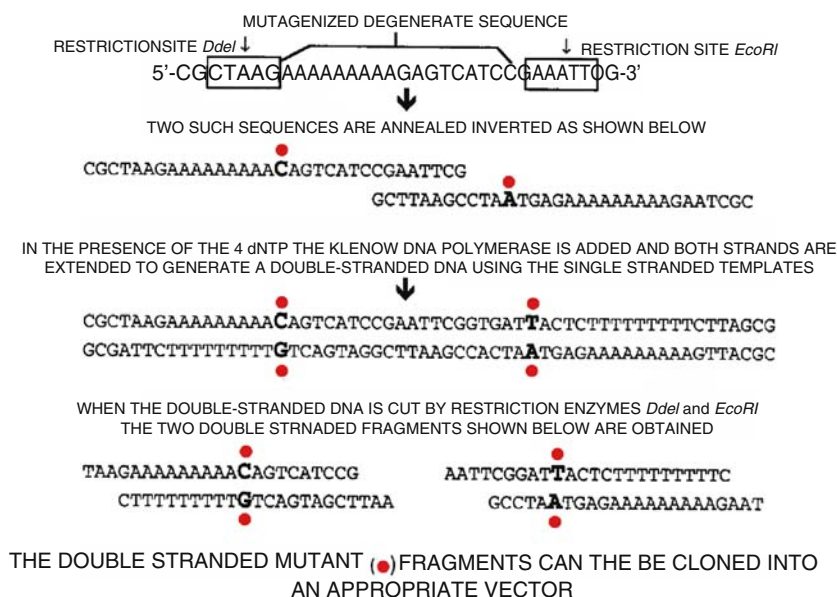

Figure D17. Degenerate oligonucleotide-directed mutagenesis

The construct is treated with Klenow fragment (a fragment of bacterial DNA polymerase I that lacks 5'→3' exonuclease activity) in the presence of the 4 deoxyribonucleotides to extend the nucleotide chains. The system produces two double-stranded mutant oligonucleotides after cleavage at the restriction endonuclease recognition sites with different base pair substitutions. Airaksinen A, Hovi T 1998 *Nucleic Acids Res* 26:576; diagram modified after Hill DE et al 1987 *Methods Enzymol* 155:558.

Degenerin: A member of a family of epithelial sodium channel proteins (interacting with collagen) in *Caenorhabditis* muscle contraction. Mutants uncoordinated (unc-105) have such a defect. Proteins MEC4 and MEC10, defective in mechanical signal transduction in the touch reception system, encode homologous proteins. Other homologs are the epithelial sodium channel (ENaC) genes of mammals. The MDEG1 protein, localized in the taste buds, appears to be a receptor for sour taste. ▶ [Liddle syndrome](#), ▶ [touch-sensitivity](#), ▶ [ion channels](#), ▶ [collagen](#), ▶ [anesthetics](#); Askwith CC et al 2001 *Proc Natl Acad Sci USA* 98:6459; Hamill OP, Martinac B 2001 *Physiol Rev* 81:685.

Degest (Differently Expressed Genes, transcripts, alternative splicing events using EST information): <http://genome.ewha.ac.kr/DEGEST/>. ▶ [alternative splicing](#)

Degradative Plasmids: *Pseudomonad* plasmids that have the ability of degrading salicylate, camphor, octane, chlorobenzoate, 2,4,5-trichlorophenoxyacetic

acid, etc. Cho JC, Kim SJ 2001 *J Mol Microbiol Biotechnol* 3[4]:503.

Degradome: The repertoire of protein-degrading enzymes, proteasome. ▶ [proteasome](#)

Degradosome: A multi-enzyme complex of polynucleotide phosphorylase (exoribonuclease), RNase E (endoribonuclease), RhlB (helicase), DnaK (heat-shock protein) and enolase (glycolytic enzyme) involved in the degradation of mRNA. The process is ATP-dependent. ▶ [ribonuclease](#), ▶ [helicase](#), ▶ [glycolysis](#), ▶ [RNA surveillance](#), ▶ [mRNA](#), ▶ [proteasome](#); Capousis AJ et al 1994 *Cell* 76:889; Blum E et al 1999 *J Biol Chem* 274:4009; Feng Y et al 2001 *J Biol Chem* 276:31651; Dziembowski A et al 2003 *J Biol Chem* 278:1603.

Degree of Freedom: The number of independent comparisons within numerical data; e.g., a 3:1 segregation has 1 degree of freedom because if one of the classes is specified within, say 4, the other can be either 3 or 1, i.e., there is only one choice. In cases where multiple comparisons can be made, e.g., in a segregation of 9:3:4 (recessive epistasis) the degree of freedom is 2 because if one class is specified as 4, the other two classes can be anything within 12/16, thus there is another choice left. In case of 9:3:3:1 segregation, degrees of freedom are 3 because if one class is chosen there are still three more to choose. In some experiments with multiple comparisons, e.g., in a variance analysis careful consideration must be given to the number of independent comparisons before the correct degrees of freedom can be determined. ▶ [analysis of variance](#)

Degree of Relatedness: ►relatedness, degree of

Degron: A signal element in the proteins liable to degradation by ubiquitin-mediated processes. The function of unknown genes can be revealed by their fusion to temperature-sensitive degron constructs that selectively destroys their protein products (Kanemaki M et al 2003 Nature [Lond] 423:720). ►N-degron, ►PEST, ►ubiquitin; Gardner RG, Hampton RY 1999 EMBO J 18:5994.

DegS: *Bacillus subtilis* kinase regulating degradative enzymes through protein DegU. (Kobayashi K et al 2001 J Bacteriol 183:7365)

DEGSAGE (differential gene expression by SAGE): http://genome.ewha.ac.kr/SAGEexpress/SAGEexpress_DEGs.htm. ►DEGEST, ►SAGE

Dehalococcoides ethenogenesis: It dechlorinates the ground water pollutants tetrachloroethene and trichloroethene (industrial solvents, hepatocellular carcinogens) to ethane/ethylene ($\text{CH}_2 = \text{CH}_2\text{CC}$), an anesthetic in higher concentrations. Its sequenced genome of 1,469,720 bp encodes 17 putative reductive dehalogenases. (Seshadri R et al 2005 Science 307:105)

Dehydrogenase: Enzymes mediating removal of hydrogen from molecules.

Dehydroepiandrosterone (DHEA): A multifunctional animal hormone enhancing immune response, and with a possible anti-diabetic, anti-obesity, anti-cancer, neurotropic, memory-enhancing and male anti-aging properties. separate entries; Yen SSC 2001 Proc Natl Acad Sci USA 98:8167; Mazat L et al 2001 Proc Natl Acad Sci USA 98:8145.

Dehydrotestosterone: A key hormone in maleness determination in mammals. It is made by steroid 5α -reductase enzyme from testosterone. Its deficiency causes defects in the development of the external male genitalia and the prostate but the epididymis, seminal vesicles and vas deferens are normal. The affected individuals are less prone to acne and baldness. The enzyme is encoded by two genes (SRD5A1, chromosome 5p15 and SRD5A2, 2p23). The dehydrotestosterone receptor deficiency leads to testicular feminization and Kennedy disease, both located in human chromosome Xq11.1-q12. ►animal hormones, ►testicular feminization, ►Kennedy disease

Deinococcus radiodurans: Gram-positive bacteria with 200-fold higher resistance to ionizing and 20-fold higher resistance to UV than *E. coli*. The genome of two chromosomes of 2,648,638 and 412,348 bp, respectively, a megaplasmid of 177,466 bp and another plasmid of 45,704 bp has been completely

sequenced. The radiation insensitivity has been attributed to the compaction of the DNA that facilitates restitution of radiation-induced breaks. Accumulation of manganese and decrease of iron in the cells facilitates the resistance to radiation (Daly MJ et al 2004 Science 306:1025). Ionizing radiation- and UV-induce hundreds of fragments by double-strand breaks that are readily reassembled into a functional 3.28-megabase genome. DNA repair process takes place in two stages, which involves *extended synthesis-dependent strand annealing* (ESDSA). At least two genome copies and random DNA breakage are requirements for effective ESDSA. Chromosomal fragments with overlapping homologies are used both as primers and as templates for massive synthesis of complementary single strands by DNA polymerase I. Newly synthesized complementary single-stranded extensions become 'sticky ends' that anneal with high precision, joining together contiguous DNA fragments into long, linear, double-stranded intermediates. These intermediates require RecA-dependent crossovers to mature into circular chromosomes that comprise double-stranded patchworks of numerous DNA blocks synthesized before radiation, and connected by DNA blocks synthesized after radiation. Thus, the radiation resistance is based on a highly effective DNA repair (Zahradka K et al 2006 Nature [Lond] 443:569). ►radiation-sensitivity, ►Taq DNA polymerase; White O et al 1999 Science 286:1571; Makarova KS et al 2001 Microbiol Mol Biol Rev 65:44; Levin-Zaidman S et al 2003 Science 299:254.

Dejerine-Sottas Syndrome (DSN, 17p11.2): Hypertrophic neuropathy, slow nerve conduction, abundant Schwann cell and basal lamina onion bulb formation, hypomyelination. Recessive mutations at the PRX locus (19q13.13-q13.2) encoding periaxin L and S are also responsible for DSN. The wild type alleles are required for the maintenance of myelin of the peripheral nerves. DSN is caused also by mutation of the periaxin proteins encoded at 19q13.1-q13.2. ►Schwann cell, ►myelin, ►Charcot-Marie-Tooth disease, ►HNPP, ►HMSN; Boerkoel CF et al 2000 Am J Hum Genet 68:325.

Delayed Early Genes (DE): These are turned on following the immediate early genes, about 2 min after phage infection. They use the early and new middle promoters. Their expression depends on protein synthesis. ►immediate early genes, ►late genes

Delayed Inheritance: The expression of some traits depends on the genotype of the diploid oocyte rather than the genetic constitution of the zygote. In such

cases the reciprocal F₁ generation may be of two types (maternal or paternal), the F₂ may be uniform (because the genetic constitution of the F₁ is identical) and segregation is delayed to the F₃. Similar phenomenon is observed when the phenotype of the male gametophyte (pollen) is determined by the diploid microsporocyte rather than by the haploid nucleus of the microspore or pollen. ▶*testa*, ▶*Lathyrus odoratus*, ▶*Limnaea*

Delayed Mutation: The expression is delayed after cell division following the mutagenic exposure in contrast to the “zero-point” mutation, which is expressed in resting cells. (Demerec M et al 1948 Carnegie Inst Year Book 47:169)

Delayed-Response Gene: It is activated by a growth factor after a lag period (about an hour). ▶*early-response gene*, ▶*early gene*, ▶*late gene*

Delete-A-Gene (deleteagene): A fast neutron mutagenesis method associated with PCR analysis of deletions (Li X, Zhang Y 2002 Functional & Integr Genomics 2:254). ▶*fast neutrons*, ▶*PCR*

Deleterious Mutation: Unfavorable for fitness, the rate of deleterious mutations is not easy to quantitate because small effects are difficult to identify. The statistical estimate for $\hat{U} = \Delta M^2 / (2V_m)$ the mutation rate U (see Fig. D18) where ΔM is the rate of change in the population and V_m is the variance of the mutation. The average homozygous mutation effect $s = 2V_m / \Delta M$. More accurate estimate can be obtained according to Keightl Bataillon TM 2000 Genetics 154:1193, by using maximum likelihood. An alternative formula for the rate of deleterious mutation is $U = 2uGC$ where U is the deleterious mutations, $2uG$ is the rate of mutation in the diploid genome and C the fraction of the sites in the genome subjected to selective constraints. Accordingly, in *Drosophila* U appears to be 1.2 per diploid genome (Haag-Liautard C et al 2007 Nature [Lond] 445:82). ▶*mutation beneficial*

Figure D18. Chromatid deletion (Courtesy of B.R. Brinkley)

Deletion: The loss of a (internal) chromosomal segment; it is generally symbolized with -, or d or Δ or *del.* Small deletions may appear as recessive null mutations or larger deletions may have a dominant phenotype. Deletions are distinguished from mutations by failing to revert to the normal allele and they may affect also the frequency of recombination.

Specifically directed deletions can be obtained in mice by taking advantage of the *loxP* and *Cre* factors of bacteriophage P1 (see Fig. D19) targeting genes. Deletions may be responsible for various human hereditary anomalies. Deletions can be generated in isolated DNAs by cutting the double-stranded molecules with the aid of restriction endonucleases leaving behind complementary single-strand overhangs. These ends then can be sliced back by Bal 31 exonuclease or S1 nuclease before ligation of the free ends. Deletions may be detected with the aid of a light microscope if the chromosomes have clear landmarks such as knobs, or when they display banding patterns such as the salivary gland chromosomes. Or it is revealed by special staining techniques or when the deleted chromosome is paired either during mitosis or meiosis with the normal chromosome. Deletions of the DNA may be detected by electronmicroscopy if a deletion and a normal strand are hybridized in vitro. At the site of the deletion the normal chromosome or the normal DNA strand buckles out because it has no partner segment to pair with.

Complete nucleotide sequences of parasitic prokaryotes indicates extensive losses of genes, which were apparently not needed because the host could supply the compounds such as amino acids, fatty acids, nucleotides, enzyme cofactors and enzymes of the Krebs cycle. Therefore, *Mycoplasma genitalium* has only 479 ORF, and *Mycoplasma pneumoniae* has only 679.

Deletions may be useful for identifying functional domains in the chromosome (see Fig. D20). Generation of deletions by insertion elements or by the Cre/LoxP or FLP/FRT recombinase system are very useful for revealing the functional role(s) of a large array of genes (Parks AL et al 2004 Nature Genet 36:288). In human populations, deletions of one to hundreds of kilobases long contribute to a large part of the variations (McCarroll SA et al 2006 Nature Genet 38:86). In mouse, megabase-size deletions of apparently gene-free regions (deserts) do not seem to affect function or viability (Nóbrega MA et al 2004 Nature [Lond] 431:988). In yeast, deletion of many genes may not result in visible (lethal) phenotype. ▶*deficiency chromosomal*, ▶*cri du chat*, ▶*Wolf-Hirschhorn syndrome*, ▶*retinoblastoma*, ▶*Prader-Willi syndrome*, ▶*Angelman syndrome*, ▶*Smith-Magenis syndrome*, ▶*Beckwith-Wiedemann syndrome*, ▶*Langer-Giedion syndrome*, ▶*Di-George syndrome*, ▶*Miller-Dieker syndrome*, ▶*Wolf-Hirschhorn syndrome*, ▶*contiguous gene syndrome*, ▶*aging*, ▶*deletion mapping*, ▶*pseudodominance*, ▶*duplication*, ▶*nested genes*, ▶*overlapping genes*, ▶*knockout*, ▶*Bal 31*, ▶*S1*, ▶*gene*

D

Figure D19. Deletion of phage λ DNA (b2) (Westmoreland, B. et al. 1969 Science 163:1343)

Figure D20. Deletion in the salivary gland X chromosome of *Drosophila* (Painter. T.S. 1934 J. Hered. 25:465)

Deletion 22q11.2 Syndrome: Quite a complex syndrome, it includes several psychiatric diseases and affects dozens of genes. Its prevalence is $\sim 4 \times 10^{-3}$ (Paylor R et al 2006 Proc Natl Acad Sci USA 103:7729), ► DiGeorge syndrome, ► velocardiofacial syndromes, ► autism, ► Asperger syndrome, ► psychoses

Deletion Analysis: Involves a number of diverse procedures, including pseudodominant expression of a recessive allele in a heterozygote when the dominant allele is deleted. Deletion mapping determines the extent of deleted segments on the basis of pseudodominance of linked genes, by genomic subtraction the normal DNA sequence extending over the gap can be isolated by molecular procedures, deletion of components of a gene (e.g., upstream regulatory elements) and their role can be identified,

etc. ► deletion mapping, ► linker scanning, ► genomic subtraction, ► pseudodominance

Deletion Generator: The *deletion-generator* technology may produce losses in defined areas within 60 kb of the insertion sites. For this purpose in *Drosophila*, a double transposable element, $P\{wHy\}$ is available. It contains within a *P* element a *hobo* transposon with flanking *W* (white eye) and *Y* (yellow body) markers. The *hobo* element within the *generator* may recombine with any *hobo* insertion within the genome. The recombination then deletes any gene(s) between the *hobo* insertion and the *generator* insertion points including one of the flanking markers, *W* or *Y*, depending on the orientation of the generator construct in the chromosome. The deletion of the *W* wild type allele produces white eye in the males and the loss of *Y* results in yellow body color. Therefore the deletions can be readily screened. Also a series of nested deletions can be obtained and the function of the unknown deleted genes can be annotated by the phenotype of the deletion animals. ► hybrid dysgenesis, ► annotation; Huet F et al 2002 Proc Natl Acad Sci USA 99:9948.

Deletion Mapping: Used in *Drosophila* and plants on the basis of pseudo-dominance, i.e., deletions of the normal sequences carrying the wild type alleles of syntenic genes identify the length of the deletions in the heterozygotes and determine their relative position (see Fig. D21).

About 2,000 mutants mapped the fine structure of the rII gene of phage T4, about 300 sites, by this principle (see Fig. D22).

Wild type was restored by recombination only between non-overlapping deletions and the crosses with the long deletion indicated that the mutation and the short deletion were both within the range of the long deletion. In an analogous manner transient-silencing genes with RNAi can generate functional maps. Bacteria expressing double-strand RNAs for specific genes can feed *Caenorhabditis*. By such a study 86% of the genes of this organism could be systematically analyzed (Kamath RS et al 2003 Nature [Lond] 421:231). ► pseudodominance, ► deficiency chromosomal, ► deletion, ► RNAi; see diagram; Slizynska H 1938 Genetics 23:291; Benzer S 1961 Proc Natl Acad Sci USA 47:403; Khush GS, Rick CM 1968 Chromosoma 23:452; Glaever G et al 2002 Nature [Lond] 418:387.

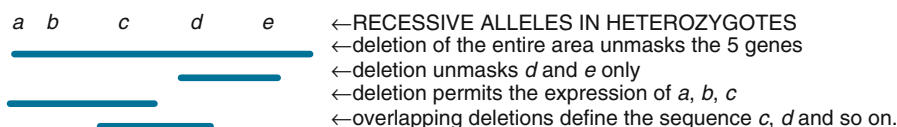

Figure D21. Deletion mapping

Figure D22. Phage T4 rII

Deletion Mutation: A lack of a portion of the genetic material that may vary in extent from a single to millions of nucleotide pairs. Deletions may be generated by molecular biology techniques using restriction endonucleases and extension of the gaps by exonuclease. Since the restriction enzymes nick at specific locations, they can be used for site-directed deletions. ►deletion unidirectional, ►ionizing radiation, ►radiation effects, ►localized mutagenesis, ►genomic subtraction

Deletion Unidirectional: DNA molecules blocked at the 3'-end by sulphur-containing nucleotides (thionucleotides) are protected from 3'→5' exonuclease action of T4 DNA polymerase are sliced back in the opposite direction in a time dependent extent. After removing the single strands left behind, nested sets of deletions of various lengths are obtained. ►Bal 31

Delila: A database manager program for selection of nucleic acid sequences in a library. <http://www.lecb.ncicrf.gov/~toms/delila/delila.html>.

Delitto Perfetto: A RAD52 requiring technique based on transformation of yeast by unpurified oligonucleotides leading to site-specific mutation in vivo within a window up to 200 bp. ►site-specific mutation; Storici F et al 2001 Nature Biotechnol 19:773.

Delphinidine: ►anthocyanin

Delta Endotoxin: ►*Bacillus thuringiensis*

Delta 1: (TPSD1, 16p13.3): A tryptase serine protease gene in humans.

Delta 88: A 7-kb *Drosophila* transposable element. ►transposable elements

Delta-Like 1 (*Dll* 1, 6q27): A mammalian ligand for Notch receptors. Interactions between *Dll*1 and Notch in trans activate the Notch pathway, whereas *Dll*1

binding to Notch in cis inhibits Notch signaling. *Dll*1 undergoes proteolytic processing in its extracellular domain by ADAM10 (Dyczynska E et al 2007 J Biol Chem 282:436). *Dll*4-specific antibody signaling deregulates angiogenesis and inhibits tumor growth (Ridgway J et al 2006 Nature [Lond] 444:1083).

►Notch, ►ADAM, ►angiogenesis

Demand Theory: Gene expression is determined by negative control when there is a low demand for the product of the gene. In case of high demand positive control is operating. The environment and evolutionary forces determine these cycles. ►negative control, ►positive control

Deme: An interbreeding population (a Mendelian population) without reproductive isolation; it is also used for denoting a natural breeding group with one male and several females.

Demecolcine (*N*-Deacetyl-*N*-methylcolchicine): Demecolcine depolymerizes microtubules and causes mitotic arrest at metaphase without significant effects on other cellular processes. It is used for karyotype analysis. ►colchicine, ►colcemid, ►karyotype

Dementia: Deterioration of mental abilities, dullness of the mind due to innate defects of the brain or developmentally programmed disease (paranoia, schizophrenia [dementia precox], Alzheimer's disease, etc.) or caused by poisonous substances or drugs affecting the nervous system. Both Familial British (FBD) and Familial Danish dementia (FDD) are caused by mutation in the *ITM2B* gene encoding the integral membrane protein 2B (ABRI). The mutation of FBD converts a stop codon to arginine at residue 267, thus extending the protein chain to 277 amino acids. In FDD, there is a 10-bp duplication between residues 265 and 266. In both, some variations exist. The clinical symptoms resemble those of early onset Alzheimer's disease but the amyloid deposits are systemic. *Frontotemporal dementia* is a heterogeneous disease involving human chromosome 3, 9 and 17 and it is characterized by apathy, restlessness, lack of judgment, mutism and dystonia. Onset is in the late 50s. This condition is not associated with β amyloid deposits. One of the G→C mutations involves the acceptor splice site of exon 6 of CHMP2B chromatin modifying protein, part of the ESCRT-1 endosome-sorting complex (Skibinski G et al 2005 Nature Genet. 37:806). ►neurodegenerative diseases, ►furin, ►endosome, ►chromatin remodeling, ►amyloids; Ghiso JA et al 2001 J Biol Chem 276:43909; Kim S-H et al 2002 J Biol Chem 277:1872.

Demethylation: It may take place by demethylase enzymes or by base excision repair. Demethylation can occur independently of replication and it may

require breaking the DNA backbone 3' to methylcytosine in the process of excision repair (Kress C et al 2006 Proc Natl Acad Sci USA 103:11112). Demethylation has significance for developmental controls in which methylation may turn off genes and demethylation may restore activity. In *Arabidopsis* mutation in the recessive gene *ddm1* may reduce the level of methylated cytosine by 70% and the demethylated condition is transmitted also through meiosis (Kakutani T et al 1999 Genetics 151:831). Demethylation results in different developmental anomalies (Finnegan EJ et al 1996 Proc Natl Acad Sci USA 93:8449). The animal spermatozoa are heavily methylated but rapidly dimethylated after fertilization. Demethylation of the egg nucleus is a gradual process after fertilization. In animals, the methylated state is reset in the new generation (Meyer W et al 2000 Nature [Lond] 403:501). De novo methylation is essential for embryogenesis and gametogenesis of mice (Okano M et al 1999 Cell 99:247). The human ICF syndrome is caused by methylation defects (Xu GL et al 1999 Nature [Lond] 402:187). Hypomethylation of DNA caused runted newborn mice, which developed later lymphomas and high frequency of chromosome 15 trisomy (Gaudet F et al 2003 Science 300:489).

The MeCP2 transcriptional repressor recruits histone deacetylases to the chromatin. In contrast MBD2, which binds methylated DNA was suggested to remove the methylation and to activate transcription. MBD2 is a member of the MeCP2 complex and—according to Ng H-H et al 1999 Nature Genet 23:58—does not demethylate DNA and it silences transcription in an alternate manner. Oxidative demethylation can revert methylated DNA bases to the normal state and thus repairs damage. The DNA glycosylase/lyase domain of ROS1 seems to be responsible for demethylation of 5-methylcytosine of DNA in *Arabidopsis* (Agius F et al 2006 Proc Natl Acad Sci USA 103:11796). The nuclear protein Gadd45a (growth arrest and DNA damage-inducible protein 45a) removes gene silencing global methylation signals with the cooperation of XPG repair endonuclease in *Xenopus* (Barreto G et al 2007 Nature [Lond] 445:671). ▶methylation of DNA, ▶trichostatin, ▶histone deacetylase, ▶ICF, ▶ROS; Cervoni N, Szyf M 2001 J Biol Chem 276:40778; Treweek SC et al 2002 Nature [Lond] 419:174; Goll MG, Bestor TH 2005 Annu Rev Biochem 74:481.

Demic Diffusion: Geographic expansion of a small deme into a large area resulting in demographic growth. The diffusion can be traced by analyzing the non-recombinant segment of the Y chromosome, mitochondrial DNA, autosomal microsatellite sequences and the mutations arising in these systems. Computer

models may analyze the front line of the expansion. ▶deme, ▶Y chromosome, ▶Eve foremother, ▶microsatellite; Edmonds CA et al 2004 Proc Natl Acad Sci USA 101:975.

Demography: The study of changes in the human populations by migration, birth, mortality, marriages, health, occupations, education, etc. Genetics became the most important tool of the study of human populations and their origin by the use of data obtained from the analysis of mtDNA, the Y chromosome and single-nucleotide polymorphism. ▶mtDNA, ▶Eve foremother, ▶Y chromosome, ▶SNIPs, ▶mortality; Wakely J et al 2001 Am J Hum Genet 69:1332; ▶out-of-Africa, <http://www.census.gov/ipc/www/idbnew.html>; <http://www.cdc.gov/nchs>.

De Novo Synthesis: The formation of molecules through synthesis from (simple) precursors rather than by cannibalization (recycling) of more complex processes of salvage.

DEN: diethylnitrosamine, an alkylating mutagen and carcinogen. ▶mutagen, ▶carcinogen

Denaturation: A loss of native configuration of DNA (frequently separation of the complementary strands) or of proteins by damaging the non-covalent bonds at elevated temperature or by chemicals, such as alkali, detergents and others (see Fig. D23). The denaturation of the DNA is often reversible (renaturation). The forces between complementary DNA strands can be measured by atomic force microscopy. Adhesive forces between complementary strands of 20, 16 and 12 base pairs was found to be 1.52, 1.11 and 0.83 nN, respectively (1 newton [N] = 1 kg m/s² = 10⁵ dyn). Local denaturation bubbles during gene replication and transcription. ▶atomic force microscope, ▶c₀t, ▶DNA thermal stability, ▶renaturation; Ginoza W, Zimm BH 1961 Proc Natl Acad Sci USA 47:639.

Figure D23. Denaturation

Denaturation Mapping: Electronmicroscopic localization of strand mismatches in DNA. ▶mismatch, ▶deletion, ▶deficiency chromosomal

Denaturing Gradient Gel Electrophoresis (DGGE): DGGE permits the separation of DNA fragments of identical size on the basis of different susceptibility to

denaturation because of mutation even in a single nucleotide. The DNA fragments are electrophoresed in polyacryl-amide gels in which there is an increasing gradient of a denaturing agent such as urea or formamide or both. The increased temperature also promotes separation of the strands of the DNA double helix. The partially denatured fragments migrate at a lower speed in the gel. ►[electrophoresis](#), ►[mutation detection](#); Myers RM et al 1987 *Methods Enzymol* 155:501.

Dendrimer: A branched molecular complex composed of monomers such as a DNA tract with a double-stranded central core and at the two ends four single-stranded, non-complementary tracts. The complex of monomers has the potential to hybridize with complementary oligonucleotides at the open single strands. These structures can then be used as devices for microarray hybridization. Dendrimers have been used as synthetic gene delivery vehicles for in vivo gene therapy. After delivering a special signal the dendrimer may self-destruct leaving the passenger molecule, e.g., an anticancer drug, at the target. ►[endosome](#), ►[PAMAM](#); Stears R et al 2000 *Physiological Genomics* 3:93; Rudolph C et al 2000 *J Gene Med* 2:269; Benters R et al 2002 *Nucleic Acids Res* 30[2]:210; ►[microarray hybridization](#), <http://www.genisphere.com>.

Dendrite: A relatively short branch of neurons that receives information from other nerve cells. ►[nerve cells](#), ►[CREST](#); Häuser M et al 2000 *Science* 290:739.

Dendritic Cell: Heterogeneous leukocytes with the primary role to capture MHC antigens and present them to T cells. Although dendritic cells chew to pieces most of antigens presented to T cells, some antigens are presented intact to B cells (Bergtold A et al 2005 *Immunity* 23:503) (see Fig. D24). The TNF receptor RANK ligand promotes dendritic cell function. The granulocyte macrophage-colony-stimulating factor (GM-CSF) promotes their differentiation. TNF- α and IL-1 β promote their maturation. RAC expression of the mature dendritic cells is required for priming of T cell (Benvenuti F et al 2004 *Science* 305:1150). Antigen capture by dendritic cells is facilitated by actin remodeling through Toll-like receptor (West MA et al 2004 *Science* 305:1153). They travel from the peripheral tissues to the lymphoid organs and promote immunity. Myeloid type dendritic cells may stimulate T lymphocytes whereas the lymphoid dendritic cells may have the opposite effect. Fusion of human dendritic cells with breast carcinoma cells activates cytotoxic T cells against the tumors. The different CD8 α dendritic cells develop from common myeloid progenitors. Dendritic cells can detect

pathogens directly or sense the products of infection such as heat shock proteins or uric acid crystals. Dendritic cells also maintain neuronal circuits. ►[antigen presenting cell](#), ►[plasmacytoid cell](#), ►[T cell](#), ►[TNF](#), ►[IL-1](#), ►[GM-CSF](#), ►[DC-SIGN](#), ►[RAC](#), ►[Toll](#), ►[actin](#); Banchereau J, Steinman RM 1998 *Nature [Lond]* 392:245; Henri S et al 2001 *J Immunol* 167:741; Pulendra B et al 2001 *Science* 293:253; Mellman I, Steinman RM 2001 *Cell* 106:255; and following reviews, Huang Q et al 2001 *Science* 294:870; in immunotherapy: Aragonese-Fenoll L, Corbi AL 2007 *Clin Transl Oncol* 9:77.

Dendritic Cell Vaccine: Antigen presenting cells primed with tumor antigens to incite CTLs against tumors. The dendritic cell may be transformed with the antigen gene using viral vectors. ►[antigen presenting cell](#), ►[CTL](#), ►[tumor vaccination](#), ►[cancer gene therapy](#)

Dendrocytes: Wrap nerve axons with myelin sheath. Oligodendrocytes (see Fig. D25) cause clustering of Na channels.

Figure D25. Oligodendrocyte

Dendrogram: A chart showing relationship among entities in a form resembling branches of a tree. ►[evolutionary tree](#), ►[character matrix](#), ►[Euclidean distance](#)

Dengue Virus (DENV, dengue fever): An icosahedral (~ 500 Å), positive strand RNA virus translated into a single 350 kDa polyprotein and causes either the dengue fever or the hemorrhagic dengue. Both of them are debilitating diseases primarily in South-East Asia. Mosquitos transmit the virus. For productive infection, dendritic cell-specific ICAM-3 grabbing non-integrin (DC-SIGN1, encoded by CD209), an attachment receptor of the virus is essential. Variants of CD209 discriminate between severe dengue fever

and dengue hemorrhagic fever (Sakuntabhai A et al 2005 Nature Genet 37:507). A way of protection was worked out involving the transformation of the mosquito (*Aedes aegypti*) by a *Sindbis* virus vector carrying a 567-base antisense RNA of the premembrane coding region of the dengue-2 virus. The transduced mosquitoes cannot support the replication and thus do not transmit the virus. ►biological control, ►antisense RNA, ►ICAM, ►DC-SIGN; Diamond MS, Harris E 2001 Virology 289:297; DENV structure: Pokidysheva E et al 2006 Cell 124:485.

D

Denhardt Reagent: Used to suppress background hybridization in Northern hybridization, RNA probing, single-copy Southern hybridization, annealing DNA immobilized on nylon membrane. It is made of Ficoll-400 (a non-ionic synthetic sucrose polymer), polyvinylpyrrolidone (an insoluble material removing phenolic impurities) and bovine serum albumin at a concentration of 2.5% (or less) each in water. ►DNA hybridization, ►Northern blot, ►BSA

Denoising: The removal of noise and improving the quality in capillary electrophoresis. ►capillary electrophoresis; Perrin C et al 2001 Anal Chem 73:4903.

Densitometry: Optical detection of increased or decreased amounts of a substance in a solution or in solid medium.

Density Gradient Centrifugation: The separation of subcellular organelles or macromolecules on the basis of their density (see Fig. D26). The density of DNA (ρ) increases with increased GC content ($\rho = 1.660 + [0.098 \{G+C\}]$). During buoyant density centrifugation the DNA is positioned at the density of CsCl that corresponds to DNA density. The density of the CsCl solution is determined by refractometry. The nuclear DNA of most eukaryotes has an AT content of about 40%, corresponding to a density of about 1.7 g/mL. The DNA of cellular organelles may have a density different from that of the nucleus and thus form a satellite band(s) in the ultracentrifuge. Single-stranded nucleic acids sediment faster and circular DNA molecules sediment slower. Among cellular organelles nuclei sediment fastest, then chloroplasts and mitochondria occupy the highest position in the centrifuge tube. For the separation of organelles either sucrose or percoll (polyvinylpyrrolidone-coated silica) are used most commonly. ►centrifuge, ►buoyant density centrifugation, ►ultracentrifugation, ►density labeling; Meselson M et al 1957 Proc Natl Acad Sci USA 43:581.

Figure D26. Density gradient centrifugation

Density Labeling: By growing cells first in dense (heavy isotope) medium, e.g., $^{15}\text{NH}_4\text{Cl}$ and then transferring to normal $^{14}\text{NH}_4\text{Cl}$ medium, the heavy and light DNA or recombinant strands can be separated by density gradient equilibrium centrifugation. ►density gradient centrifugation

Densovirus: ►parvoviruses

Dent Disease (Xp11.22): The recessive defect in the CLCN5 chloride ion channel responsible for hypophosphatemic rickets and kidney stones (nephrolithiasis). ►rickets, ►nephrolithiasis

Dental Non-Eruption: Autosomal dominant failure to cut teeth.

Dentatorubral-Pallidoluysan Atrophy (DRPLA, myoclonous epilepsy with choreoathetosis, Haw River disease): It involves involuntary jerky muscle movements, epilepsy, feeble-mindedness, ataxia, brain degeneration due to a chromosome 12p13.31 dominant condition. The mutation causes an abnormal number (49–75) of CAG repeats in the atrophin-1 protein compared to 7–23 under normal conditions. ►fragile sites, ►trinucleotide repeats, ►muscular atrophy

Denticle: Tooth-like extrusion (insects) or pulp stone in the mammalian tooth.

Dentin Dysplasia: In dentin dysplasia the pulp is absent or poorly developed, the root canal is frequently empty and/or enlarged, and the bluish teeth is spontaneously lost. Several forms of autosomal dominant expression have been observed.

Dentinogenesis Imperfecta: The dominant condition is encoded in human chromosome 4q21.3 causing blue-gray or brownish teeth due to dentin defect. The Brandywine type appears to be non-identical. ▶[dentin dysplasia](#), ▶[osteogenesis imperfecta](#), ▶[tooth](#); Xiao S et al 2001 Nature Genet 2001 27:201.

Denver Classification: This classification of human chromosomes in 1960, arranged the chromosomes into 7 groups (A to G) on the basis of decreasing length and arm ratio. ▶[human chromosomes](#), ▶[Chicago classification](#), ▶[Paris classification](#)

Denys–Drash Syndrome: A very severe (dominant negative) mutation in the WT gene ▶[Wilms tumor](#), affecting primarily the female gonads and genitalia, internal male genitalia and kidneys. ▶[Wilms tumor](#), ▶[Frasier syndrome](#), ▶[dominant negative](#)

2-Deoxyribonolactone: Oxidative damage to DNA may produce various modified products of deoxyribose such as 2-deoxypentos-4-ulose and deoxy-ribonolactone (dL) (see Fig. D27). The latter creates problems in repairing the damage because the function of polymerase β is hampered at the AP endonuclease incised dL sites. ▶[DNA repair](#); DeMott MS et al 2002 J Biol Chem 277:7637.

Figure D27. 2-Deoxyribonolactone

Deoxyribonuclease: An enzyme capable of breaking phosphodiester bonds in single- or double-stranded DNA. ▶[DNase free RNase](#), ▶[DNase hypersensitive sites](#), ▶[restriction enzymes](#), ▶[endonuclease](#), ▶[exonuclease](#)

Deoxyribonucleic Acid: ▶[DNA](#)

Deoxyribonucleotides: The building blocks of DNA, they contain only H rather than OH at the 2 position of the ribose, one of the nitrogenous bases (A, T, G, C) and phosphate. ▶[ribonucleotide](#), ▶[nucleotide chain growth](#)

Deoxyribose: ▶[ribose](#)

Deoxyribozyme: The hammerhead ribozymes contain deoxyribonucleotides yet they can cut RNA. Single-stranded DNAs may become $\text{Zn}^{2+}/\text{Cu}^{2+}$ or Pb^{2+} metalloenzymes. The $\text{Zn}^{2+}/\text{Cu}^{2+}$ enzymes may function as DNA ligase. ▶[ribozyme](#), ▶[DNA ligase](#); Carmi N, Breaker RR 2001 Bioorg Med Chem 9:2589; Wang DY, Sen D 2001 J Mol Biol 310:723; Khachigian LM 2000 J Clin Invest 106:1189.

Dependovirus: Dependovirus replicates only in the presence of a co-infecting helper virus, e.g., adeno-associated virus requires helper adenovirus or herpesvirus. ▶[adeno-associated virus](#), ▶[adenovirus](#), ▶[herpes](#)

Depression: A psychological state of sadness, despair, low self-esteem, generally accompanied by lack of appetite and sleeplessness (see Fig. D28). A major genetic factor associated with depression has been located to 12q22-q23.2 (Abkevich V et al 2003 Am J Hum Genet 73:1271). It is frequently associated with glucocorticoid over-production that may lead to hippocampal atrophy. The therapy may involve serotonin re-uptake inhibitor drugs, such as Prozac (fluoxetine). Mood is determined in the forebrain. Low activity of serotonergic neurotransmission results in depression (dysphoria) whereas high activity causes euphoria. Preliminary results indicate that in treatment-resistant depression the subgenual cingulate brain region (the cingulate gyrus is just above the middle of the corpus callosum; see diagram) is metabolically over-active.

Chronic stimulation of the white matter tract adjacent to this area reduced the local cerebral blood flow that resulted in sustained remission, antidepressant effects (Mayberg HS et al 2005 Neuron 45:651). Some mentally ill persons suffering from severe depression contributed a great deal to human culture like Vincent van Gogh the great Dutch painter. The famous painter of the seventeenth century also suffered from melancholy and later bipolar disorder (Schildkraut JJ et al 2007 J Nerv Ment Dis 195:3) (see Fig. D29). The highly acclaimed and yet often rejected great Austrian composer and performer Robert A. Schumann suffered from periodic despair among periods of great achievement and spent the last two and half years of his life in a mental asylum. ▶[glucocorticoid](#), ▶[hippocampus](#), ▶[serotonin](#), ▶[affective disorders](#), ▶[melancholy](#), ▶[bipolar mood disorder](#), ▶[BDF](#), ▶[van Gogh](#); Schafer WR 1999 Cell 98:551; Zubenko GS et al 2002 Amer J Med Genet 114:413; animal models: Flint J 2002 FEBS Lett 529:131.

Figure D28. Depression

Figure D29. Vincent van Gogh (1853–1890)

Depurination: The loss of purine from nucleic acids. In mammalian cells both G and A loss and damage may occur at high frequency ($3 \times 10^{-9} \text{ min}^{-1}$) and some of the damage is corrected by enzymatic repair, others lead to mutation in the DNA. Self-catalyzed, site-specific depurination of 5'G residues spontaneously occur across the human genome in short 29–18 sequences. These sequences can form a stem-loop structure and the catalytic intermediate is 5'G-T-G-G-3' bp in the duplex DNA adjacent to a 5'-T-A-3'. At such sites the depurination rate is several-fold higher than in other areas of the genome. The stem-loop structure is associated with superhelical stress and has likely an important biological role in nucleosome positioning, chromosome superfolding and genetic recombination (Osamova O et al 2006 Proc Natl Acad Sci USA 103:4392). ▶[apurinic site](#), ▶[excision repair](#)

DER: A transmembrane hormone-receptor tyrosine-kinase protein of the epidermal growth factor of *Drosophila*. It affects many phases of the development including photoreceptor determination, wing vein formation, etc. The activator ligand is the Spitz

protein (a homolog of TGF- α); Argos is an inhibitor of DER. ▶[EGF](#), ▶[Argos](#), ▶[Spitz](#)

Derepression: The removal of repression (so protein synthesis can go on). ▶[induction](#)

Derivative: Mathematically, it is a function f' of a function f whose value at any point x_1 in the domain of f (see formula) if such limit exists (see Fig. D30).

$$f'(x_1) = \lim_{\Delta x \rightarrow 0} \frac{f(x_1 + \Delta x) - f(x_1)}{\Delta x}$$

Figure D30. Derivative

Derivative Chromosome: Modified by chromosomal rearrangement(s).

Dermatan Sulfate: Glucosaminoglycan; repeating units of disaccharides, generally acetyl-galactosamines linked to an iuduronic acid. ▶[mucopolysaccharidosis](#)

Dermatitis, Atopic (AD, 3q21): A skin inflammation generally associated with itching, frequently evoked by allergic reactions to cosmetics, plants, animals, light, etc. The locus may be involved in paternal imprinting. AD genes are linked to psoriasis loci and may be associated with 1q21, 3p24-p22, 13q14, 15q14-q15, 17q25-q21, and 20p. ▶[skin diseases](#), ▶[imprinting](#), ▶[psoriasis](#); Cookson WOCM et al 2001 Nature Genet 27:372; Bradley M et al 2002 Hum Mol Genet 11:1539.

Dermatoglyphics: The examination of dermal ridges and creases on fingers, toes, palms and soles for the purpose of identification, diagnosis and forensic investigations. ▶[fingerprints](#); Sodhi GS, Kaur J 2001 Forensic Sci Int 120[3]:172.

Dermatome: The cell layer that generates the mesenchymal connective layer of skin.

Dermatomyosities: ▶[polymyosities](#)

Dermatosparaxis: A hereditary disease in cattle. The procollagen peptidase that cleaves a peptide from the N-terminus of the chains is defective causing disorganized, poor fiber formation resulting in extreme brittleness of the hide. ▶[collagen](#)

Deratomyotome: The primordium of the vertebrate skeletal muscles (Gros J et al 2005 Nature [Lond] 435:954)

DES (diethylsulfate, $[\text{C}_2\text{H}_5]_2\text{SO}_2$): A potent alkylating mutagen and carcinogen.

Desaturase: Enzymes—on the endoplasmic reticulum of plants—introducing double bonds into the hydrocarbon portion (cis) of fatty acids in the presence of NADPH, light generated ferredoxin and activated O_2 .

Desaturation of some fatty acids may be desirable for some oil crops and can be accomplished by mutation techniques. Fatty acid desaturase may activate the plant defense system against pathogens. ▶ [fatty acids](#), ▶ [host-pathogen relations](#); Shanklin J, Cahoon EB 1998 *Annu Rev Plant Physiol Mol Biol* 49:611; Kacharoo P et al 2001 *Proc Natl Acad Sci USA* 98:9448.

Descent: Ancestry, the descendants of a person or a family of genetic lineage.

Desensitization: Signal-response systems after prolonged stimulation display reduced responsiveness to stimulation by the same agent. The process is mediated through G protein-coupled receptors and arrestin. ▶ [signal transduction](#), ▶ [arrestin](#), ▶ [pleckstrin domain](#), ▶ [phosphoinositides](#); Lefkowitz RJ, Shenoy SK 2005 *Science* 308:512.

Deserts: Chromosomal regions with a paucity of genes or low frequency of recombination. ▶ [jungles](#), ▶ [recombination frequency](#), ▶ [recombination by replication](#), ▶ [map units](#)

Desetope: The antigen binding site of the MHC molecule. ▶ [antigen](#), ▶ [MHC](#), ▶ [agretope](#)

DESI (desorption electrospray ionization): A technique of mass spectrometry. A fine spray of charged droplets are applied to the surface of a compound from which small and large molecules are picked up, ionized as desolvated ions (release the electrostatically bound water) and are introduced into a mass spectrometer. ▶ [mass spectrometer](#), ▶ [electrospray](#), ▶ [desolvation](#)

Desktop: A computer that has the various menu bars and where the actual work is performed.

Desmin: A muscle filament protein. Desmin-related myopathies (DRM) are neuromuscular diseases affecting skeletal, cardiac and eye lens muscles. Missense mutations in the molecular chaperone α B-crystallin, encoded at human chromosome 11q21-q23, is responsible for one form. Cardiomyopathies may develop in desmin deficiency. In such cases the increased expression of Bcl-2 ameliorates the heart function. ▶ [myopathy](#), ▶ [crystallins](#), ▶ [Bcl-2](#); Weisleder N et al 2004 *Proc Natl Acad Sci USA* 191:769; diseases of filament protein: Omary MB et al 2004 *New England J Med* 351:2087.

Desmocollins: Desmosome attached proteins. ▶ [desmosome](#)

Desmoid Disease, Hereditary (5q21-q22): An infiltrative fibromatosis (tumor-like fibrous nodules) due to mutation in the APC gene distal to the β -catenin domain. ▶ [Gardner syndrome](#)

Desmoplakins: The proteins involved in cell in plakoglobin. Dominant mutation (6p24) in the desmoplakin domain may modify a phosphorylation site of plakoglobin and cause one form of arrhythmogenic right ventricular cardiomyopathy. ▶ [desmosome](#), ▶ [filament](#), ▶ [plakoglobin](#), ▶ [arrhythmogenic right ventricular cardiomyopathy](#); Rampazzo A et al 2002 *Am J Hum Genet* 71:1200.

Desmosome: A protein plaque of cell junctions (between epithelial cells) into what desmin and keratin filaments of cells are tied. Besides mediating cell adhesion, desmosomal cadherins are involved in epithelial morphogenesis. A defect of desmosomes is responsible for various skin diseases. ▶ [junction complex](#), ▶ [cadherin](#), ▶ [pemphigus](#), ▶ [intermediate filaments](#), ▶ [filaments](#), ▶ [plakoglobin](#), ▶ [p63](#), ▶ [skin diseases](#); Runswick SK et al 2001 *Nature Cell Biol* 3:823.

Desmosterolosis: Desmosterolosis involves diverse lethal malformations due to deficiency of 3- β -hydroxysterol- δ -24-reductase. ▶ [chondrodysplasia](#); Waterham HR 2001 *Am J Hum Genet* 69:685; Kelley RI, Herman GE 2001 *Annu Rev Genomics Hum Genet* 2:299.

Desmoyokin: A cell junction protein. (Nie Z et al 2000 *J Invest Dermatol* 114:1044)

Desmutagen: Chemical agents, which can interact and directly inactivates mutagenic molecules.

Desolvation: The release of electrostatically bound water or removal of solvent from polar or nonpolar atoms, removal of solvent adducts from a gas phase ion as a preparation for mass spectrometry. ▶ [mass spectrometer](#)

Destruction Box: Amino acid sequences at the N-terminal of cyclins and other proteins making them targets for ubiquitinylation: **Arg** (Ala/Thr) (Ala) **Leu** (Gly) \times (Ile/Val) (Gly/Thr) Asn. Those in bold are conserved, the others may vary. ▶ [ubiquitins](#), ▶ [amino acids](#), ▶ [N-end rule](#), ▶ [degron](#), ▶ [N-degron](#); Burton JL, Solomon MJ 2001 *Genes Dev* 15:2381.

Desynapsis: The loss of synopsis of the homologous chromosomes (after the completion of the recombination process). The desynaptic gene of maize reduced chiasma frequency in the majority of chromosomes but it increased chiasma frequency in the short arm of chromosome 6 where the nucleolar organizer is situated. ▶ [synapsis](#), ▶ [asynapsis](#), ▶ [sister chromatid cohesion](#), ▶ [chiasma](#), ▶ [nucleolar organizer](#); Dix DJ et al 1997 *Development* 124:4595.

Detasseling: The removal the male inflorescence of maize (see Fig. [D31](#)). ▶ [heterosis](#)

Figure D31. Tassel

D

Detector Proteins: Sense environmental signals (in bacteria) in the periplasmic region. ▶ [periplasma](#)

Detergent: The various types may have different chemical structures but they all have a large non-polar hydrocarbon end that is oil-soluble and a water-soluble polar end. The so-called “soft detergents” are biodegradable. In the laboratory most commonly sodium lauryl sulfate (SDS, sodium dodecyl sulfate, $n\text{-C}_{11}\text{-H}_{23}\text{CH}_2\text{OSO}_3\text{Na}^+$) is used in gel electrophoresis. Detergents are employed also for the solubilization of membrane proteins and lipid components. ▶ [SDS](#), ▶ [polyacrylamide gels](#), ▶ [Tween 20](#), ▶ [nonidet](#)

Determinate Inflorescence: The stem terminates in a flower rather than in an apical meristem. ▶ [meristem](#), ▶ [indeterminate inflorescence](#)

Determination: The establishment of a specific *commitment* to differentiation. It is a biochemical change within cells or tissues whereby they lose options for differentiation in all but one particular way. In plant cells, however, the determination may be reversible. In the processes controlled by homeotic genes transdetermination may overrule the regular pattern. In *Bacillus subtilis* the commitment to spore formation is governed by gene *SpoIIQ* under the control of transcription factor σ^F and *SpoIIP* controlled by both σ^F and σ^E . In the presence of nutrients, the forespore can exhibit rod-like longitudinal growth in the absence of SpoIIQ and SpoIIP, whereas the mother cell can do so when only SpoIIP is absent. Differentiation becomes irreversible when neither the mother cell nor the forespore can grow in the presence of nutrients (Dworkin J, Losick R 2005 Cell 121:401). ▶ [transdetermination](#), ▶ [homeotic genes](#), ▶ [transplantation nuclear](#), ▶ [heritability](#); Glotzer M et al 2001 Annu Rev Cell Dev Biol 17:351.

Determinism, Genetic: A tenuous social theory that crime, immorality, disease, poverty and all social ills are predetermined in families. Behavior genetics shows that inheritance plays a certain, variable role in behavior and by logical extension judgment of human values. Also, the question of the degree of responsibility is opened. If behavior is genetic how much is the role of free will? Ethicists and legal scholars would have difficulties to define “values”. If it is measured can it be valued? The philosopher David Hume remarked: “Good sense and genius beget

esteem: Wit and humor excite love.” The problems certainly exceed the scope of this text although the moral dilemmas are inescapable for the geneticist once Pandora’s box has been opened. ▶ [human behavior](#), ▶ [ethics](#); Alper JS 1998 Soc Sci Med 46:1599.

Deterministic Gene: A certain condition or disease is most likely to occur in its presence.

Deterministic Model: When the changes in a population are based on fixed parameters such as the selection coefficient, mutation pressure, and migration. ▶ [stochastic model](#)

Detoxication: A process by which a toxic agent is made less harmful by the metabolism.

Detoxification: The removal of a toxic agent from a biological system by extrinsic factors.

Detoxification Enzymes: ▶ [glutathione-S-transferase](#), ▶ [paraoxonase](#), ▶ [superoxide dismutase](#)

Detrimental Mutation: A mutant that has low fitness but its rate of survival is not below 10%. ▶ [beneficial mutation](#), ▶ [mutation](#), ▶ [fitness](#)

Detritus: Particulate decay product.

Deubiquitinating Enzymes (DUBs): DUBs cleave the ubiquitin–protein link and thus prevent degradation by protease. ▶ [ubiquitin](#), ▶ [monoubiquitin](#); Richert K et al 2002 Mol Genet Genomics 276:88.

Deuteranomaly: A deficiency of the photopigment, sensitive to middle wavelength yet they retain some trichromatic (three-color) vision, depending on how much short and long wavelength receptors they have. The mildest cases have differences from normal in exon 5 of the X-chromosomal gene. The next mildest anomaly involves exon 2 and either exon 3 or 4 but not both. In the most severe cases the anomaly was commonly in exon 2 but usually not in 3 or 4. Deuteranomaly affects about 5% of the US males but only 0.25% of the females because of X-linkage. ▶ [colorblindness](#), ▶ [night blindness](#)

Deuteranopia: ▶ [color blindness](#)

Deuterium: ^2H , heavy hydrogen (atomic weight: 2.014725), a stable, non-radioactive isotope.

Deuterostome: A taxonomic group characterized by blastopores behind the mouth, such as echinoderms, hemichordates and chordates. ▶ [blastopore](#), ▶ [protostome](#)

Deuterotoky: Unfertilized eggs develop into male or female. ▶ [arrhenotoky](#), ▶ [thelytoky](#), ▶ [chromosomal sex determination](#), ▶ [sex determination](#)

Development: A sequence of events beginning with determination and through differentiation leads to the

various stages of life of the organism. In multicellular organisms it begins with the fertilization of the egg and goes through epigenesis and terminates in death. The zygote grows and at an early stage polarity and segmentation becomes obvious. In animal embryos the cells move into organizing centers (gastrulation) and the development becomes rather rigidly determinate. The germline is laid down and is separated from somatic differentiation. Plant cells maintain high degree of totipotency through development and

movement of cells is restricted by the rigid cell walls. In plants, *meristems* containing totipotent cells are organized and serve as the bases of growth differentiation and development. In animals the *stem cells* assume the functions comparable to that of the meristem of plants. The development is based on a highly regulated cooperation of genes that are turned on, changed in the level of activity and turned off. Although development is potentiated primarily according to the genetic blueprint, the realization of

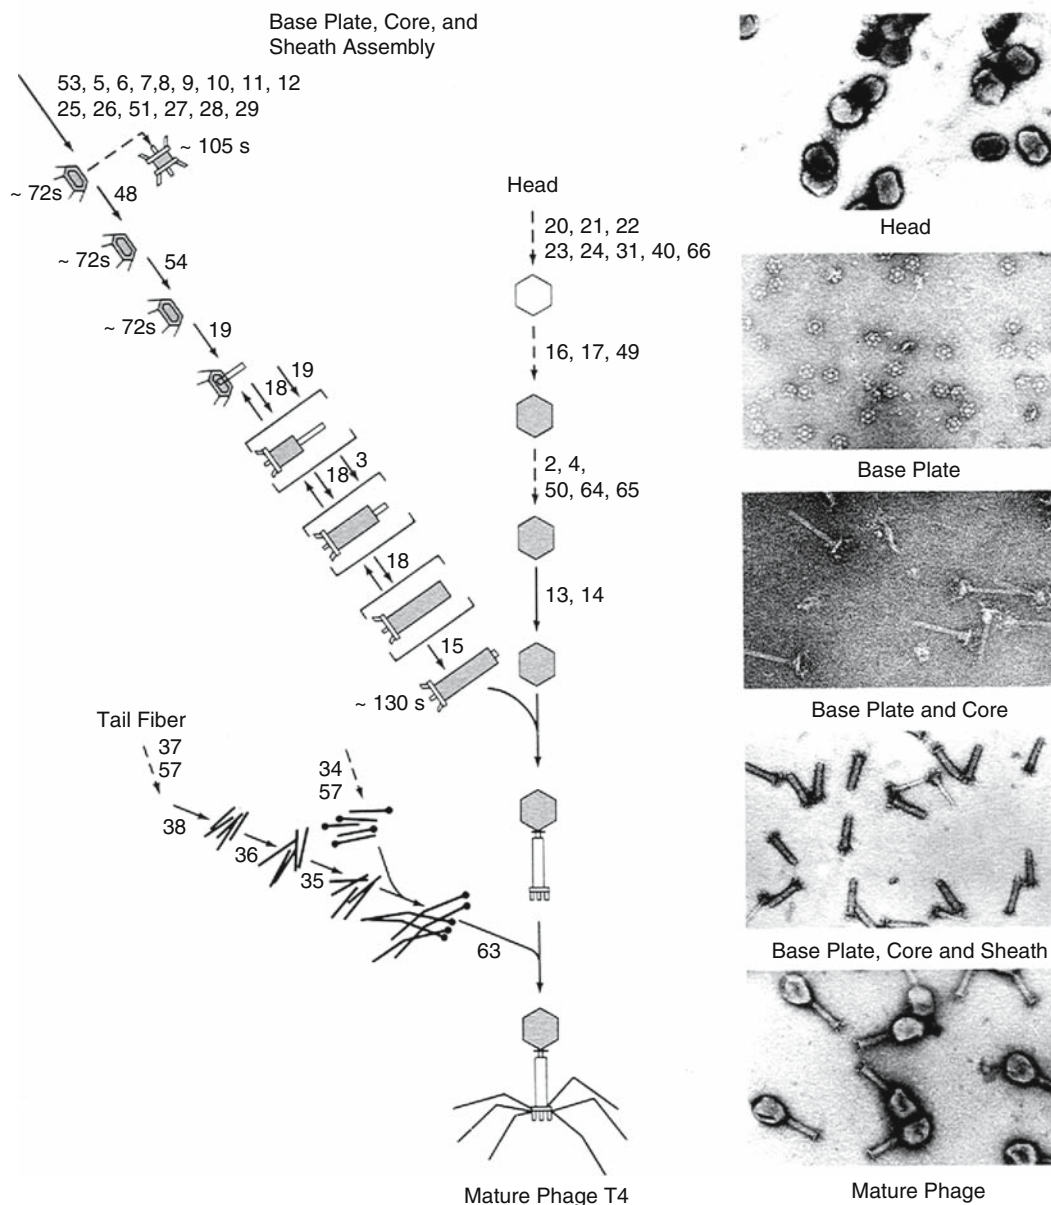

Figure D32. The morphogenetic and developmental pathway of phage T4. The numbers refer to genes. In case of mutation, incomplete phage parts may develop within the host bacteria. Many of these structures are true phage precursors and may form viable phage particles *in vitro* from appropriate mixtures of mutants blocked at key developmental steps. (After Wood WB 1980 Quarterly Rev Biol 55:353, and King J 1971 J Mol Biol 58:69)

the plan generally requires environmental cues. The signal transduction pathways provide the motivation.

Developmental events are the outcome of combinatorial action of a relatively limited number of signals and the expression of regulatory genes. The sensors of these signals may reside within the enhancers of the major genes concerned with the guidance of cellular differentiation. Development is genetically controlled in all organisms. Many genes of the bacteriophages have been identified that control individual steps of differentiation of the structures and their assembly into a mature phage particle (see Fig. D32).

Bone morphogenetic protein (Bmp4) plays an important role in beak development of ducks (see Fig. D33) and chickens (Wu P et al 2004 Science 305:1465).

The phage body is constructed according to the instructions of the viral genes but the cellular metabolism is used for execution of the project. Thus, the cooperation of both host and of the viral genomes is responsible for the product. The simplest developmental pathway of animals is seen in the nematode, *Caenorhabditis elegans*. About 90% of the genes of *Caenorhabditis* involved in the control of development are related to developmental genes of *Drosophila* and vertebrates while only ~50% of the other protein-coding genes are homologous to other taxonomic groups. Developmental mechanisms are of focal interest of research using diverse organisms. The complex interaction of many genes can be monitored by microarray hybridization.

Molecular machines can be inferred and functional relationships of genes and proteins can be studied by evaluating physical interaction (interactome), expression similarity (transcriptome) and phenotypic similarity during development (e.g., embryogenesis). In a nuclear function model 55 genes/proteins in four functional categories (DNA synthesis, histones, chromosome segregation, nucleocytoplasmic transport) were grouped and the relations were graphically represented by weights of the links/lines and size of the individual nodes. The results indicated that early embryogenesis is achieved through the coordination of a limited number of molecular machines (Gunsalus KC et al 2005 Nature [Lond] 436:861).

► *Caenorhabditis*, ► morphogenesis, ► segregation asymmetric, ► heterochronic RNA, ► GeneEMAC, ► see morphogenetic pathways diagram, ► junction of cellular networks, ► signal transduction, ► microarray hybridization, ► coordinate regulation, ► genetic networks; Boys DC et al 2001 Plant Cell 13:1499; Rougvie AE 2001 Nature Rev Genet 2:690; Freeman M, Gurdon JB 2002 Annu Rev Cell Dev Biol 18:515; Rossant J, Howard L 2002 Annu Rev Cell Dev Biol 18:541; Anderson KV, Ingham PW

Figure D33. A clear example of the genetically programmed development of simple traits of higher animals. Bottom: normal and Top: “Donald Duck” chicken embryos after 8 to 11 days of incubation. The beak anomaly is the result of homozygosity of a recessive gene. The mutants cannot be identified until the eighth day of incubation, and within two days after the onset both lower and upper beaks display the developmental defect. By later stages the condition becomes more pronounced and the afflicted chicks cannot survive. (Courtesy of Abbott UK and Lantz FH 1967 J Heredity 58:240)

Development, Autonomous: The process is independent of the (cellular, tissue) environment.

Developmental Clock: The developmental fate of an organism or structure is determined as a function of time.

Developmental Cycle: The processes during ontogenetic developments in the alternating generations. ► *alternation of generations*, ► *ontogeny*

Developmental Field: A group of cooperating cells destined to a differentiatinal fate.

Developmental Noise: A variation, which cannot be attributed to any verified cause.

Developmental-Regulator Effect Variegation: It shows some similarities to the variegation type position effect but the variegation is induced when the *Polycomb* gene and its response element are inserted at euchromatic sites of *Drosophila*. This variegation is also sensitive to the products of the *trithorax* gene. ▶variegation, ▶position effect, ▶*Polycomb*, ▶*trithorax*, ▶*bithorax*

Developmental Therapeutics Program (DPT): DPT involves information on drug discovery and is accessible: <http://epnws1.ncicrf.gov:2345/dis3d/DTP.html>.

Deviation: Difference from the usual type. ▶standard deviation, ▶variance

Dewar Photoproduct: An UV-induced valence isomer of pyrimidine-pyrimidone 6–4 adduct. It is less mutagenic than the 6–4 adduct (see Fig. D34), which inserts preferentially a G opposite to a 3' T and results in a highly mutagenic T→C transition in ~85% of the replications of *E. coli* cells. The Dewar product leads to a lower frequency but broader range of mutation by SOS repair. The Dewar product leads to insertions of A in 72% across T and 21% of the cases a G and only 13% translesion errors occur. The Dewar product causes less distortion of the DNA structure than the 6–4 photoproduct and therefore causes less hardship for repair DNA polymerase. ▶DNA repair; Lee J-H et al 2000 Proc Natl Acad Sci USA 97:4591.

Figure D34. Dewar photo product

Dexamethasone (C₂₂H₂₉FO₅): A long-active synthetic glucocorticoid with antiinflammatory and immunosuppressive action. It is usually an inducer of glucocorticoid receptors in animals but not necessarily in plants. ▶glucocorticoids, ▶GVG

DEXH/D (unwindase): Double-stranded RNA helicase, which disrupts RNA–Protein interaction and reorganizes ribonucleoproteins. These nucleic acid-activated triphosphatases have numerous functions in RNA metabolism (splicing, RNAi, etc.) and RNA unwinding may not be necessary for protein displacement. ▶unwindase, ▶RNA helicase, ▶NPH,

▶TRAP, ▶exon junction complex; Fairman ME et al 2004 Science 304:730.

Dextran: An α-1,6 linked poly-D-glucose, sometimes with α-1,4 or α-1,3 linked branches. It is present in cross-linked form in the gel-filtration and anion exchanger agent Sephadex. It is synthesized by bacterial enzymes and is an important component (along with inorganic salts and lipids) of the dental plaques, responsible for tooth decay (caries) and gum disease. ▶DEAE-dextran, ▶Sephadex

Dextrin: ▶amylopectin

Dextrinosis: ▶glycogen storage diseases (Type III)

Dextrorotatory: Rotates the plane of polarized light clockwise.

Dextrose: same as glucose.

DHFR: dihydrofolate reductase (22-kDa) controls the reaction: dihydrofolate + NADPH + H⁺→tetrahydrofolate + NADP⁺; *dhfr* deficient cells are resistant to methotrexate (amethopterin). Transformation to methotrexate resistance may be beneficial for cancer chemotherapy. The conversion of deoxyuridylic monophosphate to deoxythymidylic monophosphate

requires tetrahydrofolate. ►folic acid, ►methotrexate, ►amethopterin, ►NADP⁺, ►multidrug resistance, ►DM chromosome; Wallace LA, Robert Matthews C 2002 J Mol Biol 315:193; repression by a non-coding RNA: Martianov I et al 2007 Nature [Lond] 445:660.

D

DHR Domain: Same as PDZ domain.

Diabetes: Obesity-dependent diabetes type II (Astrup A, Finer N 2000 Obesity Rev 1:57). The high fructose sweetener consumption perturbs glucose uptake and metabolism and enhances lipogenesis and triglyceride biosynthesis (Basciano H et al 2005 Nutrition & Metabol 2;5). ►fructose

Diabetes Insipidus: An autosomal dominant type, and like all diabetes involve an imbalance in electrolyte control resulting in excessive urination and as a consequence extreme thirst. In the case of the neurohypophysis type, the defect resides within the arginine V2 vasopressin receptor gene and the controlling antidiuretic neurohypophyseal hormone. The kidneys cannot reabsorb large amounts of water and it is released, and may require a 10–15 fold higher than normal water intake (up to 20 L/day). In the autosomal dominant nephrogenic type, upon administration of antidiuretic hormone, cyclic adenosine monophosphate level increases in the urine remarkably. There is also an early onset juvenile insulin-dependent form. This may be recessive or polygenic; a problem hard to resolve because of the high frequency of the gene and the low penetrance. In another syndrome diabetes mellitus, diabetes insipidus and deafness occur together under probably autosomal recessive control. Some of the nephrogenic diabetes insipidus cases are either autosomal dominant or recessive and both encoded at 12q13 or may be encoded at Xq28. The neurohypophyseal type has been assigned to 20p13. Other somewhat less well-characterized complex forms are also known. ►diabetes mellitus, ►kidney disease, ►vasopressin, ►Wolfram syndrome, ►cAMP, ►insulin, ►neurophysin, ►MODY, ►aquaporin; Willcutts MD et al 1999 Hum Mol Genet 8:1303; Pasel K et al 2000 J Clin Endocrin Metab 85:1703; Majzoub JA, Srivatsa A 2006 Pediatr Endocrinol Rev 4 Suppl. 1:60.

Diabetes Mellitus: A recessive hereditary disease most commonly under the control of more than a single gene causing hyperglycemia due to insulin deficiency and other factors, and by defects in glucose transport from the blood to cells. Diabetes of the mother may seriously affect the fetus. The prevalence of diabetes in most human population exceeds 3% and it is increasing in the USA. The recurrence risk among sibs varies depending on the type of genetic control or primarily non-genetic type of diabetes. The

penetrance and onset are variable and dietary and other environmental factors affect it. Even monozygotic twins have less than 100% concordance sibling risk in Type I, and is about 6% higher than among unrelated but in monozygotic twins the risk of concordance is 21–70% higher than in dizygotic twins (Redondo MJ et al 2001 Rec Progr Horm Res 56:69). Type I is associated with chromosome regions 12q24, 12q13, 12p13, 16p13, 18p11 and 4q27 (Todd JA et al 2007 Nature Genet 39:857). In Type II the heritability appears somewhat lower. Environmental factors affect the expression. There is strong association between the HLA class II genes and diabetes. When 392,935 single-nucleotide polymorphisms were tested in a French case–control cohort, markers with the most significant difference in genotype frequencies between cases of type 2 diabetes and controls were found and confirmed in another cohort. Four loci including a non-synonymous polymorphism in the zinc transporter *SLC30A8* (chromosome 8), which is expressed exclusively in insulin-producing β -cells, and two linkage disequilibrium blocks that contain genes potentially involved in β -cell development or function (*IDE-KIF11-HHEX* [chromosome 8] and *EXT2-ALX4*, [chromosome 11q]) were identified (Sladek R et al 2007 Nature [Lond] 445:881). A variant of the transcription factor 7-like 2 gene (*TCF7L2*) conferred the most significant risk to diabetes Type II in Icelandic and other populations. Also, a variant in the *CDKAL1* gene that was associated with Type II (Steinthorsdottir V et al 2007 Nature Genet 39:770). Three loci were found to be associated with Type II—one in a noncoding region near *CDKN2A* and *CDKN2B*, another in an intron of *IGF2BP2*, a third in an intron of *CDKAL1*—and replicated associations near *HHEX* and in *SLC30A8* found by whole-genome association. The same work confirmed association of a SNP in an intron of glucokinase regulatory protein (*GCKR*) with serum triglycerides (Saxena R et al 2007 Science 316:1331). Altogether now at least 10 loci seem to be associated with diabetes Type II in various large populations (Zeggini E et al 2007 Science 316:1336; Scott LJ et al 2007 Science 316:1341).

Treatment involves dietary restrictions and insulin administration in the insulin-dependent diabetes. In common usage, without qualification, diabetes means the mellitus form although several other types of the condition have been identified. Diabetes is characterized by excessive amounts of sugar in the blood, and excretion of large amounts of urine, which may or may not contain excessive amount of sugar. Diabetes can be medically characterized into insulin-dependent or immune-dependent (IDDM, type I) and insulin-independent (NIDDM, type II) forms. NOD

(non-obese diabetic) mouse is a model for Type I diabetes. In NOD mice the insulin/proinsulin epitope appears to be the primary target of the autoantigens rather than the Langerhans islets (Nakayama M et al 2005 Nature [Lond] 345:220; Kent SC et al 2005 Nature [Lond] 435:224). Disruption of the MAK kinase 9 gene (encoding JNK2 protein kinase) decreases insulinitis and slows down the progression of diabetes. JNK2 seems to control of helper T cell (Th1/Th2) balance and the immune response (Jaeschke A et al 2005 Proc Natl Acad Sci USA 102:6931). Allogeneic spleen cell injection with Freund's complete adjuvant or without spleen cell alleviated NOD by stimulating insulin-producing β cell regeneration (Chong AS et al 2006 Science 311:1774; Nishio J et al 2006 Science 311:1775).

Its treatment with donor splenocytes (monocytes of the spleen) restores endogenous insulin secretion and normal glycemia and the return of pancreatic β -cells (Kodama S et al 2003 Science 302:1222). Islet cell replacement is a possibility for treatment of diabetes Type I. There is limited availability of this tissue and a life-long immunosuppression is required to prevent rejection problems. Pancreatic and duodenal homeobox gene 1 (PDX-1) has a central role in regulating adult β cell function. Transient expression of PDX-1 transgene induced functional transdifferentiation in subpopulation of liver cells in mouse. In culture, 50% of the liver cells that expressed PDX-1 activate the otherwise inactive insulin promoter. The transdifferentiated liver cells functioned for prolonged period of time, released and processed insulin in a glucose-regulated manner and ameliorated hyperglycemia upon implantation. This procedure may thus permit cell replacement therapy by using the patient's own insulin-producing system without adverse immunological consequences (Sapir T et al 2005 Proc Natl Acad Sci USA 102:7964).

Recent evidence seems to point to the cause of Type II disease as the imbalance between insulin action and insulin secretion. The insulin receptor apparently acts on two proteins, the *insulin receptor substrates* (IRSs) and the Type II disease IRS-2 may function in an aberrant manner. The IRSs apparently recruit a number of other proteins that are also involved in the pathways of insulin control. In (NOD) mice, it appears that glutamic acid decarboxylase expressed in the β islet cells of the pancreas is required for the activation of T cells, responsible for the development of the autoimmune reaction of Type I diabetes (Greely SAW et al 2002 Nature Medicine 8:399). In IDDM the loss of glucose may cause hunger and great thirst and frequent urination. The glucose loss may involve then increased catabolism of proteins and fat. As a consequence weight loss may follow. When the mobilization of fats

increases and the oxidation of fatty acids becomes incomplete, ketone bodies and acetone may accumulate. The ketones appear in the urine and the acetone may be exhaled, giving the untreated patients a special odor. IDDM is treated with insulin and properly controlled diet. The NIDDM may be caused by a defect in the glucagon receptor in human chromosome 17q25, near-telomeric region. The patients generally are overweight. A susceptibility locus was assigned for Type II at 3q27-qter and 1q21-q24. Another Type II susceptibility locus was found at 5q34-q35.2 (Reynisdottir I et al 2003 Am J Hum Genet 73:323). Recently the NIDDM1 locus was assigned to chromosome 2 and NIDDM2 to chromosome 12. More substantial evidence is in favor of association three protease locations (calpain10, [2q37.3]) carboxypeptidase E/H [chr. 4] and prohormone convertase-1 [5q15-q21] with diabetes NIDDM1. Susceptibility to diabetes Type II has been found linked to chromosome 10q in the vicinity of transcription factor TC7L2 (transcription factor 7-like) assumed to control glucose homeostasis (Grant SFA et al 2006 Nature Genet 38:320).

The calpain linkage was detected in Mexican populations and confirmed in German and Finnish individuals but rarely in other European lineages. In NIDDM obesity is a frequent sign but besides the increased blood sugar content, other symptoms may vary, depending on the cause. The latter type patients do not respond to insulin. The obesity in NIDDM seems to be regulated by TNF- α . The IPF1/IDX1 (insulin promoter factor/islet-duodenum homeobox-1, 13q12.1) factor defect is frequently associated with diabetes Type II. Peroxisome proliferator-activated receptor gamma (PPAR γ), inwardly rectifying potassium ion channel KIR6.2, hepatocyte nuclear factor 4 α , mitochondrial genetic factors, Donohue syndrome, Rabson-Mendenhall syndrome all affect substantially diabetes expression (O'Rahilly S et al 2005 Science 307:370). KLF11/TIEG2, pancreas-enriched transcription factor, is a glucose-inducible regulator of insulin and binds to its promoter in the β cells. Its mutations may be of importance in the development of type II diabetes (Neve B et al 2005 Proc Natl Acad Sci USA 102:4807). Disrupted function of pancreatic acinar cells may lead to diabetes II (Raeder H et al 2006 Nature Genet 38:54).

Chemical chaperones 4-phenyl butyric acid and taurine-conjugated ursodeoxycholic acids normalized hyperglycemia, restored insulin-sensitivity, alleviated stress of the endoplasmic reticulum and appeared effective as a treatment for Type II diabetic mouse (Özcan U et al 2006 Science 313:1137).

The first clinical test for diabetes is the glucose-tolerance test. To fasted individuals about 100 g glucose is given in water orally. In healthy individuals

the blood sugar level returns to normal after 2–3 h but not in the diabetic ones.

Various animals are also afflicted with this condition. Several forms of the insulin-dependent diabetes are associated with HLA antigen DR3/4 or 3 or 4. Diabetic and glucose intolerance symptoms are associated with a large number of syndromes. A gene involved in the control of IDDM7 has been located in human chromosome 2q34. An early onset insulin gene, IDDM2 (human chromosome 11p15.5) seems to be associated with tandemly repetitive DNA sequences that regulate insulin transcription. The principal gene for early onset (IDDM1) appears to be in human chromosome 6p21.3 and 1p although 6 indicated reasonable linkage (lod scores ~3), yet lod scores of 1.0 to 1.8 with 6 other loci were found. Another 1998 study in England also indicated only weak linkage (lod scores) with chromosomes 1p21 (1.8), 4p15 (1.9), 8p24-p21 (1.5), 12p13-pter (1.8), 16p11-q12 (2.2), and 21q11 (2.5). IL-4/IL-13 pathway seems also a modulating factor. The glucokinase gene (GCK) was located to 7p15 is also involved in IDDM. The X-chromosomal (Xp13-p11) IDDM locus is in fragment DXS1068. It was well established in people carrying the HLA-3DR antigen. Generally the male:female ratio is close to 1 at high incidence of IDDM1 but it may be low in low-incidence countries of Asia and Africa. IDDM3 was located to chromosome 15q. IDDM4 appears to be in 11q13, IDDM5 in 6q25 and chromosome 18q harbors IDDM6, IDDM9 is in 3q21-q25, IDDM10 is near the centromere of chromosome 10. The literature reported IDDM locations at 15 different chromosomal regions but an 1998 analysis could verify linkage with highly significant lod scores (<3) only at 6p21.3 and 1p although 6q indicated reasonable linkage, and lod scores of 1.0 to 1.8 with 6 other loci were found.

This is basically a polygenic autoimmune disease brought about by the destruction of insulin-producing β cells in the Langerhans islets of the pancreas by the infiltration of T lymphocytes, B lymphocytes, macrophages and dendritic cells. The variable number of tandem repeats (VNTR) in the insulin genes may contribute to juvenile obesity. The chromosomal locus 6q16.3-q24.2 is associated with childhood obesity and diabetes Type II (Meyre D et al 2005 *Nature Genet* 37:863).

CTL may be activated also either by perforin-granzyme B release or FasL. TNF, lymphotoxin, IFN- γ may also damage the pancreatic β -cells. Protein CD44 and its hyaluronic acid ligand also have an adverse role in diabetes. T_H1 cells seem to play the primary role in the process whereas the T_H2 cells may not have either promoting or protecting effect. There are some indications that retroviral infection may contribute to the expression of diabetes.

The MODY type diabetes diseases, APECED, the human X-linked neonatal diabetes mellitus, enteropathy and endocrinopathy (IPEX/Scurfy; FOXP3; Wildin RS et al 2001 *Nature Genet* 27:18), the mitochondrial tRNA^{Leu-UUR} mutations may also be involved in Type II mellitus and deafness (van den Ouweland JM et al 1992 *Nature Genet* 1:368), familial lipodystrophy, Dunnigan syndrome, aceruloplasminemia, hemochromatosis, hyperproinsulinemia, hypoglycemia, Wolfram syndrome, Friedreich ataxia, are all apparently monogenic.

Diabetes may be responsible for blindness, kidney disease, heart attacks, strokes and for the amputational needs of the lower extremities. Low blood glucose and loss of vision in mice indicates glycemic control in diabetics and retinal diseases is related to metabolic stress as macular degeneration (Umino Y et al 2006 *Proc Natl Acad Sci USA* 103:19541). Genetically engineered non-pancreatic cells carrying the insulin gene under appropriate promoter may eventually cure diabetes. Such constructs would release insulin in a modulated manner like the normal pancreatic β cells and may evade immune destruction. Mitochondrial dysfunction accounts for 0.5 to 1% of the cases of diabetes mellitus caused by loss or defect in pancreatic β -cells and diminished secretion of insulin. ▶diabetes insipidus, ▶insulin, ▶HLA, ▶Hirschsprung disease, ▶autoimmune disease, ▶ion channels, ▶blood cells, ▶calpain, ▶VENTURE, ▶T cells, ▶cytotoxic T cells, ▶Th1/Th2, ▶insulinitis, ▶JNK, ▶glucagon, ▶glycemia, ▶superantigen, ▶polygenic inheritance, ▶Langerhans islet, ▶hemochromatosis, ▶MODY, ▶APECED, ▶lipodystrophy familial, ▶Dunnigan syndrome, ▶Wolfram syndrome, ▶Friedreich ataxia, ▶Wolcott-Rallison syndrome, ▶TNF, ▶IFN, ▶IL-4, ▶IL-13, ▶lymphotoxin, ▶insulin-receptor substrates, ▶PPAR, ▶obesity, ▶HNF, ▶lod score, ▶HLA, ▶CD30, ▶glutamate decarboxylase, ▶neurod, ▶perforin, ▶granzyme, ▶FasL, ▶VNTR, ▶calpains, ▶thiazolidinediones, ▶adiponectin, ▶CTLA-4, ▶histamine; Watanabe RM et al 2000 *Am J Hum Genet* 67:1186; Bach J-F, Chatenoud L 2001 *Annu Rev Immunol* 19:131; *Nature* [Lond] 2001, vol. 414: 782–827; Amer J Med Genet 115, issue 1 [2002]; Florez JC et al 2003 *Annu Rev Genomics Hum Genet* 4:257; diabetes type I: <http://T1Dbase.org>.

Diabetes Type, Type I and Type II: ▶diabetes mellitus

DIABLO (direct IAP-binding protein with low pI): ▶Smac, ▶IAP, ▶pI, ▶caspase, Adrain C et al 2001 *EMBO J* 20:6627.

Diabody: A dimeric association of shorter than normal, variable heavy and light chains of the antibody

(ScFv). Such dimers may be monospecific, i.e., they are formed from two variable A immunoglobulin chains or bispecific when A and B chains are joined by a linker. ▶[bispecific antibody](#), ▶[humanized antibody](#), ▶[triabody](#), ▶[recombinant antibody](#); Kortt AA et al 2001 *Biomol Eng* 18[3]95.

Diagenesis: The physical and chemical alterations that take place in the geological sediments after deposition of organisms.

Diacylglycerol (DAG): A lipid in the cell membrane that activates protein kinase C (PKC). DAG regulates growth and differentiation by its modulated level within the cell nucleus. The level of DAG in the nucleus is regulated by DAG-kinase- ζ (DGK- ζ). PKC phosphorylates DGK- ζ in the MARKCS (myristoylated alanine-rich C-kinase substrate) domain (see Fig. D36). ▶[protein kinase](#), ▶[CD36epiboly](#), ▶[phosphatidate](#)

Diagnosis: To determine the nature and cause of a disease. Computational diagnosis is based on comparative genomic hybridization by using biomarkers and bioinformatics. ▶[comparative genomic hybridization](#), ▶[biomarker](#), ▶[bioinformatics](#); bio-informatics in cancer diagnosis: Narayanan R 2007 *Methods Mol Biol* 360:13.

Diagnostic Test: A test carried out to reveal the presence or absence of a suspected anomaly in a fetus or during any time of the life of an individual.

Diakinesis: A nuclear division phase characteristic only for meiosis. It resembles very closely the diplotene stage but the condensation of the chromosomes is further increased. The chiasmata tend to move toward the termini of the chromatids (terminalization) and the paired chromosomes (bivalents) begin their separation from each other as approaching metaphase. ▶[meiosis](#)

Diallele Analysis: The diallele analysis is used in quantitative genetics and (plant) breeding to assess

the breeding value of genetic stocks by crossing them in all possible combinations. The data reveal both nuclear and extranuclear contributions. The great amount of work involved, however, limits the number of stocks that can be studied. From n lines $n(n-1)/2$ single crosses and $[n(n-1)(n-2)(n-3)]/8$ double crosses are possible. Thus from 10 lines, 45 single crosses and 630 double crosses are possible. Similarly, from 40 inbred lines, 780 single crosses and 274,170 different double crosses can be made. Therefore, some geneticists prefer heritability tests involving intraclass correlation. ▶[heritability](#), ▶[intraclass correlation](#), ▶[single cross](#), ▶[double cross](#); Hinkelmann K 1977, p. 719 in *Proc Int Conf Quant Genet*; Pollak E et al eds. Iowa State Univ. Press, Ames, IA.

Dialog Box: It requests further information from the user of the computer or gives some warnings accompanied by a beep sound.

Dialysis: The removal of small molecules through a semi-permeable membrane into water or into lower concentration solutes.

Diaminopimelate (DAP): A (polylysine) peptidoglycan component of the cell wall of many bacteria. *E. coli* strain EK2 (χ 1776), is blocked in its synthesis and prevents the organism to survive in the mammalian gut, was used as a host for genetic vectors for recombinant DNA to assure containment. ▶[biohazards](#), ▶[biological containment](#)

2,6-Diaminopurine: A mutagenic analogue of adenine (see Fig. D37).

Figure D37. Diaminopurine

Diamond Code: The code suggested in various arrangements to account for the arrangement of DNA and proteins (Gamow G 1954 *Nature [Lond]* 173:318). It was later abandoned, as experimental observations failed to support it.

Diamond-Blackfan Anemia (DBA): Human chromosome 19q13 erythroblastopenia (deficiency of red blood cells) caused by defects (breakage point) in the gene encoding ribosomal protein S19. Mostly neonates and infants are afflicted. The decrease of erythroid precursors is frequently associated with

upper limb, face and other malformations. Allografted bone marrow restores blood cell formation.
 ▶ [ribosomal proteins](#), ▶ [allograft](#)

Diandry: Fertilization of a single egg by two spermatozoa. ▶ [methylation of DNA](#)

D

Diapause: A relatively inactive period in the life cycle of an organism such as during pupation, hibernation, seed stage, etc.

Diapedesis: Exit of corpuscular elements (virus) through intact blood vessels. ▶ [extravasation](#)

Diaphorase: ▶ [NAD](#), ▶ [methemoglobin](#)

Diaphyseal Aclasis: ▶ [exostoses](#)

Diarrhea (diarrhoea): Diarrhea may have diverse origins. A rare autosomal dominant type responded to steroid hormone treatment. Autosomal recessive forms include a defect in chloride absorption and occurs at a frequency of about 7.6×10^{-5} . Another different recessive form was affected in the Na^+/H^+ exchange and a rare X-linked form was found to be very susceptible to infections and other complex problems, eczema, thyroid autoimmunity, diabetes, hyperimmunoglobulinemia D, etc.

Diastase: An enzyme complex that can hydrolyze starch into sugar.

Diastematomyelia: An autosomal recessive disease causing a split in the spinal cord by either fibrous or bony material and each half is wrapped. It is often associated with spina bifida, atrophy of the legs and other defects. ▶ [neuromuscular diseases](#), ▶ [spina bifida](#), ▶ [atrophy](#)

Diastereomer: Stereoisomers, which are not enantiomorphs, i.e., are not mirror images of each other, for e.g., galactose/glucose. ▶ [enantiomorphs](#), ▶ [galactose utilization](#)

Diastole: The rhythmic expansions of the heart cavities and filling it with blood. Diastolic dysfunction is common cause of heart failure. ▶ [systole](#), ▶ [hypertension](#)

Diastrophic Dysplasia (DD): An autosomal recessive (human chromosome 5q31-q33 or q34) anomaly with curved spine (scoliosis), clubbed foot, backward-bending abnormal thumb, abnormal earlobes, premature calcification of rib cartilage, short stature, respiratory and cardiac insufficiencies, etc. The basic defect is in a sulfate transporter. Various hereditary bone diseases share similar symptoms. ▶ [stature in](#)

[humans](#), ▶ [limb defects in humans](#), ▶ [dwarfism](#), ▶ [epiphyseal dysplasia](#), ▶ [atelosteogenesis](#), ▶ [scoliosis](#), ▶ [club-foot](#)

Diatoms: Unicellular photosynthetic algae. The genome ($n = 24$) of *Thalassiosira pseudonana* has (in bp) a nuclear genome of 34×10^7 (~11,242 protein-coding genes), plastid genome 12.9×10^4 (144 protein-coding genes), and its mtDNA is 44×10^3 (40 protein-coding genes), and are sequenced. (Armbrust EV et al 2004 Science 306:79; EST database: <http://avestha.gen.sznbowler.com>)

Diauxy (diauxie): ▶ [glucose effect](#)

Diazotized Paper: A modified filter paper (Whatman 540, Schleicher & Schuell 589 or equivalent) used for nucleic acid transfers and Western blots. The paper is first treated with nitrobenzyloxymethyl pyridinium (NBPC) that leads to the formation of NBM paper that is then reduced with sodium bisulfite ($\text{Na}_2\text{S}_2\text{O}_4$) to aminobenzyloxymethyl (ABM) paper and through a reaction with nitrous acid (HNO_2) the amino group is converted into the diazo group of the DBM (diazotized) paper. NBM and ABM papers are commercially available. The stability of these modified papers depends on the conditions of storage.
 ▶ [Western blot](#)

Dibasicaminoaciduria: An autosomal recessive defect involving accumulation of lysine, arginine and ornithine when protein-rich food is consumed without any increase in cystine. The anomaly may lead to liver and bone defects. ▶ [hyperlysinemia](#), ▶ [argininemia](#), ▶ [citrullinemia](#), ▶ [cystine-lysinemia](#), ▶ [amino acid metabolism](#)

dic (X): dicentric X chromosome. ▶ [dicentric chromosome](#)

Dicentric Bridge: A dicentric bridge is formed when a dicentric chromosome is stretched because at anaphase the two centromeres are pulled in opposite direction (see Fig. D38). ▶ [breakage-fusion-bridge cycles](#), ▶ [paracentric inversions](#), ▶ [dicentric chromosomes](#), ▶ [bridge](#) (for photomicrographs).

Figure D38. Dicentric bridge

Dicentric Chromosome: This has two centromeres. It is usually an unstable structure because at anaphase the two centromeres are pulled toward opposite poles and that generates a bridge that may be ruptured at any point, leading to unequal distribution of the genes of that chromosome (see Fig. D39).

The dicentric chromosomes usually do not transmit through meiosis by being trapped in between the two poles. In mammals, dicentric chromosomes with short interval (4–12 Mb) between the two centromeres may function as if they would be monocentric because one of the centromeres is inactivated. ▶breakage-fusion-bridge, ▶inversion paracentric, ▶Robertsonian translocation, ▶Turner syndrome; Thrower DA, Bloom K 2001 Mol Biol Cell 12:2800.

Figure D39. Dicentric chromosomes. Dicentric chromatids result from four-strand double-crossingover within a paracentric inversion

D

Dicentric Ring Chromosomes: These are formed when there is a sister-chromatid exchange in a ring chromosome(see Fig. D40). At mitotic anaphase the sister-centromeres are pulled toward the opposite poles causing the chromatids to break at potential

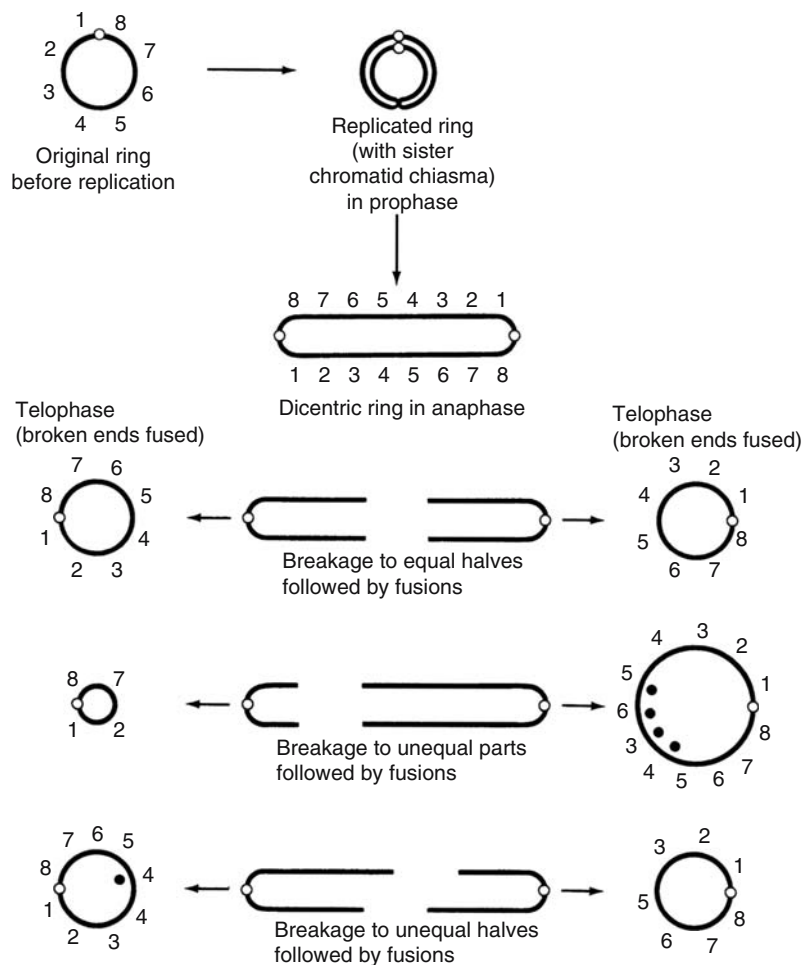

Figure D40. Dicentric ring chromosomes may be a source of genetic instability. If sister chromatid exchange takes place in the following anaphase, double chromatid bridge is formed that may break equally, and in this case the distribution of the genes to the poles is normal. (Numbers represent the genes). The chromatids may break also unequally resulting in unequal distribution of the chromatin (genes) that may be detected if appropriate markers are present. The broken ends usually heal and new dicentric ring chromosomes of different sizes are formed. (After B. McClintock 1941 Genetics 26:542; see also photo below)

points of stress and thus leading to unequal distribution of the genes (duplications and deficiencies in the cells). The broken ends may fuse and the process may continue and the resulting somatic instability is revealed by sectors if appropriate genetic markers are present. ►ring bivalent, ►ring chromosomes, ►translocation chromosomal; see Fig. D41.

D

Figure D41. Sectorial maize leaf homozygous for a deficiency and carries a ring chromosome

Dicer (DCR, DCL): RNase type III ribonucleases with somewhat different specificities in different organisms, and preferentially processing single-stranded (DICER-1) (see Fig. D42) or double-stranded RNA (Dicer-2/R2D2). Dicer is important for animal development and in its absence multipotent stem cells cannot be formed and embryonic death occurs. Three domains of the acquired human immunodeficiency (AIDS) virus trans-activating response RNA-binding protein (TAR) are integral parts of the DICER complex (Chendrimada TP et al 2005 Nature [Lond] 436:740). *Arabidopsis* plants normally contain four Dicer enzymes; DCL1 produces microRNA, DCL2 is responsible for some virus-derived siRNA, DCL3 produces RNA-dependent RNA polymerase and DCL4 is the primary processor of endogenous RDR6-dependent trans-acting siRNA (Gascioli V et al 2005 Current Biol 15:1494). DICER interacts with more than a dozen proteins, which determine its specificity in various RNAi and microRNA pathways (Duchaine TF et al 2006 Cell 124:343). ►RNAi, ►microRNA, ►PAZ domain, ►tasiRNA, ►AIDS, ►Drosha, ►RNase III; Lee YS et al 2004 Cell 117:69; *Giardia*; crystal structure of *Giardia intestinalis* Dicer: MacRae IJ et al 2006 Science 311:195.

Dichlorodiphenyltrichloroethane (DDT): An insecticide, now almost entirely avoided in the industrialized countries of the Northern Hemisphere because it

weakened the eggshells of birds preying on insects and due to its accumulation in mammalian fat tissues, etc. (see Fig. D43).

Figure D43. DDT

Some insects developed resistance to it by eliminating HCl from the molecule with the aid of increased levels of DDT dechlorinase enzyme. It is toxic to humans: oral LDLo 6 mg/kg. Although it was suspected to be carcinogenic, the final tests did not confirm this. Recently, it was discovered that main metabolite of DDT, p,p'-DDE is potent anti-androgen by binding to the androgen receptor. It is not in use for over 20 years, it still persists in the environment (its half-life being ~100 years). It is blamed for reduced human sperm counts, increased testicular cancer, and other anomalies of the reproductive system. DDT, thus, became an anathema although it is the most effective weapon against mosquitos, responsible for malaria. In December 2000, the World Health Organization (WHO) allowed the temporary use of DDT in 25 countries with very high incidence of malaria (Kapp C 2000 Lancet 356:2076), and the endorsement of its use is still maintained by WHO in 2006. ►LDLo, ►sperm, ►malaria

2,4-Dichlorophenoxyacetic acid (2,4-D): A synthetic plant growth hormone. ►auxins; for formula see ►2, 4-D

Dichotomous Trait: A qualitative trait, however, its determination may be only partly genetic, and environmental factors have substantial role in its etiology. ►quantitative trait

Dichroic Mirror: It transmits light in one color and when reflected, passes it in another color. ►circular dichroism

Dicistronic Translation: Transcripts carrying internal ribosomal entry sites (IRES) and may be co-translated (expressed) in appropriate gene fusion vectors in the same sequence. ►IRES, ►ribosome scanning, ►picornaviruses

Dicot (dicotyledonous): A taxonomic category of plants with embryos having two cotyledons.

Figure D42. Organization of a human Dicer. (DUF: domain of unknown function; PAZ: PAZ domain; dsRBD: double-strand RNA binding domain)

Dictionary of Biomedical Terms ⇔ **Acronyms:** <http://www.ncbi.nlm.nih.gov/cancerinfo/terminologyresources/>;
<http://www.nlm.nih.gov/medlineplus/plusdictionary.html>.

Dictyosomes: Golgi apparatus.

***Dictyostelium discoideum*:** A haploid ($x = 6$), unicellular amoeba with a genome size of ~33,887,060 bp. They contain also diverse sets of high copy number nuclear plasmids. Its sequenced mitochondrial genome is 54 kb. Diploid cells have also been observed. The cells form colonies that upon starvation differentiate into structures reminding of multicellular organisms. Actually, they form two types of cells, spores and stalk cells. At a stage when they are about 70% pre-spore and 30% pre-stalk they form aggregates that are called slugs, appearing somewhat similar to gastropod animals (Fig. D45). They make during the growth phase about 3,000 to 5,000 different mRNAs and during differentiation between 800 and 2,000, i.e., within the same order as lower animals (see Fig. D44). During the growth phase *Pre-Starvation Protein Factor* (PSF) accumulates and when its level reaches the critical point it serves as a signal for development by activating adenylate cyclase, cAMP receptor and a Gα protein required for signal transduction although development may take place in the absence of camp.

Figure D44. Venn diagram of the distribution of PFAM domain proteins among the major eukaryotic groups. The big numbers indicate presence and the small gray numbers indicate absence in *Dictyostelium*

The steroid *Differentiation Inducing Factor* (DIF) is made by the end of aggregation. The interaction of these two factors leads to culmination and formation of the fruiting body. All the functions required for growth and development involve the regulated expression of about ~12,500 proteins transcribed

and translated from 6 linkage groups of genes. The mean gene length is 1,756 bp and 69% has introns. At the end of each chromosome there is a ribosomal RNA repeat supposedly representing telomeres. The centromere-like structure is represented by clustered repeats. It appears that *Dictyostelium* retained more of the ancestral genome preceding the differentiation of the major eukaryotic forms Eichinger L et al 2005 (Nature [Lond] 435:43). ▶ cAMP, ▶ adenylate cyclase, ▶ signal transduction, ▶ Gα protein, ▶ DIRS, ▶ PFAM, ▶ Venn diagram; Wilkins A, Insall RH 2001 Trends Genet 17:41, <http://www.tigr.org/tdb/tgi>; <http://dictybase.org/>.

Dictyotene Stage: A late prophase stage of meiosis in human females. Meiosis in the oocyte begins by about the fourth month of the fetus but it is completed only before each ovulation (see Fig. D46). Meiotic

Figure D46. Late meiotic prophase

arrest is mediated by cAMP. With the surge of luteinizing hormone before ovulation meiosis is resumed. Thus, some cells remain in dictyotene for 30–40 years (until the end of ovulation). It has been hypothesized that this prolonged meiotic stage may be responsible for some of the chromosomal anomalies observed as a function of increasing age. In the human males, cell divisions in the germline continue to advanced age and point mutations increase in proportion to the advance of age. ▶ meiosis, ▶ Down's syndrome, ▶ atresia, ▶ chromosome replication, ▶ oogenesis

Dicytoplasmic System: The plastids are uniparentally transmitted (e.g., conifers) by the male whereas the

Figure D45. *Dictyostelium discoideum* life cycle

mitochondria are uniparentally inherited through the female.

Dideoxy Fingerprinting: A variation of the single-stranded conformation polymorphism (SSCP) technique that detects single-base or other subtle alterations in the DNA. One lane of the Sanger dideoxy termination reaction is electrophoresed in a non-denaturing gel. Mutations may show up as the presence of an extra segment or the absence of one or by altered mobility. ▶ [single-strand conformation polymorphism](#), ▶ [DNA sequencing](#) (Sanger).

Dideoxy Nucleotides: ▶ [DNA sequencing](#)

Dideoxyribonucleotide: It lacks an O atom at both the 2' and 3' position of the ribose (see structural formulas below) (see Fig. D47) and because of the latter feature; it is incapable of supporting DNA chain elongation that is required for the DNA polymerase to add nucleotides to the chain. Therefore, these molecules can be used for selective chain-terminators in the Sanger method of DNA sequencing. ▶ [DNA sequencing](#), ▶ [formula d](#)

Figure D47. 2',3'-Dideoxycytidine

Diego Blood Group System: It is polymorphic in Mongolian, Chinese and American Indian populations. ▶ [blood groups](#)

Dielectrophoresis: Induced motion of polarizable particles in non-uniform fields, a method for the separation of bioparticles such as cells, viruses and proteins. Dielectrophoresis in a microfluidic device greatly increases the efficiency of marker-specific selection of cells (Hu X et al 2005 Proc Natl Acad Sci USA 102:15757). ▶ [electrophoresis](#), ▶ [cell sorter](#), ▶ [microfluidics](#); Hughes MP 2002 Electrophoresis 23:2569.

Dielectric: The transmission of electric signal by induction and not by conduction. It may shield electrostatic fields and dissipates minimal energy in a medium.

Diencephalon: The part of the brain that includes thalamus, hypothalamus, epithalamus and subthalamus. ▶ [brain](#)

Diepoxybutane: ▶ [DEB](#)

Diethylnitrosamine: ▶ [DEN](#)

Diethylstilbestrol: A non-sterol, yet sterol-like action chemical. It had been used for geese to increase the size of the liver (see Fig. D48). Until 1971, it was a prescription drug to prevent miscarriage in women. In utero exposed female offspring had a high incidence of malformations in their reproductive organs and adenocarcinoma. Estrogen favored carcinogenicity. ▶ [estrogen](#); Newbold RR et al 1990 Cancer Res 50:7677.

Figure D48. Diethylstilbestrol

DIF (differentiation-inducing factor): A TNF involved in mitogen-promoted blood cell differentiation. ▶ [TNF](#); Kanno T et al 2001 Dev Growth Differ 43:709.

Differrante Syndrome: ▶ [mucopolysaccharidosis](#)

Differential Centrifugation: The partition of particles (cellular organelles) by their different rates of sedimentation in aqueous or organic liquid medium (sucrose, percoll, etc.) during centrifugation. ▶ [centrifuge](#)

Differential Display (DD): Reveals the profile of protein(s) or RNA differently expressed, e.g., in healthy versus diseased states. ▶ [RNA fingerprinting](#); Liang P, Pardee AB 1992 Science 257:967; Pei L, Melmed S 1997 Mol Endocrinol 11:433.

Differential Hybridization Mapping: The tissue-specific expression of genes can be determined by hybridization to DNA, the transcript prepared during different stages of the differentiation or development. ▶ [tissue-specificity](#); Shoemaker DD et al 2001 Nature [Lond] 409:922.

Differential Psychology: The study of behavior differences among individuals and groups that seeks out genetic differences in behavior rather than average characteristics, the object of "experimental psychology". ▶ [IQ](#)

Differential Segment: The region of the X and Y chromosomes that lacks homology and those

chromosomal areas, in general, fail to pair. Also, a particular borrowed chromosomal segment in a congeneric strain. ▶sex linkage, ▶holandric genes, ▶congenic

Differentiation: The morphological and/or functional specialization of originally totipotent cells to meet particular needs of the organisms. Differentiation is determined by morphogen gradients, asymmetric distribution, cell position, etc. The pattern of differentiation is regulated in anterior/posterior, dorsal/ventral and by left/right gradients of the morphogens under genetic control. ▶determination, ▶development, ▶segregation asymmetric, ▶polarity embryonic, ▶morphogenesis, ▶selector genes, ▶morphogenesis in *Drosophila*, ▶mRNA targeting, ▶compartmentalization, ▶primitive streak, ▶inter-cellular immunization, ▶intracellular immunization

Differentiation of Plastid Nucleoids: The SN (scattered nucleoids) in the small plastids are distributed between the thylakoids and grana (land plants and many algae). The CN (central nucleoids) are located at the center of the plastids (red alga, undifferentiated proplastids of higher plants). CL (circular lamellar) types occur as ring-shaped structures within the girdle lamella (brown algae). The PS (peripherally scattered) type lie near the inner plastid envelope and the SP type spreads around the pyrenoid. The proplastids may be of 0.2 µm diameter with 1–2 cpDNA genomes or 2–3 µm in diameter with several cpDNA genomes. The smaller (proplastid precursors) may divide into structures like themselves or form the larger proplastids and change into colorless etioplasts in darkness and the latter upon illumination differentiate into green chloroplasts. In the *Chlamydomonas* alga the 5–6 nucleoids each may have 13–16 cpDNA, while in *Euglena* the number of nucleoids may be 20–34 with 3–15 DNA rings each; in the chloroplasts of higher plants the 12 to 25 nucleoids each may contain 2–5 cpDNAs. ▶chloroplasts, ▶DNA replication in plastids, ▶DNA replication in mitochondria

Diffraction: ▶X-ray diffraction analysis

Diffuse Large B-Cell Lymphoma (DLBCL): A highly morbid disease with less than 50% chance for cure. Microarrays of 6,817 genes in diagnostic tumors treated with cyclophosphamide, adriamycin, vincristine and prednisone (a type of cortisone) classified by supervised learning revealed two potential survival categories (70% and 12%). Thus, there is a predictable target for successful therapy. separate entries; Shipp MA et al. 2002 Nature Med 8:68.

Diffusion: The movement of molecules from a higher to a lower concentration in a solution. Diffusion of proteins within a cell from its origin along an axis can

be determined as $S = (4Dt/\pi)^{1/2}$ where D is the diffusion coefficient and t = time. Examples: D of 10 µm²/S diffuses on average 4 µm in a 1 S period. A membrane-bound protein diffuses <0.8 µm and transmembrane protein <0.25 µm. Cell signals are transduced either by protein—protein binding interactions or by second messenger-mediated interactions between signaling τ = the lifetime of the activated state. If τ = the time by 63% of the proteins to be inactivated then the 2-dimensional $r = (2D\tau)^{1/2}$ and for the 3-dimensional diffusion $r = (3D\tau)^{1/2}$. ▶signal transduction, ▶demic diffusion, ▶diffusion genetic; Teruel MN, Meyer T 2000 Cell 103:181.

Diffusion, Genetic: The distribution in a wave like manner of gene(s) in the function of a variable such as geographic region, infestation by a parasite, etc. The rate of advance per generation under steady state condition is $v = \sigma\sqrt{2s}$ where σ = standard deviation and s = selection coefficient. The length of the wave advance is: $\sigma([1/2]s)^{1/2}$. The rate of advance is obtained by $\sigma(2s)^{1/2}$ and if we arbitrarily substitute $\sigma = 20$ and $s = 0.01$ the km, the spread per generation would be $20(2 \times 0.01)^{1/2} \approx 2.83$ km. ▶cline, ▶legit

DiGE: Difference gel electrophoresis for detecting changes in protein extracts in a single gel using fluorescent tagging. Two-dimensional DiGE using fluorescent protein labels permits classifications of cancer cell signatures and trace metastatic tumors to origin (Seike M et al 2004 Proteomics 4:2776; Unlu M et al 1997 Electrophoresis 18:2071).

Digenic Diseases: The presence of two mutations is required for the full expression of the disease phenotype and one of the independent events alone has no or slight deleterious effect. In retinitis pigmentosa, controlled by 26 genes, heterozygosity, at least two loci results in disease. In the Bardet–Biedl syndrome (6 loci) the disease may be based on triallelic condition, i.e., one of the loci is heterozygous and another is homozygous for the mutation. Deafness controlled by DFNA12 or the connexin 26 encoding locus are also in this category of diseases. Hirschsprung disease (6 genes) is manifested when the RET gene mutation is coupled with mutation in one or the other RET ligands (glial cell-derived neurotrophic factor or neurturin). Similar digenic requirement exists in diabetes. Some of the glaucoma families segregate for two different genes. The Usher syndrome gene USH1B seems to reinforce the expression of USH3. Epidermolysis bullosa may display mutation in both COL17A1 and the β3-polypeptide subunit of laminin 5. Polycystic kidney disease genes PKD1 and PKD2 each may evoke the disease alone but in families segregating for both the symptoms appear more severe. Waardenburg

Syndrome may involve mutation in the MITF (responsible for hearing deficit) and the tyrosinase locus (responsible for defect in pigmentation). The complex holoprosencephaly is close to a polygenic disease that is based on mutations at different loci. the diseases named; Ming JE, Muenke M 2002 Am J Hum Genet 71:1017).

D

DiGeorge Syndrome: An autosomal dominant (human chromosome 22q11.2) defect of thymus and parathyroid formation and a variety of other anomalies (malformed ears, broad nasal bridge, far apart eyes, abnormal U-shaped mouth, small jaws, heart disease, etc.), including immunodeficiency. Apparently autosomal recessive form has also been observed. This anomaly is frequently associated with deletions (1.5 to 3 megabase long) in chromosome 22 and some of the defects in this rather heterogeneous syndrome are due to a deletion in chromosome 10p13. This latter deletion accounts also for hypoparathyroidism associated with the velocardiofacial syndrome (VCFS), sensorineural deafness and renal anomaly (HDR). The 200-kb region involved in HDR contains the GATA3 Zinc-finger transcription factor controlling vertebrate development. In some instances, transplantation of fetal thymus alleviated some of the symptoms. The 22q11 locus has been cloned and includes several components, including WD40 repeats similar to the yeast transcriptional co-repressors Hir1p and Hir2p most likely associated with chromosome remodeling by controlling histone transcription. Their mammalian homolog, HIRA interacts with the Pax3 transcription factor. The DiGeorge syndrome may be a defect in the CDC45 ligand. T box haplo-insufficiency may also elicit parts of the syndrome. The so-called critical region 8 (DGCR8) encompassing about 35 kb upstream of exon 1 mediates microRNA biosynthesis in both humans and *Drosophila* (Landthaler M et al 2004 Current Biol 14:2162). Tumor growth factor β (TGF- β) signal inactivation (controlling the 22q11.2 gene) resulted in DiGeorge symptoms (Wurdak H et al 2005 Genes Dev 19:530). ▶immunodeficiency, ▶deletions, ▶velocardiofacial syndrome, ▶cat eye syndrome, ▶face/heart defects, ▶CATCH, ▶Pax, ▶chromatin remodeling, ▶CDC45, ▶GATA, ▶haplo-insufficient, ▶T box; Jerome LA Papaioannou VE 2001 Nature Genet 27:286; Guris DL et al *ibid.* p. 293, Baldini A 2002 Hum Mol Genet 11:2363.

Digestion: Enzymatic hydrolysis of molecules in vitro or in the digestive tract in vivo.

Digital Karyotyping: Quantitative estimation of DNA copy numbers by isolation and counting short DNA sequence tags of genomic loci. ▶karyotype

Digital Organism: Simulation of self-replication, genome expression, interaction and environmental responses by computer programs in virtual reality. (Lenski RE et al 1999 Nature [Lond] 400:618)

Digitoxin: A cardiotonic alkaloid (glycosid) present in the ornamental-medicinal plants (see Fig. D49), *Digitalis*. ▶ATP-ase

Figure D49. Digitoxin

Diglyceride: ▶diacylglycerol

Digoxigenins: Aglycones of the steroid nucleus digoxin; they are used in non-radioactive forms to label amino acids, DNA and glycoconjugates (see Fig. D50). ▶non-isotopic labeling; Broketa M et al 2001 J Clin Virol 23:17.

Figure D50. Digoxigenin

Digynic: It has two sets of maternal chromosomes in a normally diploid cell or triploid cell. ▶methylation of DNA

Dihaploid: An individual having half the somatic chromosome number of that of a tetraploid from where it descended. Dihaploid plants are obtained generally by crossing tetraploids by diploids and among the offspring, diploids selected carry some advantageous genes of the tetraploid that were not present in the parental diploid. ▶haploid, ▶autotetraploid

Dihybrid: Heterozygous for two pairs of alleles, e.g., *A/a* and *B/b*. ► [Mendelian segregation](#), ► [modified Mendelian ratios](#), ► [checkerboard](#)

Dihydrofolate Reductase (DHFR): The enzyme synthesizes tetrahydrofolate, an essential precursor in the biosynthesis of thymine, purines and glycine. ► [methotrexate](#), ► [amethopterin](#), ► [DHFR](#); Boehr DD et al 2006 Science 313:1638.

Dihydropyridine Receptor (DHPR): A voltage sensor in the L-type Ca^{2+} ion channels and ryanodine enhances the DHPR function. ► [ion channels](#), ► [ryanodine](#)

Dihydropyrimidine Dehydrogenase (DPYD, 1p22): DPYD mediates the catabolism of uracil and thymine. Its recessive deficiency leads to excessive amounts of pyrimidines in the urine. DPYD may catalyze the degradation of the anticancer drug 5-fluorouracil. DPYD deficiency may result in severe complex reaction to 5-fluorouracil. ► [5-fluorouracil](#)

Dihydrouracil: It may be formed by oxidizing effects and ionizing radiation of nucleic acids (see Fig. [D51](#)).

Figure D51. Dihydrouracil

Dihydrouridine (5,6-dihydro-2,4-dihydroxyuracil nucleoside): a post-transcriptionally modified uridine in the tR(5,6-dihydro-2,4-dihydroxyuracil nucleoside): NA. ► [tRNA](#); Bishop AC et al 2002 J Biol Chem 277:25090.

Dihydroxybenzil: synthetic non-steroid ligand of estrogen receptor (see Fig. [D52](#)). (Chockalingham K et al 2005 Proc Natl Acad Sci USA 102:5691)

Figure D52. 4,4'-Dihydroxybenzil

3,4-Dihydroxyphenylalanine: ► [DOPA](#)

Dihydrozeatin: A natural cytokinin. ► [cytokinins](#)

Di-Isosomic: in wheat, $20''+i''$, $2n = 42$, [$''$ = bivalent, i = isosomic].

Di-Isotrisomic: in wheat $20''+(i'')1'''$, $2n = 43$, [i = isochromosome, $''$ = disomic, $1'''$ = trisomic]

Dikaryon: A single cell has two nuclei; the nuclei may be genetically identical (homokaryon) or genetically different (heterokaryon). These regularly occur in fungi after fusion of somatic cells and in other eukaryotes if the nuclei do not fuse. ► [fungal life cycles](#)

Dikaryote: Cells with two unfused nuclei. ► [dikaryon](#)

Dimer: The association of two units (e.g., two polypeptides). Dimerization may regulate the function of certain enzymes. (Mellado M et al 2001 Cell Mol Biol 47:575; Lodmell JS et al 2001 J Mol Biol 311:475; Gomes I et al 2001 J Mol Med 79:226)

Dimer 14-3-3: A protein factor that assists dimerization of Raf, an oncogene and a key player in the mitogen signal transduction pathways. ► [raf](#), ► [signal transduction](#), ► [protein 14-3-3](#)

Dimerizer: The system is based on a 'structural' complementation by revealing the function of a gene product, either from the RNA or the protein that it encodes in connection to a particular or a class of molecules (see Fig. [D53](#)). One moiety is a high-affinity ligand for another protein connectable by a chimeric "dimerizer" that facilitates the functional association with an enzyme. The protein components can be, e.g., dihydrofolate reductase that is connected via methotrexate- β -lactam cephalosporin and dexamethasone by a peptide bond (Mtx-cephem-Dex). The dihydrofolate reductase is fused also to the LexA DNA binding domain and to the B42 protein-glucocorticoid receptor activation domain. When the Mtx-cephem-Dex dimerizer assists to establish a non-covalent linkage, the RNA polymerase transcribes and facilitates the expression of the β -galactosidase reporter. In case lactamase is active, the expression of the galactosidase is abolished because dimerization link disintegrates. This is thus a method of chemical complementation independent from the reaction and it is similar to the three-hybrid test. ► [cephalosporin](#), ► [dexamethasone](#), ► [lactamase](#), ► [galactosidase](#), ► [three-hybrid system](#)

Dimethylglycine Dehydrogenase (DMGDH): An enzyme of the mitochondrial matrix involved in the biosynthesis of choline. It causes fish-like body odor, chronic muscle fatigue. The levels of the muscle form of creatine kinase and DMGDH in the serum are elevated. (Binzak BA et al 2001 Am J Hum Genet 68:839)

Dimethylsulfate: ► [DMS](#)

Dimethylsulfoxide (DMSO): A very effective solvent of a wide range of organic chemicals with moderate toxicity. It also protects cells against low temperatures. DMSO may facilitate cellular DNA uptake and

Figure D53. Dimerizer

thus transformation of eukaryotic and prokaryotic cells.

Di-Mon Cross: It involves dikaryotic and monokaryotic fungi. ► [Buller phenomenon](#)

Dimorphic: Dimorphic displays two forms whether the two are chromosomes, cells or organisms.

Dimorphic Fungi: Potential human pathogens, which in the environment (soil, 25°C) display filamentous morphology but upon ingestion by humans (37°C) they switch to yeast-like shape as they become pathogenic (see Fig. D54). The morphological transition is mediated by a hybrid histidine kinase, which also regulates cell wall integrity, sporulation and the expression of virulence genes (Nemecek JC et al 2006 Science 312:583).

Figure D54. Dimorphic fungi

Δi-mRNA: Fully spliced nuclear mRNA. ► [splicing](#)

2,4-Dinitrophenol: An indicator of pH, wood preservative, and insecticide. It is highly toxic to animals by being an uncoupler of electron transport and oxidative phosphorylation. It blocks ATP formation by respiration. Uncoupling oxidative phosphorylation generates heat in hibernating animals, in those adapted to cold or in newborns.

Dinoflagellates: Members of the marine plankton and may appear as red tide, and by their vast number deplete the oxygen in their habitat and cause the death of sympatric animals. In addition, they may secrete a

neurotoxin which may be ingested by shellfish and may poison other creatures consuming shellfish. Their yellow, brown or red color is due to the pigments of their primitive chloroplasts. These chloroplasts contain a very small number of genes and curiously each of them (~9) appear to be in a separate circular DNA plasmid. The majority of the normally plastid genes are within their nucleus. Some *Pfiesteria* strains are toxic to fish and mammals (Burkholder JM et al 2005 Proc Natl Acad Sci USA 102:3471). ► [chloroplasts](#); Saldarriaga JF et al 2001 J Mol Evol 53:204.

Dinucleotide Abundance: ► [dinucleotide odds ratio](#)

Dinucleotide Odds Ratio: The frequency with which CpG or TpA sequences occur. Statistical survey of sequenced DNAs in different species indicates that the dinucleotide abundance within a species for different classes of DNAs (coding, intron, intergenic) tend to be similar but different in unrelated ones. (Gentles AJ, Karlin S 2001 Genome Res 11:540)

Dinucleotide Repeats: Such GpT/ApC and ApG/CpT may cause genetic instabilities by slipped-strand mispairing and generating deletions or additions. ► [trinucleotide repeats](#); Stalling RL et al 1991 Genomics 10:807; Renwick A et al 2001 Genetics 159:737.

Diode: A simple vacuum tube with an electron-emitting cathode and an electron accepting plate. The cathode emits electrons when it heated by an enclosed filament. Various laboratory equipments contain diodes.

Dieocious: The two sexes are represented by separate individuals like the majority of animals, fungi, and also some plants (<4%) such as spinach, *Asparagus*, date palm, poplar, osage orange, etc. ► [breeding system](#)

Dioxin: A family of carcinogens and (frameshift) mutagens. It may occur as a contaminant in various industrial chemicals and among the products of

burned peat. LD₅₀ orally for mice is 114 µg/kg. There are large differences among animals in the sensitivity to dioxin. If the aromatic hydrocarbon-binding receptor (AHR) has lower binding affinity, there may be 250 fold differences in sensitivity (e.g., between tern [*Sterna hirundo*] bird and chicken [*Gallus gallus*]). Two amino acids (Val-325 and Ala-381) in the ligand-binding domain of AHR of the tern are responsible for reduced activity (see Fig. D55) (Karchner SI et al 2006 Proc Natl Acad Sci USA 103:6252). Dioxin may have anti-estrogenic effects it can as well induce endometriosis and estrogen-dependent tumors. ▶environmental mutagens, ▶estradiol, ▶endometriosis, ▶LD⁵⁰; Ohtaki F et al 2003 Nature [Lond] 423:545; Harper JW 2007 Nature [Lond] 446:499.

Figure D55. 2,3,7,8-Tetrachlorodibenzo *p*-dioxin

DIP: (Database of Interacting Proteins): <http://dip.doe-mbi.ucla.edu>.

Diphosphoglycerate Mutase Deficiency (7q31-q34): The enzyme controls oxygen affinity in red blood cells by binding to deoxyhemoglobin. Its deficiency leads to a type of hemolytic anemia. ▶anemia

Diphtheria Toxin: A single-chain (535 residue) very potent toxin produced by *Corynebacterium diphtheria* carrying a lysogenic phage. It has applied significance in cancer research because it blocks eukaryotic peptide chain elongation (eEF-2). Rat and mouse are resistant to this toxin because they lack its membrane surface receptor. Humans, guinea pigs and rabbits are, however, sensitive to it. The human sensitivity is encoded in chromosome 5q23. The virulence of the bacterium is a response to the expression of the toxin gene (*tox*) regulated by the toxin repressor (DtxR) activated by transition metal ions. The metal ion (iron, Ni^{II}) triggers the two different DtxR subunits to embrace—at opposite sides—33-bp of the DNA of the *tox* operator. Transformation by the diphtheria toxin gene has been employed for ablation of cells and to inhibit protein synthesis in targeted cells. ▶toxins, ▶biological weapons; Saito M et al 2001 Nature Biotechnol 19:746.

Diploblasts: Animals with only ecto- and endodermic germ layers. ▶ectoderm, ▶endoderm, ▶triploblast

Diplochromosome: It displays 4, (rather than 2) chromatids in each arm because of replication

without splitting of the centromere (see Fig. D56). ▶endoreduplication, ▶salivary gland chromosomes

Figure D56. Diplochromosomes

Diplococcus pneumoniae (old name *Pneumococcus*): A member of the genus in the tribe *Streptococceae* and the family *Lactobacillaceae*. This is the most common cause of pneumonia. The lanceolate cells occur in doublets. The virulent forms are encapsulated and form shiny (smooth) colonies; the avirulent forms lack the protective coat (and form rough colonies) and are destroyed by the enzymes of the host cells. Genetic transformation was discovered with this bacterium in 1928. ▶transformation

Diploid: A diploid has two complete basic sets of chromosomes, characteristic for the zygotes and for most of the body cells of the majority of animals and plants, and for the premeiotic phase of several other eukaryotes (fungi, algae, etc.). Some diploids may have only a single sex chromosome in the somatic cells as a normal condition.

Diplonema: The structure of the chromosome thread at the diplotene stage of meiosis (see Fig. D57). ▶meiosis, ▶diplotene, diplotene chromosome picture by courtesy of B John.

Figure D57. Diplonema

Diplont: A diploid individual (cell).

Diplontic Selection: Competition among diploid cells within multicellular organisms. This can take place only when dominant mutation or other dominant-acting change(s) occur.

Diplophase: The diploid phase of an organism that exists also as a haploid.

Diplospory (apogamety): A non-reduced embryosac develops without meiosis or by restitution. ▶restitution nucleus

Diplotene Stage: The diplotene stage of meiosis is preceded by pachytene when the chromosomes begin to appear as clearly bipartite, doubled threads (diplonema) through the light microscope. The

pairing (synapsis) of the bivalents appears somewhat relaxed but the four chromatids are held together by the chi-shaped (χ) structures of the overlapping chromatids, the chiasmata. The synaptonemal complex is generally the most conspicuous (by electron microscopy) when chiasmata are visible. ▶meiosis, ▶chromatid, ▶chiasma, ▶synaptonemal complex

D

Diplo type: The combination of two haplotypes; it is frequently identical with genotype. The genotype may not reveal, however, the allelic configuration in each of the two strands or the two haplotypes. ▶haplotype; Kitamura Y et al 2002 Ann Hum Genet 66:183.

Dipole: Molecules that have two equal and opposite charges separated in space. A simple dipole molecule is H_2O . ▶protein dipole server: <http://biportal.weizmann.ac.il/dipol/>.

Diquat: It can serve as electron acceptor in photosystem I of photosynthesis. It is also a light-dependent herbicide. ▶photosynthesis, ▶herbicides

Direct DNA Transfer: The incorporation of DNA into plant protoplasts without bacteria using only plasmids or perhaps other “naked” DNA. ▶transformation, ▶naked DNA

Direct Repeats: Adjacent or non-adjacent repeats of identical or similar nucleotide sequences of the same order such as ATG...ATG. These are common at the termini of insertion elements. ▶insertion elements, ▶transposons, ▶transposable elements

Direct Suppressors: They modify the final product of the gene so the mutation is not (fully) expressed. ▶suppressor mutations

Directed Expression: The *GAL4* activator element of yeast can be inserted into any genome at random locations by transformation. The promoter of the target gene drives the expression of *GAL4*. If a gene containing the *GAL4* binding site in its promoter is transduced into the system, it is expressed at any of the *GAL4* locations and permits the study of its effect on development. ▶*GAL4*, ▶transcriptional activator; Brand AH, Perrimon N 1993 Development 118:401.

Directed Mutation: A controversial (Lamarckian) notion that mutations of advantageous phenotype are preferentially induced in an adaptive environment, i.e., mutations would not be random and preferentially selected as required by the ideas of neo-Darwinian theory. Although supportive evidence has been put forth even recently, none of them can be completely defended against the alternative, conservative, classical interpretations ▶acquired characters. In depth analysis of adaptive mutation (directed mutation) in *E. coli* revealed that these adaptive reversions of the *Lac* alleles required *F'* plasmid

transfer replication and homologous recombination involving *F'* plasmid elements that may contain revertant alleles, and may so account for the apparent directed mutations. In bacteria, the so-called *adaptive mutations* took place only in the presence of a functional RecBCD recombinational pathway. Others have pointed out that *Lac* locus may be amplified—to cope with the reduced function due to mutation—and the increased number of copies appear to be responsible for the rise in overall reversions without an increase of mutability in the individual copies. The notion of the existence of true adaptive mutations is thus controversial. Directed mutations can be obtained, however, by manipulating the DNA in vitro using the techniques of molecular biology and transformation. In somatic hypermutation activated BV lymphocytes activate cytidine deaminase resulting in several fold increase in transition of C→T. ▶acquired characters, ▶localized mutagenesis, ▶RNAi, ▶PCR-based mutagenesis, ▶TAB mutagenesis, ▶linker scanning, ▶Kunkel mutagenesis, ▶cysteine-scanning mutagenesis, ▶homologue-scanning mutagenesis, ▶lamarckism, ▶lysenkoism, ▶soviet genetics, ▶neo-darwinian evolution, ▶somatic hypermutation, ▶hypermutation, ▶epimutation, ▶transgenerational effect, ▶staggered extension, ▶RNA-peptide fusion; Xia G et al 2002 Proc Natl Acad Sci USA 99:6597; Zheng Q 2003 Genetics 164:373; Storici F et al 2001 Nature Biotechnol 19:773.

Directional Cloning: Vector DNA termini are ligated with different linkers that produce different cohesive sequence at the two ends after restriction endonuclease cleavage. The passenger DNA (insert) can be ligated thus in a chosen orientation only (see Fig. D58). ▶vectors; Bubler U, Hoffman BJ 1983 Gene 25:263; Ohara O, Temple G 2001 Nucleic Acids Res 29(4):e22.

Figure D58. Directional cloning

Directional Evolution: The biased distribution, e.g., of the different length of microsatellites. ▶microsatellite; Hutter CM et al 1998 Mol Biol Evol 15:1620; Demetrius L 1997 Proc Natl Acad Sci USA 94:3491.

Directional Selection: Alters the population mean in either plus or minus direction. ▶selection types

Directionality: phage λ *chi* sites may enhance recombination more on the left than on its right side or the

transposase may be more functional in one orientation. ► [orientation selectivity](#), ► [lambda phage](#)

Directory: Reveals the contents of the folders (documents generated by the user) in a computer.

Dirichlet Distribution: A beta distribution of a multivariate type $f(x_1, x_2, \dots, x_q) = \frac{\Gamma(\nu_1 + \dots + \nu_q)}{\Gamma(\nu_1) \dots \Gamma(\nu_q)} x_1^{\nu_1-1} \dots x_q^{\nu_q-1}$. The distribution can be applied to the distribution of non-synonymous codon distribution across a sequence during natural selection (Huelsenbeck JP et al 2006 Proc Natl Acad Sci USA 103:6263). ► [beta distribution](#), ► [multivariate normal distribution](#), ► [non-synonymous codon](#), ► [synonymous codon](#)

DIRS: *Dictyostelium* intermediate repeat sequence elements occupy the ends of each chromosome and presumably represent centromeres. In other organisms, similar repeat elements are scattered. ► [Dictyostelium discoideum](#)

DIRVISH (direct visual hybridization): A mapping procedure for DNA sequences using fluoro-chrome-labeled samples hybridized to highly stretched DNA strands and their location is visualized with the aid of fluorescence microscopy. ► [FISH](#), ► [fluorochromes](#); Buckle VJ, Kearney L 1993 Nature Genet 5:4; Aerssens J et al 1995 Cytogenet Cell Genet 71:268.

Disaccharide: Covalently bound two monosaccharides, e.g., sucrose (glucose:fructose).

Disaccharide Intolerance: A collective name for the inability of proper metabolism of sugars. The sucrose intolerance is caused by sucrase–isomaltase malfunction. The enzyme is present but does not function normally, resulting in diarrhea when sucrose is consumed. Sucrose, maltose and starch are well tolerated in lactase deficiency but lactose cannot be reabsorbed and causes bloating, diarrhea and general discomfort because of the high gas production by intestinal microbes. The congenital lactase deficiency (alactasia) is caused by recessive mutations in human chromosome 2q21 (Jarvela I et al 1998 Am J Hum Genet 63:1078). Two types of lactase-phlorizin hydrolase activity are distinguished. One type generally appears as a developmental defect after age 5. Its frequency may be quite variable in different populations. Its frequency is low where dairy farming is prevalent and high where milk is absent from the diet. The lactase persistence (LCT*P, 2q21) to adulthood is controlled by a genetic factors closely associated with the lactase gene locus. A single nucleotide polymorphism (*C-13910T*) in an enhancer element 13.9 kb upstream of the lactase gene (*LCT*) involves *-13910*T*. This allele occurs at very high frequency in northern Europeans as part of a very long haplotype (known as A), and promotes binding

of the transcription factor Oct-1. The frequency *-13910*T* allele is very low in many African milk drinking pastoralist groups where lactase persistence phenotype has been reported at high frequency. In Sudanese populations, there is no association of *-13910*T* or the A haplotype with lactase persistence (Ingram CJE et al 2007 Human Genet 120:779).

Its worldwide distribution follows the availability of dairy product in the diet (Beja-Pereira A et al 2003 Nature Genet 35:311). The frequency of the dominant LCT*P in populations of northern European ancestry is ~0.74–0.78 or higher (except the Finns, 0.59). Several haplotypes for lactose tolerance/intolerance can distinguished based on mutation and recombination of the different alleles. The frequency of the lactose tolerance gene is very low or high, respectively depending on dairy farming. The frequency of lactase persistence decreases across southern Europe and the Middle East (50% in Spanish, French and pastoralist Arab populations) and is low in non-pastoralist Asian and African populations (1% in Chinese, 5–20% in West African agriculturalists). Lactase persistence is common in pastoralist populations from Africa (90% in Tutsi, 50% in Fulani). There is a difference in the expression of this trait due to different modifiers in the populations (Tishkoff SA et al 2006 Nature Genet 39:31). The lactase-persistence gene appeared low in neolithic, European human populations as DNA evidence from skeletal remains indicates (Burger J et al 2007 Proc Natl Acad Sci USA 104:3736).

Taking tablets of microbial β -galactosidase before eating dairy products can alleviate lactose intolerance. A new possibility is gene therapy by oral administration of adeno-associated viral vectors with the good β -galactosidase gene. Rat experiments with such a treatment produced somatic cure for up to 6 months because the vector was readily incorporated across epithelial barriers. The sucrase–isomaltase deficiency gene is at human chromosome 3q25-q26. ► [fructose intolerance](#), ► [lactose intolerance](#), ► [glycosuria](#), ► [phlorizin](#), ► [gene therapy](#), ► [adeno-associated virus](#), ► [stratification](#); Hollox EJ et al 2001 Am J Hum Genet 68:160; Enattah NS et al 2002 Nature Genet 30:233; Swallow DM 2003 Annu Rev Genet 37:197.

Disarmed Vector: Agrobacterial genetic vector from which the oncogenes (encoding phytohormones) have been deleted in the T-DNA (and usually replaced by foreign, desirable genes). ► [Ti plasmid](#), ► [Agrobacterium](#), ► [plant hormones](#), ► [transformation genetic](#)

Disassociation: The separation of the two strands of DNA. ► [C₀t curve](#), ► [Watson and Crick model](#)

Disassortative Mating: The mating partners are less similar in phenotype than expected by random

choice. ▶assortative mating, ▶breeding systems, ▶sexual selection; Reusch TBH et al 2001 Nature [Lond] 414:300.

DISC: ▶disk

DISC: A death-inducing signaling complex of FAS, FADD, and caspase 8. ▶FAS/CD95, ▶FADD, ▶caspase, ▶apoptosis

Discontinuous Gene: The translated exons are separated by introns. ▶introns, ▶exons

Discontinuous Replication: ▶Okazaki fragments, ▶replication fork

Discontinuous Variation: It is caused by qualitative genes and the expression can be classified into discrete groups with relatively low environmental effects. ▶continuous traits

Discordance: Dissimilarity of a trait between individuals because of genetic difference. The term is also used for gene loci carrying two different alleles in a diploid. Monozygotic twins are generally concordant in all traits yet, occasionally, they can be discordant regarding a particular disease. ▶dizygotic twins, ▶twinning, ▶zygosis, ▶monozygotic twins, ▶penetrance, ▶expressivity, ▶concordance

Discriminant Function: Estimates statistically the overlap between two populations and it has uses for classification and diagnosis, for the study of relations between populations and as a multivariate extension of the *t*-test (see Table D1). Example: a single variate *X* is distributed in two populations with means μ_1 and μ_2 ; the standard deviations (σ) are assumed to be the same. To know to which of the two populations does the specimen *X* belong, we classify *X* to population 1 if $X < (\mu_1 + \mu_2)/2$ and to population 2 if $X > (\mu_1 + \mu_2)/2$. If *X* is from population 1, our decision is wrong if $X > (\mu_1 + \mu_2)/2$ or when δ (the distance between the two means) = $(\mu_2 - \mu_1)$. $(X - \mu_1)/\sigma$ follows the normal distribution and misclassification is probable in the tail from $\delta/2\sigma$ and ∞ in both cases. The δ/σ must exceed 3.0 to consider the classification accurate. The δ/σ is also called distance between two populations. Analysis of variance of the discriminant function can be used

Table D1. Discriminant function

| | Sum of Squares | Df* |
|----------------|-----------------|----------|
| Between Groups | $(n/2)D^2$ | 2 |
| Within Group | D | $2n - 3$ |
| Total | $D(1 + [n/2]D)$ | $2n - 1$ |

*Df: degrees of freedom

as follows: where *D* is the difference between \bar{X}_1 and \bar{X}_2 . The significance of the difference can be determined by *z*. ▶multivariate analysis, ▶analysis of variance, ▶recursive partitioning, ▶*z*; Mather K 1965 Statistical Analysis in Biology. Methuen; London; UK; Venables WN, Ripley BD 1994 Modern Statistics, Springer, New York.

Discrimination, Genetic: The use of actual or predictive genetic information for employment or insurance and causing emotional, financial or social disadvantage/ advantage based on genetic constitution alone. In the majority of states in the USA, such discrimination is against the law although the definition of discrimination is not unanimous. On February 17, 2005 the US Senate failed to pass bill S. 306 by a vote of 98 to 0 on genetic information nondiscrimination act. On April 25, 2007 the US House of representatives passed the bill GINA (Genetic Information Nondiscrimination Act) prohibiting discrimination on the basis of medical condition, or hiring, firing or job placement on the basis of genetic information and there is a high chance that the President will sign the bill after Senate approval. By 2007, 35 states have laws against genetic discrimination in employment, and 47 have laws against genetic discrimination in health insurance. However, the state-by-state approach provides an inconsistent framework, and the scope of protection provided by many state laws is extremely narrow (Hudson KL 2007 New England J Med 356:2021). ▶gender discrimination

Discriminator Region: It is in the -10 to +1 region of prokaryotic promoters where in amino acid starving cells 5'-diphosphate 3'-diphosphate (ppGpp) binds (see Fig. D59). The σ subunit contacts the non-template strand of *E. coli* 2 base position downstream of the -10 element within the discriminator region and provides a short-lived complex for the RNA polymerase binding factors of the ribosomal RNA promoter and provides a means of regulation (Haugen SP et al 2006 Cell 125:1069; Bernardo LM et al 2006 Mol Microbiol 60:749). ppGpp (alarmone) and RNA polymerase binding protein DksA are synthesized under starvation conditions, control rRNA protein genes and activate amino acid operons. The ppGpp-repressed promoters are GC rich, the ppGpp-activated promoters are richer in AT in the discriminator region. ▶stringent control; Pemberton IK et al 2000 J Mol Biol 299:859.

Figure D59. Discriminator region

Diseases in Humans: Deviation/deviations from the normal physiological, structural and neural characteristics of the individual body, including a state of infections by virus, bacterium, fungus or protist parasites. The disease may be genetic, congenital or acquired or a combination of all these factors. In the twenty-first century the basis/bases of disease is sought in molecular terms (DNA, RNA, protein and small molecules), unlike in previous epochs when disease was considered in broader terms only. The future is to identify the cause of diseases and disease susceptibility in the genetic constitution of the host (human) and the pathogen and/or environmental factors. Human epidemiological studies indicate that prenatal and early postnatal environmental factors influence the adult risk of developing various chronic diseases, such as cancer, cardiovascular disease, diabetes, obesity and even neural diseases such as schizophrenia (Jirtle RL, Skinner MK 2007 *Nature Rev Genet* 8:253). Increasing evidence accumulates that modifier genes may seriously alter (+/−) the expression of the major genes responsible for disease (Nadeau JH, Topol EJ 2006 *Nature Genet* 38:1095). The symptoms of the diseases are based on the interacting network of factors. Genes associated with similar disorders show both higher likelihood of physical interactions between their products and higher expression profiling similarity for their transcripts, supporting the existence of distinct disease-specific functional modules. It appears that essential human genes are likely to encode hub proteins and are expressed widely in most tissues. This suggests that disease genes also would play a central role in the human interactome. The vast majority of disease genes is nonessential and shows no tendency to encode hub proteins, and their expression pattern indicates that they are localized in the functional periphery of the network (Goh K-I et al 2007 *Proc Natl Acad Sci USA* 104:8685). These findings have important implications for precise and valid diagnosis of syndromic cases and for the development of drugs with serious side effects and point toward the need of individualized medicine.

Disequilibrium: A lack of equilibrium. ► [linkage disequilibrium](#) and [linkage equilibrium](#), ► [Hardy-Weinberg theorem](#)

Dishevelled (Dsh): A protein that mediates dorsal–ventral positioning and polarity in the embryo and the formation of a secondary axis.

Disintegration: The reversal of the integration process mediated by integrase. ► [integrase](#), ► [dpm](#)

Disintegrin: A metalloproteinase controlling cell migration. ► [metalloproteinases](#)

Disjunction: The separation of bivalents (chromosomes) during meiosis I, or of chromatids in mitosis. ► [meiosis](#), ► [mitosis](#), ► [nondisjunction](#)

Disk (disc): A magnetic surface on which information can be recorded and later retrieved by the appropriate command to the computer. The capacity of amount of information stored is expressed in kilobytes (K) or megabytes (MB). The floppy disks (about $9 \times 9 \text{ cm}^2$) can be low-density (400 K, single-sided or 800 K, double-sided) or high-density disks (1.4 MB), the Zip disk can store information up to 100–250 Mb. CDs accommodate 700–800 Mb. The hard disks hold from 20 MB to several GB (gigabyte) or more information. 1 K = 1024 characters, about 170 words in English.

Dislocated Hip (hereditary): Its prevalence in human population is about 0.075% and its recurrence risk among sibs is about 5%. It is autosomal dominant and usually more common among females than males. It occurs sometimes as part of the recessive Marfan and the Ehlers–Danlos syndromes. ► [Marfan syndrome](#), ► [Ehlers-Danlos syndrome](#)

Disome: Two homologous chromosomes.

Disomic: An individual or cell with one specific or any of the chromosomes represented twice. *Maternal or paternal disomic* individuals arise from hybrids in case of nondisjunction for a particular chromosome in translocation heterozygotes (Robertsonian translocations). *Uniparental disomy* may be associated with trisomy when one of the three chromosomes, derived from one of the parents, is lost and the result is homozygosity (disomy) for the other parent's chromosomes. The frequency of human gametic disomy, estimated on the basis of trisomic conceptuses, varies according to chromosomes: X: sperm/ova 0.04/0.04; 16: 0/1; 13, 18: 0/0.17; 21: 0.03/0.40. ► [Beckwith–Weidemann syndrome](#), ► [Prader–Willi syndrome](#), ► [Angelman syndrome](#), ► [Robertsonian translocation](#), ► [trisomy](#)

Dispensability: The feature of a gene conveying limited fitness in a certain environment of a population.

Dispermic Fertilization: When two sperms enter into one egg. ▶[double fertilization](#); Palermo GD et al 1995 Hum Reprod 10 Suppl. (1) 120.

D

Dispersed Genes: These are members of (multi) gene families. ▶[gene family](#)

Dispersed Repeats: ▶[SINE](#), ▶[LINE](#)

Dispersion Index: It indicates the extent by which a set of data deviates from their mean. For the Poisson distribution, e.g., it is determined by a formula (see box). Also $R(t) = \text{Var}(S_t)/E(S_t)$ where S_t = number of amino acid substitutions at any site. Var and E stand for variance and expectation, respectively (see Fig. D60). In case of neutral substitutions the variance to mean ratio, $R(t) \sim 1$, except when the mutations occur premeiotically (i.e., in clusters). In case the variances of the evolutionary rates exceed the expectations on the basis of Poisson distribution, the phenomenon is called overdispersion of the molecular clock. ▶[variance](#), ▶[Poisson distribution](#), ▶[evolutionary clock](#)

$$D = \sum_{i=1}^n \frac{(x_i - \bar{x})^2}{\bar{x}}$$

Figure D60. Dispersion

Dispersive Replication: The polynucleotide strands are a mosaic of old (blue) and newly synthesized (red) sequences (see Fig. D61). This old assumption has not been confirmed experimentally. ▶[semi-conservative replication](#); Delbruck M, Stent GS 1957 In: McElroy WD, Glass B (eds) The Chemical Basis of Heredity. Johns Hopkins Press, Baltimore, MD pp 699.

Figure D61. Dispersive replication

Displacement (t): In population genetics t = the number of standard deviations difference between the mean values of homozygotes AA and aa (arbitrarily assuming that the variance within genotype is the same for each genotype). ▶[genetic variances](#)

Displacement Loop: ▶[D loop](#)

Display Technologies: allow the expression of large pool of modularly coded biomolecules, analyze and select diverse and specific proteins at a very large scale.

▶[phage display](#), ▶[ribosome display](#); Ma D, Li M 2001 J Cellular Biochem 37:34.

Disposable Soma: A theory that the evolution of aging requires the preservation of the body that limits the resources available for reproduction. After reproduction, aging does not affect evolution because the soma is already met its purpose. Aging is caused by wear and tear of the body. Longevity genes are generally involved in energy metabolism. In its simplest form, longevity is favored by producing fewer offspring. The disposable soma applies to higher animals but not to higher plants; somatic tissues of plants can be regenerated into intact individuals. In addition, body parts of hydras can be regenerated into perfect animals with immortal germ line. Somatic embryonic stem cells of higher animals can also give rise to any type of tissue including those of the germline. ▶[aging](#), ▶[stem cells](#), ▶[reprogramming](#), ▶[aging](#), ▶[longevity](#); Lycett JE et al 2000 Proc Roy Soc Lond B Biol Sci 267:31; Rando TA 2006 Nature [Lond] 441:1080.

Disruptive Selection: As a consequence of the process, the population breaks up into two (contiguous) groups with different mean values. ▶[selection types](#)

Dissection, Genetic: It analyzes the mechanism of genetic determination of a process.

Disseminated Sclerosis: ▶[multiple sclerosis](#)

Dissociation Constant: K_d is the equilibrium constant for the dissociation of a complex of molecules (AB) into components (A) and (B); K_a is the dissociation constant of an acid into its conjugate base and a proton. The smaller the K_d value $\frac{(A)(B)}{(AB)}$ the tighter is the binding between the components.

Dissolution: Dissolution processes double Holliday junction-containing recombination intermediates into noncrossover products. ▶[Holliday junction](#), ▶[Holliday model](#); Wu L et al 2006 Proc Natl Acad Sci USA 103:4068.

Distal Marker: It is situated in a direction away from the centromere or another gene, or in bacterial conjugation it is transferred after a particular site. ▶[centromere mapping](#), ▶[conjugational mapping](#)

Distal Mutagen: It is formed when a promutagen through chemical modification is first converted into an intermediate (proximal mutagen) that finally becomes the ultimate or distal mutagen. ▶[mutagens](#), ▶[carcinogens](#)

Distalization Rule: In differentiation when new cells are generated (regenerated), each intercalary cell division produces progressively more distal cells until the circumferential filling of missing values are

completed. ► [polar coordinate model](#); French V 1981 Philos Trans Roy Soc Lond B Biol Sci 295:601.

Distance Matrix: ► [character matrix](#)

Distichiasis: Double eyelashes, lymphedema.

Distorted Segregation: It is seen when the transmission of one of the alleles is not the same as that of the other. The cause of this anomaly can be chromosomal defects, lethal or semilethal mutations or genes like the *Segregation distorter* (*Sd*, map location 2–54) in *Drosophila*. The distortion may reduce either the dominant or the recessive class depending on the linkage phase and map distance of the marker to the factor that disturbs normal phenotypic or genotypic proportions. ► [segregation distorter](#), ► [meiotic drive](#), ► [gametophyte factor](#), ► [certation](#), ► [preferential segregation](#), ► [megaspore competition](#), ► [gene conversion](#); Schimenti J 2000 Trends Genet 16:240; Pardo-Manuel de Villena F; Sapienza C 2001 Mamm Genome 12:331.

Distortion in Cloning: Different DNA fragments, because of their nature, length, etc., may be replicated at different rates in the vectors and may bias the representation of the sequences in the library. ► [library](#), ► [vectors](#), ► [replication](#)

Distribution-Free: An analysis that does not suppose a distribution and it is, therefore, nonparametric. ► [non-parametric tests](#)

Distributions: ► [normal distribution](#), ► [Poisson distribution](#), ► [exponential distribution](#), ► [binomial distribution](#), ► [Bernoulli process](#), ► [trinomial distribution](#), ► [multinomial distribution](#), ► [hypergeometric distribution](#), ► [negative binomial](#), ► [gamma distribution](#)

Distributive Circuit in Signal Transduction: One kinase may initiate multiple responses. ► [signal transduction](#)

Distributive Pairing: In distributive pairing, the chromosomes may recombine during meiosis and are then distributed to the poles normally (*exchange pairing*). Chromosomes that are not involved in exchange display *distributive pairing* and may suffer nondisjunction. A *Drosophila* mutation *nod* (*no distributive disjunction*; map location 1–36) when homozygous, may display high (800 fold) frequency of chromosome loss and nondisjunction of chromosome 4 during meiosis I. Recent information indicates that in the distribution of achiasmate chromosomes the heterochromatin adjacent to the centromere plays an important role. More than 70% of the nondisjunctions are the result of achiasmate meiosis. ► [chromosome pairing](#), ► [achiasmate](#), ► [heterochromatin](#), ► [chromokinesis](#); Hawley RS, Theurkauf WE 1993 Trends Genet 9:310; Grell RF 1985 Basic Life Sci 36:317.

Disulfide Bridge: A covalent bond between two sulphur atoms (–S–S–) of two cysteine residues of a polypeptide chain(s) affecting conformation. DsbA (disulphide bond) is a small periplasmic protein. In the active form, it has two cysteines joined by a disulphide bond. Disulphide bonds are formed with an exchange between the oxidized DsbA and the reduced cysteine residues of the substrate. This results in inactive, reduced DsbA. DsbB reoxidizes the molecule and restores the active form. ► [protein structure](#); Kadokura H et al 2004 Science 303:534.

Ditelo-Monotelosomic: in wheat, $20''+t''+t'$, $2n=43$, [$''$ = disomic, $'$ = monosomic, t = telosomic]

Ditelosomic: in wheat, the chromosome constitution is $20''+t''$ ($2n=42$) [$''$ indicates disomy, t = telosomic]

Ditelotrisomic: in wheat, $20''+(t'')1'''$, $2n=43$, [$''$ = disomic, $'''$ = trisomic, t = telosomic].

Dithioerythritol (DTE): 2,3-dihydroxybutane, Cleland reagent; it protects SH groups.

Dithiothreitol (DTT): DL-threo-1,4-dimercapto-2,3-butanediol; protects SH groups.

Ditype: A tetrad with two kinds of spores. ► [tetrad analysis](#)

Diuretic: It promotes discharge of urine. ► [aquaretic](#), ► [hypertension](#)

Diurnal: A response or behavior displaying daily cycles.

Diuron: A herbicide interfering with photosynthesis.

Divergence: Evolutionary differences in morphology, cytology and/or in the primary structure of nucleic acids and proteins that are believed to have descended from common ancestry. The divergence can be quantitatively estimated on the basis of average chiasma frequencies of the genomes if the species can be crossed. The average frequencies of amino acid substitutions in the proteins or base substitutions in nucleic acids can be used to estimate genetic distance and the time required to achieve it. Some caution may be required in interpreting evolutionary divergence because similarity may be based also on evolutionary convergence and reverse mutation. Mutation, chromosomal rearrangements and recombination may bring about divergence. The recombinational force in *E. coli* appears to be 50 times higher than that of mutation in clonal divergence. ► [convergent evolution](#), ► [genetic distance](#), ► [chiasma](#), ► [chimpanzee](#); <http://Ins00.psi.ch/nobugs2004/papers/paper00099.pdf>.

Divergent Dual Promoter: Juxtapositioned promoters may carry out transcription in opposite directions. ► [promoter](#), ► [divergent transcription](#), ► [catabolite repression](#)

Divergent Transcription: It proceeds from two promoters in opposite orientation. ▶promoter, ▶transcription

Diversification: ▶combinatorial diversification, ▶junctional diversification

D

Diversity (Shannon–Weaver index): $H = (n(\log N - \sum \log n_i))/N$ where H = diversity, N = total number of individuals, n_i = number of individuals of different phenotypes. Molecular genetic diversity (π) can be assessed at the nucleotide level. Based on thousands of human genes π values in the non-translated 5' and 3' regions averaged 0.0003 ± 0.0001 , non-synonymous and synonymous values of π were found to be 0.0001 ± 0.0001 and 0.0005 ± 0.0002 , respectively. Diversity at the protein level is inversely proportional to the number of subunits because the greater functional constraints. Mutation rate, however, is increasing in proportion to the size of the genes because of the larger mutational target although the mutations may be subject to selective screening for survival or even elimination. There are substantial variations among various genes. Diversity also affected by the size of the habitat (Rauch EM, Bar-Yam Y 2005 Proc Natl Acad Sci USA 102:9826). Only a relatively small fraction of the diversity is limited to specific ethnic groups although, in general, the most ancient populations, e.g., Africans display greater diversity than the newer ones. Population size is generally positively correlated with diversity of nuclear genes in animals but this rule does not hold for mitochondrial genes (Bazin E et al 2006 Science 312:570). Locally coexisting species represent α diversity and β diversity means spatial change in composition of species whereas γ diversity indicates regional diversity in species. ▶SNIP, ▶neutral mutation, ▶adaptive radiation, ▶polymorphism, ▶mutation rate, ▶microarray hybridization, ▶DArT, ▶microsatellite, ▶minisatellite, ▶species; Chakravarti A 1999 Nature Genet 21 Suppl. 56, Yu N et al 2002 Genetics 161:269, maintenance of diversity of plant genetic resources: Esquinaz-Alcázar J 2005 Nature Rev Genet 6:946, worldwide distribution of animal habitats: <http://www.worldwildlife.org/wildfinder>.

Dizygotic Twins: They develop from two separate eggs fertilized by separate sperms. Dizygotic twinning seems to be linked to the peroxisome proliferator activated receptor PPARG at 3p25. ▶twinning, ▶monozygotic twins, ▶zygosis, ▶pedigree analysis, ▶PPAR

$\Delta(lac - proAB)$: A deletion for the bacterial *lac* (lactose; map position 8) and *prolineA* and *prolineB* (map position 6 for both; blocks before glutamate semi-aldehyde) genes. ▶*Lac* operon

D-loop: ▶displacement loop

DM: The HLA DMA and DMB gene products that are required to exchange CLIP from Class II major histocompatibility proteins so the T cell can be loaded with the antigen. The DM α and β subunits are similar to the α and β chains of the Class II molecules. ▶MHC, ▶HLA, ▶CLIP

DM (double minute) Chromosome (DM): It has no centromere and can be maintained only under selective pressure for the gene(s) it carries and absent from the rest of the genome. In several types of cancer, oncogenes are amplified either in double minutes or in *homogeneously stained regions* of the chromosomes or both (see Fig. D62).

Sub-lethal doses of hydroxyurea (HU) may cause a loss of DMs and thus the oncogenes. The loss of amplified epidermal growth factor receptor (EGFR) reduces tumor growth. Amplified dihydrofolate reductase genes (DHFR) in DMs in methotrexate-resistant mouse cells were also selectively reduced in the presence of MTX (methotrexate) and HU, but after a week resistance to HU developed and DHFR was reamplified. This type of elimination of extra DNA from the eukaryotic cells may be considered as a functional substitute for the restriction–modification system of prokaryotes (Shimizu N et al 2005 Nucleic Acids Res 33:6296). ▶YAC, ▶homogeneously stained regions, ▶amplification, ▶DHFR, ▶methotrexate, ▶hydroxyurea; Hahn PJ 1993 Bioessays 15:477; Nevaldine BH et al 1999 Mutation Res Genomics 406:55.

Figure D62. Scanning electron micrograph of a double-minute chromosome with ~30 looping interconnecting 17 nm fibers. The chromatin fibers (CFD) are ~32 nm in diameter. (From P.V. Schoenlein et al 1999 Chromosoma 108:121)

dm: When placed in front of a gene or protein symbol, it indicates *Drosophila melanogaster* homology.

DMBA (9,10-dimethyl-1,2-benzanthracene): A carcinogen standard, a mutagen; forms covalent DNA adducts. ▶carcinogen, ▶adduct

DMC1 (disrupted meiotic cDNA gene): A protein product in yeast controlling meiotic recombination. Similar function is carried out by RAD51, which is required for both meiotic and mitotic recombination and its role is similar to bacterial *RecA*. The Dmc1 protein acts only during meiosis. In humans, the hDmc1 mediates recombination by nucleation into single-stranded DNA to form a helical nucleoprotein filament (Sehorn MG et al 2004 Nature [Lond] 429:433). Dmc1 and Sae4 meiotic proteins are involved in loading Dmc onto the recombination chromosomes (Hayasi A et al 2004 Cell 119:927). Dmc1 is indispensable for repairing double-strand breaks. ▶*RecA*, ▶*RAD51*, ▶*nucleation*; Gupta RC et al 2001 Proc Natl Acad Sci USA 98:8433; Chen Y-K et al 2004 Proc Natl Acad Sci USA 101:10572.

$(\delta\mu)^2$ (delta mu square): A measure of the genetic distance based on the square of the difference (δ) between average repeat size (μ) in two populations. At reproductive isolation mutation and genetic drift in equilibrium within the ancestral and derivative populations indicates the time elapsed since separation. This parameter is highly variable and may be of limited utility. ▶*evolutionary distance*, ▶*coalescent*, ▶*F_{ST}*

$\Delta\mu\text{H}^+$: An energy donor, it promotes translocation through cellular membranes.

DMH (differential methylation hybridization): DMH is used to determine the relative frequencies of methylated and unmethylated cytosine in two DNA samples, e.g., normal and tumor cell DNA. The two DNAs, the normal and tumor cell DNAs, are digested to smaller fragments by the four-base recognizing MseI restriction enzyme (T'TAA) that does not cut CpG and rarely affects CpG islands. The fragments are equipped with priming linkers for PCR. Then using a methylation-sensitive restriction enzyme, the amplified methylated DNA is not digested but the unmethylated is cut and thus, the latter cannot be amplified by PCR. Then the fragments from both sources are labeled, e.g., by Cy3 (green fluorescence) the normal and by Cy5 (red fluorescence) the tumor DNA and co-hybridized onto a microarray glass slide containing CpG island DNA probe. The spots of different color indicate the degree of hybridization. Red spots on the slide indicate hypermethylation, green spots hypomethylation and yellow spots indicate that the extent of methylation was the same in the two DNAs (equal mixture of red and green fluorescence). In cancer cells, the tumor suppressors are hypermethylated (silenced) and the oncogenes are hypomethylated (activated). ▶*methylation of DNA*, ▶*restriction enzymes*, ▶*microarray hybridization*, ▶*fluorescent*; Yan PS et al 2001 cancer Res 61:8375.

DMS: dimethylsulfate, an alkylating agent, mutagenic and carcinogenic. ▶*alkylation*

Dms: ▶*double minutes*

DMSO: ▶*dimethyl sulfoxide*

dna: Bacterial mutations involved in DNA replication.

DNA: deoxyribonucleic acid, the genetic material of all eukaryotes and bacteria and many viruses (see Fig. D63).

The most direct proof for DNA being the genetic material was provided by genetic transformation. DNA is measured either in base pairs (bp) or spectrophotometrically: 1 unit of optical density (OD) of double-stranded DNA (at 260-nm wavelength) is about 50 $\mu\text{g}/\text{mL}$. One OD of single-strand DNA is about 40 $\mu\text{g}/\text{mL}$; 1 $\mu\text{g}/\text{mL}$ DNA contains about 3.08 μM phosphate (▶*DNA types*); 3000 nucleotides are about 1 μm in length, 1 pg DNA is about 0.60205×10^{12} Da [$10^{-12}/(1.6661 \times 10^{-24}$ g)]. DNA types. ▶*Watson and Crick model*, ▶*hydrogen pairing*, ▶*spectrophotometer*, ▶*transformation*, ▶*xDNA*

DNA Annealing: The reassociation of two complementary single strands into a double-stranded molecule. ▶*C₀t curve*, ▶*DNA hybridization*

DNA Bank: A collection of safely stored and identified DNA samples that can be used for comparative research or for forensic purposes.

DNA Base Composition: It varies among different organisms (see approximate values in the table). At an early stage of molecular biology, this information indicated that DNA is the genetic material, and it was used for designing the Watson and Crick model of the double helix. The differences between the amounts of A and T, and G and C, respectively, were caused by analytical errors (see Table D2).

DNA Bending: Two distant DNA sites are brought closer together because of the non-straight run of the double helix caused by phosphate neutralization due to

Table D2. DNA base composition

| Species, DNA Base Composition | A | T | G | CΣ |
|---|------|------|------|------|
| Humans | 30.7 | 31.2 | 19.3 | 18.8 |
| Wheat (<i>Triticum aestivum</i>) | 25.6 | 26.0 | 23.8 | 24.6 |
| Budding yeast (<i>Saccharomyces cerevisiae</i>) | 31.3 | 32.9 | 18.7 | 17.1 |
| <i>Escherichia coli</i> | 26.0 | 25.2 | 24.9 | 23.9 |
| <i>Mycobacterium pheli</i> | 16.5 | 16.0 | 34.2 | 33.2 |
| Bacteriophage T4 | 32.4 | 32.4 | 18.3 | 17.0 |

ΣMethylcytosine and hydroxymethylcytosine combined

Figure D64. DNA binding protein domains

protein binding. The DNA may also bend by attaching a sequence-specific ligand to two sites separated by say 10 nucleotides. The lambda phage *Cro* repressor binds to three specific operator sites and causes DNA bending. Bending of chromatin may increase the chances of affinity of the TATA box-binding protein by over 100 fold and may also block gene expression. Repair of DNA by MutS also requires bending of DNA. ▶looping of DNA, ▶DNA kinking, ▶lambda phage, ▶TBP, ▶flexer, ▶high mobility group proteins, ▶mismatch repair, ▶inter-chromosomal interaction, ▶looping of DNA; Hagerman PJ 1990 Annu Rev Biochem 59:755; Wu J et al 2001 J Biol Chem 276:14614, *ibid.* 14623.

DNA Binding: *N*-methyl imidazole and *N*-methylpyrrole amino acids can recognize specific base pairs or short base sequences in the DNA and bind to them. There are also many DNA-binding proteins in the cells. Understanding the number, kind and strength of binding of proteins (transcription factors) to DNA reveals a great deal on expression of genes and several methods are available for the quantitative evaluation of binding (Liu Z et al 2005 Nucleic Acids

Res 33:546). ▶DNA-binding protein domains, ▶transcription factors

DNA Binding Protein Domains: There is a variety of DNA-binding proteins and they have some common structural motifs belonging to four major groups: zinc fingers, helix-turn-helix, leucine zipper and helix-loop-helix (see Fig. D64).

Proteins binding to DNA and RNA have important regulatory and potential therapeutic use (Harbison DB et al 2004 Nature [Lond] 431:99). The entire genome can be scanned for binding sites by generating a permuted library of 8–10 base pairs on microarray platform. Fluorescently labeled ligands are applied to the microarray grid to detect binding sites containing the total possible permutations of 8 (=32,896 molecules). Because the binding site size in the majority of metazoans is 6–10 bp, this array represents the genome reasonably well. Evaluation was possible in an unbiased, rapid and unsupervised/noncurated manner (Warren CL et al 2006 Proc Natl Acad Sci USA 103:867).

DNA, Blunted: It lacks (single-stranded) cohesive termini such as the cohesive end and cannot circularize without modification of ends (see Fig. D65).

Figure D65. Blunted, Cohesive

DNA Brushes: DNA monolayers can be used for elucidating charged polymers at interfaces. Their internal ionic microenvironment determines to a large extent their physical behavior. In general, a critical attribute of a ssDNA-modified surface is efficient and reproducible hybridization with target DNA and it is usable at nanoscale. ►ssDNA; Shen G et al 2006 J Am Chem Soc 128:8427.

DNA Chemical Synthesis: the 5'-end of the first nucleotide is protected by dimethoxytrityl (DMT) while a linker to silica attaches the OH end. The reactive groups of all nucleotides are chemically protected. Afterwards DMT is removed by washing and the next nucleotide is activated and attached to the 3'-OH group. Using iodine, the 5' to 3' linkage is oxidized to generate a phosphotriester bond (one of the O of the phosphate group is methylated). The reaction is continued until the desired chain length is reached. About 70–80 residue polymers can be made this way. The process has also automated versions and routine synthetic services are commercially available. (Linkletter BA et al 2001 Nucleic Acids Res 29:2370)

DNA Chimera: A DNA molecule ligated together from originally different molecules.

DNA Chips: It is a combinatorial array of oligonucleotides synthesized on a solid support (modified glass or polypropylene) in situ at specific “addresses” in a checkerboard like arrangement (see Fig. D66). The synthesis requires the use of masks to protect areas of the array. They may use the 4 nucleotides (A, C, G, T) in any sequence length (4^8) up to many thousands. These procedures are expected to be exploited for mass, automated sequence analyses, mutation detection, etc. in a way analogous to the electronic microchip technology. This type of technology can be used to

synthesize a vast array of nucleotide sequences at staggering speed. ►microarray hybridization

Figure D66. Fluorescent image of an array containing more than 280,000 different 25-mer oligonucleotide probes in an area of $1.28 \times 1.28 \text{ cm}^2$. The array contains probe sets for more than 6,800 human genes, and the image was obtained after overnight hybridization of an amplified and labeled human mRNA sample. (From Fields S et al 1999 Proc Natl Acad Sci USA 96:8825)

The procedure is a modification of the photolithography used by commercial printing for several decades. A mercury light is directed to a photolithographic mask and through it to a solid surface. There it activates at specific areas of nucleotides for chemical coupling. The 5' ends are protected. Subsequent exposure then removes the protection and potentiates the reaction of the end with another nucleotide. The cycle is then continued. The specificity of the nucleotides to be chosen is controlled by the mask. Chips of $1/6 \text{ cm}^2$ can accommodate hundreds of thousands of sequences of $20 \mu\text{m}$. The space occupied by an oligonucleotide sequence of millions of molecules is called a *feature*. Each wafer contains a grid of 49–400 chips. The generation of the chips and the synthesis is mechanically controlled with minimal human labor and the whole process requires about half an hour. When the synthesis is complete, the chips are separated and hybridized with an appropriate fluorochrome-labeled nucleic acid (DNA or RNA) probe. After removal the unhybridized probe sequences, the fluorescence analysis by a confocal microscope required about half an hour. The resolution is going to be improved to $20 \mu\text{m}$ in the future and each chip may permit the resolution of 400,000 probes/chip.

The ~3,000,000,000-nucleotide mammalian genome may require only 10 chips. Detection of single base pair mutations is a much more elaborate process than monitoring the expression of genes.

The cost of the technology is comparable to an automatic sequencer. The DNA chip technology can be extended to mapping gene functions to chromosomal locations and obtaining information on all the genes contributing to a particular function. The total genomic DNA is arranged in fragments over the wafers with a minimum of 20 oligonucleotide probes of 25 base length for each open reading frame of the yeast genome. Probes from the coding sequences were placed in order of their position in the genetic map (chromosome). Mismatches in the hybridization to the same array of the two genetically different strains are detected with aid of a confocal laser scanner on the basis of the fluorochrome used for staining. The location of the chromatid exchanges can be physically identified by color and the information using known genetic markers can be verified by classical tetrad analysis. Since the total nucleotide sequence (representing all the genes) of a large number organisms is already known these new technologies may detect simultaneously the turning on and off of thousands of genes and may distinguish the differences between a healthy and diseased body. The information may lend great help to design more efficient drugs and it should greatly further the knowledge how a cell or billions of cells work together in the body. (For more see Southern EM 1996 Trends Genet 12:110; Nature Genetics 14, No 4, Fodor SPA 1997 Science 277:393; Winzeler EA et al 1998 Science 281:1194; see also ►SHOM, ►photolithography, ►nanotechnology, ►genomics, ►microarray hybridization; www.gene-chips.com, for optical lithography see Ito T, Okazaki S 2000 Nature [Lond] 407:1027; Lockhart DJ, Winzeler EA 2000 Nature [Lond] 405:827).

DNA, Circular: The majority of plasmids, prokaryotic, and organellar (mitochondrial, plastid) DNAs form a covalently closed circle and a circular genetic map. ►genetic circularity

DNA, Circulating: DNA has been detected in the blood plasma of cancer patients and the majority of the maternal blood samples obtained from women carrying male fetuses revealed Y chromosome-specific sequences (Lo YM et al 1997 Lancet 350:485). These circulating DNA molecules have applicational potentials for non-invasive prenatal diagnosis of disease and for the detection of the sex of offspring after 7–16 weeks of gestation (Chiu RW, Lo YM 2002 Expert Rev Mol Diagn 2:32; Sekizawa A et al 2001 Clin Chem 47:1856). ►prenatal diagnosis, ►plasma nucleic acid; Ding C et al 2004 Proc Natl Acad Sci

USA 101:10762; Anker P et al 2003 Int J Cancer 103:149.

DNA Cloning: ►cloning

DNA Complexity: ►C₀t curve

DNA Computer: It is based on the 4 four bases in the DNA. Theoretically, it makes possible to conduct simultaneously several different operations. At present, the technical problems do not allow their practical construction although in theory it is promising. DNA actually meets the requirements of an automaton for managing the cellular processes. A 3-symbol-3-state automaton uses as hardware of two enzymes an endonuclease and ligase and it computes autonomously with superior performance (Soreni M et al 2005 J Am Chem Soc 127:3935). ►Hamiltonian path, ►RNA computer, ►automaton, ►biocomputer; Chen J, Wood DH 2000 Proc Natl Acad Sci USA 97:1328; Sakamoto K et al 2000 Science 288:1223; Joachim C et al 2000 Nature 408:541; Cox JC, Ellington AD 2001 Curr Biol 11:R336; Benenson Y et al 2003 Proc Natl Acad Sci USA 100:2191.

DNA Conformation: ►DNA types

DNA Consensus: ►consensus

DNA Crystals: These may be used to explore molecular structures at the finest scale. Antiparallel-recombinant DNA molecules are tiled in order to generate lattices at periodic patterns. The crystal is an arrangement of molecular units in two- or three-dimensional periodicity. An understanding of the forces involved may assist in the design of special catalysts, enzymes or industrial biochips, etc. ►tiling, ►chip; Packer MJ, Hunter CA 2001 J Am Chem Soc 123:7399.

DNA Damage: ►chromosome breakage, ►DNA repair

DNA Damage Checkpoint Response: The phosphatidylinositol 3-kinase-related protein kinase (PIKK) family members have been shown to be key DNA damage sensors and signal transducers in the checkpoint response. Of these, ATM (ataxia telangiectasia mutated) is mainly responsible for initiation of the checkpoint response elicited by double-strand breaks caused by ionizing radiation or radiomimetic agents. Another PIKK family member, ATR, initiates the DNA damage checkpoint response caused by UV radiation and UV-mimetic agents that produce base damage such as *N*-acetoxy-2-acetylaminofluorene (*N*-Aco-AAF) (Choy JH et al 2007 Proc Natl Acad Sci USA 104:13301). (See review: Tembe V, Henderson BR 2007 Cell Signal 19:1113; polymerases: Lindsay-Boltz LA, Sankar A 2007 Proc Natl Acad Sci USA 104:13213).

DNA Data Bases: ►databases

DNA Dating: ►racemate

DNA Denaturation: The separation of the two strands of DNA duplexes by breaking the hydrogen bonds and the hydrophobic interactions among bases; it results also in reduced viscosity. This is accomplished by raising the pH or the temperature above 70°C or 80°C. The “melting temperature” also depends on the base composition because G=C binds by 3 and A = T by 2 hydrogen bonds. By lowering the temperature below 60°C renaturation may begin. ►denaturation, ►hyperchromicity, ►hypochromicity, ►DNA, ► c_0t , ►DNA thermal stability, ►DNA thermal stability, ►diagram at denaturation

DNA, Denatured: Hydrogen bonds are disrupted between the two strands; thus it is single stranded. ►DNA denaturation

DNA Density: (see Fig. D67) ►density gradient centrifugation, ►ultracentrifugation

Figure D67. DNA density

DNA Density Shift: This may occur if heavy isotopes (^{13}C or ^{15}N) or 5-bromodeoxyuridine is incorporated into the DNA during replication, replacing the normal atoms or nucleotides.

DNA Dependent Protein Kinase: ►DNA-PK

DNA-Dependent RNA Polymerase: It uses DNA template for the synthesis of RNA. ►transcription

DNA Diagnostics: ►prenatal analysis, ►genetic screening

DNA Driven Hybridization: In the molecular hybridization medium the DNA is in excess relative to RNA. ►DNA hybridization

DNA Extraction: There are a large number of procedures applicable to the major taxonomic groups. Only some basic outlines can be provided here. BACTERIA: 1. Grow bacteria in culture medium of choice to a high density (one to several days). 2. Harvest cells by centrifugation. 3. Lyse cell pellet in TE buffer (Tris-EDTA) containing SDS (sodium dodecyl sulfate) and proteinase K (free of DNase) at 37°C for an hour. 4. Make it 0.5 M for NaCl and add CTAB (cetyl trimethylammonium chloride) to precipitate cell wall,

polysaccharides, proteins, etc. but keep DNA in solution. 5. Add equal volume of chloroform:isoamyl alcohol and centrifuge to remove CTAB and polysaccharides. 6. Save supernatant. 7. Remove protein by phenol:chloroform:isoamyl alcohol and centrifuge. 8. From supernatant precipitate DNA by isopropanol. 9. Wash the precipitated DNA with 70% ethanol. 10. Take up DNA in TE buffer and store it in refrigerator. PLANTS: 1. Use 10–50 g clean young tissue (from plants which have been kept in dark for 2 days to reduce starch). 2. Grind it to powder in liquid nitrogen. 3. Extract DNA in pH 8 Tris-EDTA buffer containing a detergent (SDS or Sarkosyl) for about 1 to 2 h at 55°C. 4. Pellet debris by centrifugation at 4°C (6,000 rpm, 10 min) and collect supernatant DNA. 5. Precipitate DNA from supernatant by 0.6 volume cold isopropanol (–20°C) by centrifugation (8,000–10,000 rpm, 4°C, 15 min). 6. Pellet is taken up in TE buffer. MAMMALIAN TISSUES: 1. Tissue or cell pellet (0.2–1 g) washed clean, and powdered in frozen liquid nitrogen. 2. Lysis of cells (in NaCl, Tris buffer, EDTA, SDS, pH 8, proteinase K). 3. Extraction of DNA in phenol:chloroform:isoamyl alcohol and centrifuge (10 min, 10,000 rpm). 4. To supernatant add 0.5 vol. 7.5 M ammonium acetate and 2 vol. cold ethanol to precipitate DNA by centrifugation (2 min, 5,000 rpm). 5. Wash DNA by 70% ethanol. 6. Suspend DNA in TE buffer. All of the above procedures are very similar. Further purification may be necessary by ultracentrifugation in CsCl. Quantity may be determined on the basis of absorption of ultraviolet light of 260 nm (quartz cuvettes) in a spectrophotometer. In a reasonably pure DNA preparation the ratio of OD260: OD280 is about 2:1. One OD is about 50 µg/mL for double-stranded DNA and 40 µg/mL for single-stranded DNA; 1 pg DNA is about 6.5×10^{11} Da. ►centrifuge, ►ultracentrifuge, ►spectrophotometer, ►SDS, ►Sarkosyl, ►TE buffer, ►EDTA, ►CTAB, ►Tris, ►proteinase K

DNA Fingerprinting: has been developed since the 1980s as a molecular tool for the genetic specification of an individual, a taxonomic, or other related groups (see Fig. D68). DNA fingerprinting is an important tool for the study of evolution, for establishing the degree of relatedness of genetic stocks, and its application is relevant to civil and criminal court decisions requiring identifications with high precision(see Fig. D69). The perfect definition of identity would come from the complete sequencing of the genomes but that is not practical for routine purposes. The best approximation is to use Southern hybridization with some repetitive sequences as probes isolated from minisatellite DNAs of common occurrence in the eukaryotic genomes ►SINE

Figure D68. Minisatellite DNAs

D

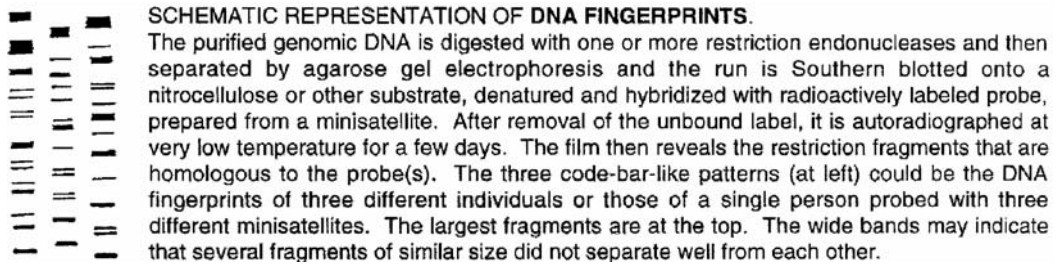

Figure D69. Schematic representation of DNA fingerprints

The first such probe was obtained from the four, 33 basepair repeats in the intron I of the human myoglobin gene. These repeats have a core sequence very similar to the *chi* elements that are responsible for meiotic recombination hot spots. These elements generate unequal crossingover at high frequency but are silent in the somatic cells. Because of this nature, they generate a high degree of specific genetic diversity. Actually, it appears that each individual is different from others (except monozygotic twins or clones). These minisatellite DNA sequences differ from each other but share the highly conserved core.

The minisatellites are distributed widely in the human (and other eukaryotic genomes) within the chromosomes. In addition to the minisatellite probes, microsatellites can also be used.

These are generally mononucleotide to tetranucleotide repeats, occurring very frequently and dispersed in the eukaryotic genomes. When isolated genomic DNA is digested with one or more restriction endonuclease(s), separated by agarose gel electrophoresis, Southern blotted and hybridized to minisatellite probes that are radioactively labeled, the autoradiograms appear similar to the diagram. The total DNA without probes cannot be used because its quantity and complexity is too large and the individual bands cannot be distinguished because many of them share the same or almost the same position in the gel. Such a gel would not appear cross-banded but it would look like a smear. Generally, the bottom of probed gels contains a larger number of small fragments that are barely or not separated (not shown in the diagram). For the analyses, fresh DNA samples are preferred because in older specimens degradation may take place and the larger fragments (closer to the start point [top]) become very weak or

vanish. However, some fingerprinting may be feasible in frozen flesh or in over 2000 year-old mummies. In the same gel, appropriate full range molecular size markers are also run at both sides to facilitate identification of fragment length with appropriate accuracy. The fragment length estimated on the basis of mobility in the gel compared to that of a corresponding size marker might have an error of 3–4%.

If one assumes that apparently co-migrating bands in the gels of A and B individuals represent identical alleles of the same minisatellite locus, the probability x that an allele in A is also present in B is proportional to the frequency of that allele according to $x = 2q - q^2$. If the frequency of the allele in the homozygotes is low then, the mean probability, $\hat{x} \approx \hat{q}^2$. Also if it is assumed that there is little variance among allelic frequencies, then the number of alleles $n \approx 1/\hat{q}$ and the mean homozygosity is approximately $\sum_i^n q_i^2 \approx n\hat{q}^2 = \hat{q}$. A certain propor-

tion of the co-migrating bands in A and B belong to different minisatellite loci, and the estimates of mean allele frequency and homozygosity so estimated are maximal, and the true estimates will depend on the accuracy of the resolution and estimation of the size of the fragments in the gels. The mean probability that all fragments detected by probe 33.15 (see Table D3) is also present in individual B is $0.08^{2.9} \times 0.20^{5.1} \times 0.27^{6.7} \cong 2.78 \times 10^{-11}$. (Note that the probabilities were raised to the power of the corresponding mean fragment number). Because the current population of the earth is about 6×10^9 , about more than 50-fold increase in the current population would be needed to find perhaps two individuals with identical genetic constitution. The precision of the analysis is further

Table D3. In an experiment with 20 Englishmen, the following information was obtained. (Data and methods of calculations after A. J. Jeffreys, et al. 1985. *Nature* 316:76)

| DNA Fragment Size, kb | No. of Fragments M \pm Standard Deviation per Individual | | Probability x That Fragment in A Individual Is Present in B Individual | | Max. Mean Allelic Frequency per Heterozygosity | |
|-----------------------|--|---------------|--|-------|--|-------|
| ↓ | Probes–33.6 | 33.15 | 33.6 | 33.15 | 33.6 | 33.15 |
| 10–20 | 2.8 \pm 1.0 | 2.9 \pm 1.0 | 0.11 | 0.08 | 0.06 | 0.04 |
| 6–10 | 5.1 \pm 1.3 | 5.1 \pm 1.1 | 0.18 | 0.20 | 0.09 | 0.10 |
| 4–6 | 5.9 \pm 1.6 | 6.7 \pm 1.2 | 0.28 | 0.27 | 0.14 | 0.14 |

improved by the use of several probes. In the American forensic laboratory practice four or five probes are used that detect only two allelic variations each, and making the precise reading of the bands easier because only two are shown by each run. This type of analysis still provides 99.9% accuracy for determining the identity of a person. The power of this procedure is also indicated by the fact that 0.5 to 5 μ g DNA (present in a drop of blood, in a few thousands of cells) may be enough for an RFLP test. The procedure described above is the DNA fingerprinting or RFLP (restriction fragment length polymorphism). RFLP has superior analytical value to PCR because the former is based on the entire DNA whereas in the latter only fragments of the DNA are amplified.

If RFLP is coupled with say 200,000-fold amplification of a sample using PCR, its efficiency may be further increased. The DNA sample prior to amplification may be as low as 500 pg (0.5 ng), however, somewhat larger quantities (2 ng) may give better results. The most efficient techniques may permit DNA analysis from palm swabs, briefcase handles or telephone handles, gloves, coffee mugs, etc. A single PCR amplification does not, however, deal with an entire genome-size DNA but only with an extremely small fragment, defined by the two 5'-terminal primers. By the use of Taq DNA polymerase, starting with pg quantities of DNA of 2 kb in length can be increased up to 1 μ g in 30–35 cycles, and after dilution it can be subjected to even further amplification. For RFLP tests, not just larger quantities of the DNA are required but it must be fresh or non-degraded. PCR analysis can be carried out not just with more minute samples, but some degradation may not prevent its suitability for the test. For forensic PCR tests, generally the DNA of the second exon of the human leukocyte antigen (HLA)-DQ- α is used most commonly. Actually one test kit, *Amplitype HLA-DQ-alpha Forensic Kit*, marketed by the Perkin-Elmer Company is commercially available. This procedure has an accuracy of 98–99% but a newer PCR procedure, the *Poly-Marker Test* (PM)

is supposed to have up to 99.7% precision. The PCR methods use dot blot hybridization and fluorochrome labels that eliminate the waiting period involved in exposing the Southern blot to X-ray film. The Amplitype relies on differences in six allelic types (n) that determine 21 different genotypes according to the general formula $[n(n+1)]/2$. The PCR method is less accurate than the RFLP test but its value can approach that of the latter by the use of larger number of probes. In both types of assays, the proper statistical procedure is very important. The power of the statistics depends on databases revealing the frequencies of the allelic variations in the general or ethnic populations, so the genotype of the individual to be tested can be compared to other similar or identical types. In other words, the statistics will tell the probability of how many other individuals may have the same DNA fingerprint as the suspect. In court, then along with the DNA fingerprints, other evidence is considered that may further improve identification (such as dermatoglyphics, alibi, time frame, etc.).

For DNA fingerprinting a variable section of the mitochondrial DNA can also be successfully used. Since the size of this DNA is more limited than that of the nuclear DNA fragments, the potential information to be gained is less.

DNA fingerprinting can identify with great certainty members of a biological family. If the total number of identifiable bands of putative mother (M) and father (F) is T and of that n is shared by offspring (O), then the probability that (O) would share all the bands in common between (M) and (F) is Y^T where $Y = 1 - (1 - x)^2$ [for the definition of x see above]. The probability that (O) would share the specific maternal or the specific paternal fragments is x^{Mf} and x^{Ff} where Mf and Ff are the number of mother- or father-specific fragments. The use of DNA evidence in the criminal courts have been questioned on statistical grounds and because some of the crime or biological laboratory contractors may have based unwarranted conclusions on poorly performed and/or incompetently evaluated DNA tests. The statistical

D

arguments brought forward are as follows. If the only evidence is the DNA profile and the probability of match for a particular individual is $1/1,000,000$ but there may be 500,000 individuals who could be responsible for the case if the DNA evidence is not considered. There are then two possibilities: either the suspect is the criminal and he displays a perfect match to the DNA sample collected at the crime scene or another individual among the other 500,000 is the criminal and the DNA analyses match only by chance. The probability for the first case is $1/(500,001) \times 1 = 0.000001999$. The probability for the second case is $500,000 \times (1/500,001) \times (1/1,000,000) = 0.000,000999$. Since the ratio of these two fractions is about 0.5, and $1.5/0.5 = 3$. Thus, the statistical chance that the suspect is innocent is $1/3 \approx 0.33$. These methods are particularly useful to rule out identity, i.e., rule out that the blood, semen or tissue sample left at the crime scene did not come from a particular suspect or that a particular person may not be a relative to an individual. Positive identification is also likely at an extremely high probability. The technology and the experience of the technicians have improved since the 1980s. Also, the removal of contaminants from the specimens (sulfur, dyes of the clothing, etc.) may be facilitated by new procedures of purification of the DNA. Several of the commercial testing laboratories follow the guidelines recommended by the *Technical Working Group on DNA Analysis Methods* (TWIGDAM). The greatest care is still required in the use of these powerful techniques because in murder trials life or death of the suspects may depend on the correct identification. There are still some questions regarding the best procedures and the acceptance of DNA fingerprints and its statistical evaluation as evidence in the different courts of the USA. The best statistical procedures for the criminal justice system should be to determine the ratio of the conditional probabilities (Pr) of the claims of the prosecution (C) and the defense (C') based on the evidence (E) as $Pr(E|C)/Pr(E|C')$. Currently—because of the great facility of accurate identifications—DNA fingerprinting is the most effective identification system in forensic repertory. DNA fingerprinting has wide applicability outside of the judicial system for identification of modern or ancient biological samples.

Comparison of the diploid set of DNA of Craig Venter and the National Center for Biotechnology Information human reference assembly revealed more than 4.1 million DNA variants, encompassing 12.3 Mb. These variants (of which 1,288,319 were novel) included 3,213,401 single nucleotide polymorphisms (SNPs), 53,823 block substitutions (2–206 bp), 292,102 heterozygous insertion/deletion events (indels)(1–571 bp), 559,473 homozygous

indels (1–82,711 bp), 90 inversions, as well as numerous segmental duplications and copy number variation regions. Non-SNP DNA variation accounts for 22% of all events identified in the donor, however, they involve 74% of all variant bases. Genotyping and cluster analysis of 750 unique SNP loci discovered showed that the donor's 99.5% similarity to individuals of European descent and it could be further corroborated by an extensive five-generation family history. The donor was found to be heterozygous for variants in the KL gene that have been associated with a lower risk for coronary artery disease. However, the donor was found to be also homozygous for the 5A/5A in rs3025058 in the promoter of the matrix metalloproteinase-3 that was associated with higher intra-arterial levels of stromelysin and has a higher risk of acute myocardial infarction. Furthermore, the donor displayed heterozygosity for the GSTM1 gene, which may increase susceptibility to environmental toxins and carcinogens. A 4-bp novel heterozygous deletion was found in Acyl-CoA Oxidase 2 (ACOX2) causing a protein truncation. ACOX2 encodes an enzyme activity found in peroxisomes and associates intimately with lipid metabolism and further was found to be absent from livers of patients with Zellweger syndrome. The donor's LCT genotype should confer adult lactose tolerance (Levy S, Sutton G, Ng PC, Feuk L, Halpern AL et al 2007 PLoS Biol 5[10]: e254).

The mammalian mitochondrial DNA D loop is rich in variable base substitutions. In addition, the copy number of this DNA is very large making its analysis rewarding even from samples highly degraded such as in exhumed corpses or ancient DNA. In such instances, DNA amplification is usually required. More recently, techniques are being developed that permit DNA typing from single cells. Essentially the same total DNA procedures have been used for the analysis of feral populations of animals, for anthropological studies, on ancient biological samples, to check the authenticity of cell cultures or plant varieties, etc. DNA fingerprinting has been used for the generation of sequencing-ready large insert BAC or PAC clones (Marra MA et al 1997 Genome Res 7:1072). The inserts are labeled by ESTs and connected by chromosome walking. ►fingerprinting, ►bisulfite reaction, ►minisatellite, ►microsatellite, ►VNTR, ►MVR, ►ceiling principle, ►forensic genetics, ►Southern blotting, ►dot blot, ►nick translation, ►gel electrophoresis, ►PCR, ►RFLP, ►phylogenetic analysis, ►mtDNA, ►probe, ►SINE, ►myoglobin, ►intron, ►chi elements, ►labeling, ►fluorochrome, ►autoradiography, ►electrophoresis, ►molecular marker, ►allelic frequencies, ►HLA, ►feral, ►mtDNA, ►Bayes' theorem, ►conditional probability, ►Romanovs, ►heteroplasmy,

DNA Flap: A stable 99-nucleotide overlap in the center of the HIV-1 reverse transcription-generated DNA. HIV-1 synthesizes the DNA as two discrete half-genomic segments. A central polypurine sequence initiates the synthesis of the downstream part of the (+)-strand. The upstream tract of the (+)-strand is initiated at the 3'-end of the polypurine, proceeds until the center of the genome and terminates after a discrete strand displacement. This event of the reverse transcription is mediated by the central termination sequence that removes at this stage the HIV reverse transcriptase. Thus, the final product of the (+)-strand replication of the linear DNA has an overlap or flap. The integrity of the polypurine tract and the central termination sequence are essential for the retroviral life and the flap is also involved in the nuclear import of the HIV-1 genome. ►acquired immunodeficiency, ►lentiviruses; Whitwam T et al 2001 J Virol 75:9407.

DNA Forms: Form I is superhelical and circular, II nicked circular, III linear. These conformational states affect electrophoretic mobility in gels. ►nick, ►electrophoresis

DNA Function: Music of Life—representation of transcription, translation, metabolism and replication in musical terms. German composer Thilo Krigar is creating DNA functions in concert: <http://www.dna-in-concert.de>.

DNA, Genomic: Natural and complete nucleotide sequences of genes, introns included.

DNA Glycosylase: ►glycosylase

DNA Grooves: B DNA double helix displays a 3.4 nm pitch including a wider (major) and a narrower (minor) groove (furrow) along its helical structure. Molecules that specifically recognize base pairs in the major or minor groove provide means of regulation of gene activity. The various binding proteins and transcription factors have been and are still thoroughly investigated but so far, no general recognition system between nucleotide base (pairs) and amino acids are known. The four base pairs (A·T, T·A, G·C, C·G) may be distinguished in the major groove on the basis of hydrogen binding properties (see Fig. D70).

Oligonucleotides may recognize the double helix and form triple helix structures but do not provide sufficient single base (pair) specificity. Some antibiotics (such as distamycin [$C_{22}H_{27}N_9O_4$]) modified by replacing the pyrrole (Py) rings with an imidazole (Im) ring provided limited ability to recognize G·C

pairs. Two distamycins effectively recognize, however side-by-side A·T sequences in the minor groove. In 1998, new recognition codes were reported capable of distinguishing all four base pairs in the minor groove: Py/Im→ C·G, Im/Py→ G·C, Hydroxypyrrole (Hp)/Py→ T·A and Py/Hp→ A·T. This development does not provide discrimination among human genes because for that 17 base pairs would be needed. By further progress new approaches may, however be opened not just to gene regulation but also for drug design. ►DNA types, ►pitch, ►Watson and Crick model; Hélène C 1998 Nature [Lond] 391:436; White S et al *ibid.* 468.

Figure D70. DNA grooves. Two major and one minor groove are shown in this space-filling model of DNA

DNA Gyrase: A DNA-binding protein, a topoisomerase, controlling coiling, site-specific nicking, and it is functional in replication, transcription, recombination and DNA repair. These enzymes are members of the DNA topoisomerase family. ►topoisomerase, ►nick; structure: Costenaro; L et al 2005 Structure 13:287.

DNA, Heavy Chain: The chains of a DNA duplex can be separated and annealed with poly-inosine-guanine (PI-G). The chains rich in cytosine bind more of PI-G and form a heavier band and sediment faster upon ultracentrifugation in CsCl. Therefore, it is called heavy or C chain whereas the complementary chain is called light chain (W). The density of DNA can be increased also by substituting bromodeoxyuridine in place of thymidine or by (N^{15} or C^{13}) heavy isotopes. ►bromouracil, ►ultracentrifuge

DNA Heteroduplex: ►heteroduplex, ►models of recombination

DNA Hybridization: Annealing single-stranded DNA with complementary single-stranded DNA or RNA either for measuring the degree of homology or for labeling it before selective isolation. Either hybridization can be carried out in a solution or with DNA immobilized on a membrane filter (Southern blots) or in situ, in denatured chromosomes or in microbial colonies (dot blots). The material intended for hybridization is labeled either radioactively (3H , ^{14}C , ^{32}P) or with biotin and fluorescent dyes. ►chromosome painting, ►FISH, ►in situ hybridization, ►Southern blotting, ►Grunstein–Hogness screening, ►Benton–Davis plaque hybridization,

►Northern blot; Marmur D, Lane J 1960 Proc Natl Acad Sci USA 46:453; Doty P et al 1960 Proc Natl Acad Sci USA 46:461; Hall BD, Spiegelman S 1961 Proc Natl Acad Sci USA 47:137.

DNA Immunization: ►immunization genetic, <http://www.genweb.com/Dnavax/dnavax.html>.

DNA Index: It reveals the amount of DNA in a cell relative to pre-S phase diploid cell (= 1). ►cell cycle

DNA Isolation: ►DNA extraction

DNA Junction: Three-way or four-way arrangements are generated by recombination (Holliday junction) or repair of the DNA (see Fig. D71).

Figure D71. DNA junction. One type of three-way junction. (Modified after Assenberg R et al 2002 Nucleic Acids Res 30:5142)

DNA Kinking: The regulation of transcription depends on protein-induced localized modification of the DNA structure (bending). This modification depends on the nature of the proteins recruited for the tasks and the base sequences in the DNA. The bases stacked in the major and minor grooves ('the rungs') of the helix may cause four major categories of architectural alterations relative to each other: (1) twist [slight rotation of the rung], (2) roll [slightly lifting the broader side of a rung], (3) tilt [uplifting the rung at one side], and (4) rise [slipping the rungs away from each other]. The elastic properties of the DNA determine how it is wrapped around histones in the nucleosomal structure, the packing of phage DNA into capsids, super-coiling, DNA looping, etc. These changes are reversible and depend on the physical environment of the DNA. ►nucleosome, ►super-coiling, ►DNA looping, ►triple helix formation, ►DNA bending; Beylot B, Spassky A 2001 J Biol Chem 276:25243.

DNA Knots: Catenated (interlocking ring) DNA. ►catenated, ►catenene, ►knotted circle; Podtelezhnikov AA et al 1999 Proc Natl Acad Sci USA 96:12974.

DNA Library: A collection of restriction endonuclease-generated fragments, each containing different segments of the genome. ►restriction enzyme, ►fragment recovery probability

DNA Ligases: Enzymes joining DNA termini in the cell nucleus. DNA ligase I (125 kDa) is the most important ligase in animal cells, DNA ligase II (72 kDa) and DNA ligase III (100 kDa) have minor role in mammalian cells. DNA ligase IV mediates joining of the ends of DNA in eukaryotic non-homologous recombination. Other organisms have different DNA ligases. Bloom's syndrome and acute lymphoblastic leukemia are caused by DNA ligase deficiency. ►vectors, ►Bloom's syndrome, ►lymphoblastic leukemia, ►deoxyribozyme, ►non-homologous recombination, ►Ku, ►double-strand break; Bentley D et al 1996 Nature Genet 13:489; Pierce AJ, Jasin M 2001 Molecular Cell 8:1160; DNA ligase I structure: Pascal JM et al 2004 Nature [Lond] 432:473, history of discovery: Kresge N et al 2007 J Biol Chem 282(2):e1.

DNA, Light Chain: ►DNA, ►heavy chain

DNA Likelihood Method: A type of maximum likelihood procedure for the calculation of branch length in evolutionary trees. ►evolutionary distance, ►evolutionary tree, ►unrooted evolutionary trees, ►least square methods, ►neighbor joining method, ►four-cluster analysis, ►minimum evolution methods

DNA Looping: ►looping of DNA, ►LCR

DNA Machine: A short DNA sequence capable of binding to protein/proteins and thus regulating gene expression.

DNA Markers: Special isolated or identified DNA sequences such as restriction fragments, RAPDS, microsatellites, minisatellites, EST and other sequences which can be used as probes or followed by molecular or genetic/molecular analysis. terms under separate entries.

DNA Methylation: ►methylation of DNA

DNA Methyltransferase (DNMT): ►methyltransferase DNA, ►methylation of DNA

DNA Microarray: ►DNA chips, ►microarray hybridization

DNA Mobility Shift: ►gel retardation assay

DNA Modification: ►methylation of DNA, ►restriction enzymes, ►5-azacytidine

DNA Mutation: ►mutation spontaneous

DNA, Native: The hydrogen bonds between the two strands are intact. ▶[Watson and Crick](#)

DNA Nicking and Closing: ▶[topoisomerases](#)

DNA, Non-Genic: ▶[non-genic DNA](#)

DNA, Nonpermuted: A nonpermuted DNA is terminally redundant, e.g., 123456789012 and all molecules have the same sequence. ▶[DNA permuted](#)

DNA Overhang: In a double-stranded DNA one of the chains protrudes at the end as shown. Such a structure is frequently generated by restriction endonuclease cuts (see Fig. D72). ▶[restriction enzyme](#)

Figure D72. DNA overhang

DNA Packaging: The insertion of a piece of (concatameric) DNA into a phage capsid. ▶[packaging of DNA](#), ▶[packing ratio](#), ▶[condensation of chromosomes](#)

DNA Pairing: The formation of hydrogen bonds between complementary bases of two single-stranded DNA. ▶[DNA](#), ▶[Watson and Crick model](#), ▶[hydrogen pairing](#)

DNA Passenger: ▶[passenger DNA](#)

DNA, Permuted: Phage DNA may be repetitious as the concatameric molecules cut off at different positions but to the same length. Therefore, collections of these molecules may appear (with numbers substituted for nucleotides). ▶[DNA non-permuted](#), ▶[redundant Permuted sequences](#)

DNA Photolyase: It splits pyrimidine dimers during direct repair. DNA repair; ultraviolet light; pyrimidine dimer; cyclobutane dimer; cryptochromes.

DNA Polarity: The first base in a DNA chain has a 5' phosphate (triphosphate) at the beginning and the subsequent bases are added to it at the 3'-OH position (see Fig. D73). From the nucleotide triphosphate, two phosphates are removed and the third one (α group) forms a phosphodiester linkage with the first one. Thus the chain growth is $3' \leftarrow 5'$. The complementary DNA chain also has polarity and the two run antiparallel

Figure D73. Opposite polarity

DNA Polymerases: prokaryotes and eukaryotes have several DNA polymerase enzymes with polymerase (and exonuclease) functions (see Tables D4 and D5).

DNA pol III holoenzyme forms a particle of 10 subunits, and it is responsible for the replication of the prokaryotic chromosome. The T7 phage DNA polymerase, encoded by gene 5 is 80 kDa. It associates with the bacterial-coded thioredoxin and polymerizes thousands of nucleotides. It also requires the hexameric protein DNA polymerase III holoenzyme and forms a particle of 10 subunits and it is responsible for the replication of the prokaryotic chromosome.

Prokaryotic DNA polymerase III displays no similarity with other polymerases yet the crystal structure of its active site is similar to DNA polymerase β and nucleotidyltransferases (Lamers MH et al 2006 Cell 126:881). The T7 phage DNA polymerase, encoded by gene 5 is 80 kDa. It associates with the bacterial-coded thioredoxin and polymerizes thousands of nucleotides. It also requires the hexameric protein of T7 primase-helicase and a T7 single-strand binding protein that controls at the replication fork the synthesis of the leading and lagging strands. Prokaryotic DNA polymerases IV (DinB) and V (UmuD₂ complex) enzymes have mutator function in the SOS repair pathway. The

| 5'→3' exonuclease | No 5'→3' exonuclease | None |

majority of the pol IV mutations are small deletions (Kobayashi S et al 2002 J Biol Chem 277:34087). *Saccharomyces cerevisiae* pol δ with a methionine (M) replacing conserved leucine (L) 612 at the polymerase active site has normal processivity and slightly higher polymerase specific activity. The substitution mutant L612M pol δ also has normal 3' exonuclease activity, yet it is impaired in partitioning mismatches to the exonuclease active site, thereby reducing DNA synthesis fidelity. Error rates in vitro for L612M pol δ are elevated for both base substitutions and single base deletions but in a highly biased manner (McElhinny SAN et al 2007 J Biol Chem 282:2324).

Recently, **pol ζ** was discovered in yeast (Rev3, Rev7); it does not have 3'→5' exonuclease function although it is a repair enzyme that can bypass more efficiently thymine dimers than the other polymerases. Pol ζ is error-prone, yet it has an essential role during the development of mouse embryos. DNA **pol η** (encoded by gene RAD30) of yeast has function similar to pol ζ but it is distinct from it.

Pol η bypasses cis-syn thymine dimers efficiently and accurately. **Pol ι** (iota) has a high rate of misincorporation of deoxynucleotides opposite especially across pyrimidines. The human Pol ι requires Hoogsteen base pairing for correct replication (Johnson RE et al 2005 Proc Natl Acad Sci USA 102: 10466). DNA pol ζ immediately follows and extends the misrepair although it alone does not insert mispaired bases. Pol ι also has base excision repair activity. DNA polymerase **pol θ** , cannot bypass thymine dimers or 6-4 photoproducts or abasic sites. Its error rate with deoxyribonucleotides is 10^{-3} to 10^{-4} . It incorporates two adenines opposite the thymine dimer. It is also responsible for C/G mutations during somatic hypermutation of immunoglobulin G genes (Masuda K et al 2005 Proc Natl Acad Sci USA 102:13986). Special DNA polymerases are the telomerase and the terminal nucleotide transferase. **Polymerase κ** is essential for DNA replication of

yeast and humans, along with pol α , δ and ϵ , and it mediates sister chromatid cohesion. Enzyme pol κ , with some homology to pol β , in cooperation with other proteins mediates also in DNA repair. **Polymerase λ** is involved in base excision repair. **Polymerase μ** mediates non-homologous end joining. **Polymerase σ** has a function in sister chromatid cohesion. **REV1** polymerase mediates bypass synthesis and **TdT** is involved in antigen receptor diversity. Pol5 (**DNA polymerase ϕ**) of yeast is localized in the nucleolus and it is involved in the synthesis of rRNA (Shimizu K et al 2002 Proc Natl Acad Sci USA 99:9133). The human genome encodes at least 15 DNA polymerases (see Fig. D74).

The catalytic domains of the DNA polymerases are well conserved although the other structural domains are variable. Improved processivity for PCR can be conveyed to DNA polymerase by fusing the enzymes to double-strand-binding proteins (see Fig. D75) (Wang Y et al 2004 Nucleic Acids Res 32:1197). This modification does not reduce catalytic activity of enzyme stability ▶**pol enzymes**, ▶**DNA replication in eukaryotes and prokaryotes**, ▶**recombination**, ▶**DNA repair**, ▶**mutator genes**, ▶**ABC excinucleases**, ▶**reverse transcription**, ▶**PCNA**, ▶**sliding clamp**, ▶**replication fork**, ▶**replisome**, ▶**telomerase**, ▶**terminal nucleotidyl transferase**, ▶**thymine dimer**, ▶**DNA repair**, ▶**reverse transcriptases**, ▶**cis-syn dimer**, ▶**DNA repair**, ▶**error-prone repair**, ▶**X-family of DNA polymerases**, ▶**Y-family of DNA polymerases**, ▶**sister chromatid cohesion**; Patel PH; Loeb LA 2000 Proc Natl Acad Sci USA 97:5095; Zhang Y et al 2000 Nucleic Acids Res 28:4147; Zhang Y et al 2001 Nucleic Acid Res 29:928; Guo D et al 2001 Nucleic Acid Res 29:2875; Glover BP, McHenry CS 2001 Cell 105:925; Sutton MD, Walker GC 2001 Proc Natl Acad Sci USA 98:8342; Burgers PMJ et al 2001 J Biol Chem 276:43487; Hübscher U et al 2002 Annu Rev Biochem 71:133; Rattray AJ, Strathern JN 2003 Annu Rev Genet 37:31.

DNA Repair: It may be brought about by different mechanisms. The frequency of single-strand breaks/Gy is about 25 times higher than that of double strands of DNA. The bulk of information is available from prokaryotic systems. The direct repair and the excision repair systems are error free because in the former, no new DNA synthesis is required and in the latter the undamaged DNA strand provides a normal template so there is no increase in errors beyond the normal level for the polymerase involved. The *SOS repair* is an error-prone repair mechanism that is operating when structural distortions block the path of the regular DNA polymerase and the enzyme is stalled and in the distress (lacking appropriate template), incorporates nucleotides in an unorthodox manner thus leading to mutation.

I. DIRECT REPAIR systems remove pyrimidine dimers (cyclobutane dimers) by activating splitting enzymes, photolyases, upon exposure to visible light (Light repair). These enzymes contain chromophore cofactors, such as reduced flavin adenine dinucleotide (FADH₂) and folate to absorb light. The *Bacillus subtilis* spore photoproduct lyase breaks between C–C bonds of 5-thymine-5,6-dihydrothymine, rather than cyclobutane dimers. Another direct repair enzyme is O⁶-methylguanine methyltransferase that

accepts at a cysteine site an O⁶ alkyl group from mutated guanylic acid or other methylated bases and restores the normal purine at the expense of its own inactivation. Direct repair does not involve any “unscheduled” DNA synthesis. Prokaryotes have two, mammals have only one repair methyltransferase.

D

II. EXCISION REPAIR SYSTEMS involve various and limited amounts of unscheduled DNA synthesis. 1. *Mismatch repair*: MutS protein binds to various mismatched bases. MutH protein binds to a GATC tract in the DNA and MutL protein links the other proteins into a repair complex. The dam methylase (*dam*) enzyme recognizes the old DNA strand at replication and methylates it at a C site within the 5'-GATC tract. At that time, the nascent DNA strand is still unmethylated. Mismatches are recognized (G–T well, C–C, poorly) and repaired within a 1 kb range of the GATC sequence as long as the new strand is not yet methylated. The MutH protein is an endonuclease that cuts 5' to GATC. The nicked strand then unwinds with assistance of helicase II (*uvrD* gene product). A single-strand binding protein (SSB, *ssb*) braces the site, and the defective single strand is sliced off 3' to 5' by exonuclease I (*sbcB*) through the defect. On the 3' side of GATC the mismatch is removed either by exonuclease VII or *recJ* 5' to 3' exonuclease. Then DNA polymerases (*pol I*, *pol II* or *pol III*) repair the gap and the new ends are ligated (*dnaL*). 2. *Base excision repair* (BER): cutting the N-glycosyl bonds by DNA glycosylases and leaving behind apurinic and apyrimidinic (AP) sites lifts defective bases out. The glycosylases remove deaminated cytosine (= uracil), deaminated adenine (= hypoxanthine) bases alkylated by alkylating mutagens, etc. Hydrolytic deamination of cytosine may occur 100 to 500 times per day in a human cell and 5-methylcytosine may be deaminated about 3-times more frequently (Shen JC et al 1994 *Nucleic Acids Res* 22:972). Genes *ada* and *alkA* of prokaryotes are involved. After the base is removed, AP endonucleases cut out the deoxyribose phosphates and possibly more nucleotides. The BER pathway corrects more than 10⁴ lesions daily in each human cell. In humans, several glycosylases have been mapped ►[glycosylases](#). The gap is filled in by pol I or pol β and ligation completes the repair process. Pol β is a highly error-prone polymerase. In mammalian cells, apurinic/apyrimidinic nuclease (APE1) may correct the process by exonucleolytically removing the incorrect bases from the ends (Chou KM, Cheng Y-C 2002 *Nature [Lond]* 415:655). Some of the uridines in the DNA may be the results of replicational errors or by deamination of C. Uridine nucleotide glycosylase (UNG) also plays important role in generating antibody diversity and cancer (Rada C et al 2002

Current Biol 12:1748). Another enzyme SMUG, with little homology to UNG, also has uracil-DNA glycosylase activity with preference to single-stranded DNA (Haushalter KA et al 1999 *Current Biol* 9:1743). Thymine-DNA glycosylase (TDG) excises from T:G mispairs. In mammalian cells, about a dozen different glycosylases are known. Oxidative damage to guanine may commonly produce 8-oxoguanine, which also requires removal. The MYH DNA glycosylase removes adenine from 8-oxoguanine:A mispairs (Fromme JC et al 2004 *Nature [Lond]* 427:652). Mut T-encoded hydrolase removes 8-oxo-deoxyguaninetriphosphates from the nucleotide pool. 3-methyl-DNA glycosylases (MPG) remove methylated purines, importantly me-A, which is very toxic. Transfer of the methyl group to cysteine residues by a specific methyltransferase repairs the highly mutagenic O⁶-meG. Mammalian cells have dioxygenases, which demethylate 1-methyl adenine and 3-methyl cytosine (Duncan T et al 2002 *Proc Natl Acad Sci USA* 99:16660). Oxidases are known which remove oxidized pyrimidines. The prokaryotic pol I has an intrinsic proof-reading exonuclease activity. The BER repair depends on the relative activities of APE, ARP and POL β , various replication factor proteins in a sequential manner and finally on DNA ligase (Sukhanova MV et al 2005 *Nucleic Acids Res* 33:1222). 3. *Nucleotide excision repair* (NER): damages to the DNA involving longer tracts are cut at two sites by the ABC excinuclease system and the intervening sequences are removed. This complex is encoded by genes *uvrA* (coding for the ATPase subunit of endonucleases), *uvrB* and *uvrC* (coding for the endonuclease subunits) of the excinuclease of *E. coli*. UvrD is a helicase that releases the excised oligomer. DNA pol I carry out repair synthesis and the M_r 75 ligase ties the ends. Excision repair may involve just a few and up to a few thousands of nucleotides. The gaps are filled in by any of the four DNA polymerases of prokaryotes. The human excinuclease complex contains single or combined activities of 16 polypeptides. In humans, BER is the only mechanism to escape UV-caused genetic damage. 4. *Transcription-coupled repair*: is a type of excision repair when the pyrimidine dimers are more readily removed from the transcribed strand than from the non-transcribed strand. This type of repair may be coupled with the more common excision repair system (Svejstrup JQ 2002 *Nature Rev Mol Cell Biol* 3:21). Such a mechanism was first detected in *E. coli* but it turns out that the failure of this mechanism is the most common cause of base mismatches in colorectal human cancer. The vertebrate enzyme DNA polymerase β is involved in excision repair and in the release 5'-terminal

deoxyribose phosphates from incised apurinic-apyrimidinic sites. The repair is confined to the transcribed strand and in mammals to genes transcribed by pol II. In humans, there is a requirement for the transcription–repair coupling protein (TRC). The Cockayne syndrome is a defect of two TRC factors. *E. coli* also requires a TRCF encoded by *mfd* gene. The crystal structure of TRCF sheds light on its function (Deaconescu AM et al 2006 Cell 124:507). The human diseases Xeroderma pigmentosum F and Trichothiodystrophy are excision repair defects. Human DNA excision repair also requires XPA, a zinc finger protein and HSSB, a human single-strand binding protein, RPA another damage-recognition protein, the transcription factor TFIIH with multiple subunits of helicase, Zinc finger, kinase, and cyclin functions. Furthermore XPC, a ubiquitin, XPF (5' cut) and XPG (3' cut) nucleases, RFC an ATPase, PCNA, an auxiliary protein to DNA polymerase δ , repair polymerases ϵ/δ and DNA ligase are used (Sancar A 1996 Annu Rev Biochem 65:43; Wood RD 1996 Annu Rev Biochem 65:135).

III. SOS REPAIR is required when there is extensive damage to the DNA (presence of cyclobutane rings and adducts formed by UV light, cross-linking caused by chemical mutagens, etc.) that prevent the movement of the DNA polymerase III enzyme along the strands and the template cannot lend itself for accurate copying. The repair system is in distress and becomes error-prone. Shortly after the damage has taken place the activity of the RecA protein increases up to 50 times. Next, the LexA repressor is cleaved and that initiates the activity of a series of genes including the excinuclease system, *UmuC* and *UmuD* (repair functions), *hima* (with multiple functions in replication, recombination and regulation). The DinB prokaryotic and eukaryotic homologs make replication by polymerase IV error prone. Rad30A operates the error-free polymerase η that bypasses the UV lesions. Rev1 deoxycytidyl-transferase also assists in the bypass but it is error-prone. LexA repression targets a SOS box (containing a consensus CTG-N₁₀-CAG) in the vicinity of the promoter of its objects. Most commonly, dAMP is inserted opposite the abasic site. Eukaryotic DNA polymerase ζ and η can bypass pyrimidine dimers but pol ζ may be hypermutagenic. The SOS repair usually involves extensive DNA repair synthesis. SOS repair is considered to follow either the pathway of *damage avoidance* (DA), i.e., the complementary strand is used to rescue the blocked replication fork or by relies on *translesion synthesis* (TLS), i.e., the repair enzyme reads through the replication block. The block generated by the DNA-damaging agent determines the route of the SOS repair. In bacteria, the DNA polymerase V in the presence of protein UmuD',

RecA and a single-strand DNA binding protein produce point mutations at a frequency of 2.1×10^{-4} per nucleotide, an increase of ~40-fold over that of the effect of DNA polymerase III holoenzyme. About 53% of the mutations are transversions. ▶*translesion*; Johnson RE et al 1999 Proc Natl Acad Sci USA 96:12224; Sutton MD et al 2000 Annu Rev Genet 34:479; Aartsen A, Michiels CW 2006 Trends Microbiol 10:421.

IV. RECOMBINATIONAL REPAIR makes corrections by exchanging the defects with correct sequences through recombination (gene conversion). In double-stranded human DNA the observed breakage rate 5.8×10^{-3} /Mbp/Gy was found for both 80 and 160 Gy and about 75% rejoined correctly within 2 h (Lobrich M et al 1995 PNAS 92:12050). RecA/Rad51 and Rad52 (in yeast) have pivotal function in homologous recombination repair. Rad52 promotes the end-to-end joining of DNA. Ku70 and Ku80 proteins protect the ends from nuclease degradation. DNA ligase IV, XRCC, Mre11, Rad50 mediate repair of DNA double-strand breaks. Non-homologous DNA end-joining (NHEJ) requires the presence of DNA-dependent protein kinase, XRCC4 and ligase IV. NHEJ is generally necessary for V(D)J recombination in generating the appropriate immunoglobulins. In vertebrates, soon after double-strand breaks, histone H2AX is phosphorylated and this is followed by accumulation of repair proteins. Phosphorylation of H2A is followed by loss of H2B and H3 histones. Histone loss also requires the presence of MRX damage sensor and INO80 nucleosome remodeling complex. MRX and chromatin remodeling are required for efficient recombination (Tsukada T et al 2005 Nature [Lond] 438:379). At this stage nuclease-sensitivity is increased (see Fig. D76).

In *Drosophila*, chromosome breakage, induced by the P transposable element, is repaired by recombination and the efficiency of this repair is up to five times higher when the homologous sequence was syntenic within, at any position, of the X-chromosome rather than somewhere in trans position, in an autosome. In double-strand repair, the DNA remains in a fixed position within the nucleus and 30 min after the breakage the Mre repair enzyme moves to the site of the damage. In bacteriophage T4 DNA replication and double-strand break repair are closely coupled. ▶*histone variants*, ▶*MRX*, ▶*INO80*

Figure D76. Recombination repair

D

V. TRANSCRIPTION-COUPLED REPAIR. When RNA polymerase (RNAP) encounters DNA damage that blocks continuation of transcription the bacterial Mfd protein can remove the RNAP and it recruits nucleotide excision repair proteins to the defective site. Mfd can block transcription to prevent synthesis of RNA that would carry downstream defect. Mfd can also remove proteins that would block transcription and thus represses “roadblocks” and reinstates transcription (Smith AJ, Savery NJ 2005 *Nucleic Acids Res* 33:755).

►recombination, molecular mechanisms in prokaryotes, ►DNA polymerases, ►P element, ►Mre11, ►V(D)J, ►XRCC, ►RAD, ►DNA ligase, ►sister chromatid exchange, ►double-strand breaks, ►histone variants; Cox MM et al 2000 *Nature* 404:37; Cox MM 2001 *Proc Natl Acad Sci USA* 98:8173; George JW et al 2001 *Proc Natl Acad Sci USA* 98:8290; Bleuit JS et al 2001 *Proc Natl Acad Sci USA* 98: 8298; Kuzminov A 2001 *Proc Natl Acad Sci USA* 98:8461; Fukushima T et al 2001 *J Biol Chem* 276:44413.

Retrotransposons or parts of them may be inserted into double-strand breaks and heal the defects. It is not known how frequent such events may be, but most eukaryotic genomes have a large number of retrotransposon elements and this repair function may justify their evolutionary maintenance. Specialized retroposons such as HeT-A and TART of *Drosophila* or the Ty5 yeast element may use their reverse transcriptase and RNA template to heal telomeres in case the telomeres are shortened by aging or if breaks damage them. The repair mechanisms of eukaryotes are much less well understood than in prokaryotes. The numerous *RAD* genes of yeast control radiation responses and are involved in repair. Short-patch DNA repairs (such as damages caused by alkylating agents) requires the function of DNA polymerase β , a ubiquitous housekeeping enzyme. Repair of UV lesions involves DNA polymerase ϵ . For e.g., xeroderma pigmentosum F, a human hereditary condition controlled by several dominant and recessive genes the defect in excision repair of UV lesions may be connected with polymerase ϵ . It has been estimated that each cell under normal conditions loses more than 10,000 bases from the spontaneous breakdown of DNA, and the damaged spots have to be repaired. The efficiency of repair in eukaryotes depends on the time available before the onset of the S phase of the cell cycle. Proteins p53, p21, PCNA and other cellular proteins may have cell cycle-stalling functions. The efficiency of repair varies at different sites within a gene.

Generally, areas near active genes are more efficiently repaired than in inactive regions. The most rapid repair is found in the transcribed strands of

active genes. The DNA repair systems play a role also in the cell cycle and tumorigenesis. In 1994, *SCIENCE* magazine declared DNA repair enzymes the molecules of the year. DNA repair in eukaryotes is complicated by the nucleosomal organization of the chromatin. Progress in DNA sequencing identified ~130 genes involved in human DNA repair. (Wood RD et al 2001 *Science* 291:1284, *Biological Responses to DNA Damage* 2001 Cold Spring Harbor Symp Quant Biol Vol. 65).

Detection of DNA damage is important in mutation analysis, carcinogenesis, cancer therapy, and aging, etc. The nature of the lesions can vary from base modifications, strand breaks to DNA-protein and DNA-chemical crosslinks. Gas chromatography–mass spectrometry, high performance liquid chromatography, immunoassays, etc. have been used for the identification of modified bases. A newer method, using immunochemical recognition and capillary electrophoresis and laser-detected fluorescence detection may identify lesions with a limit of 3×10^{-21} moles is available (Le XC et al 1998 *Science* 280:1066). ►excision repair, ►glycosylases, ►X-ray repair, ►mismatch repair, ►bypass repair, ►radiation sensitivity, ►mutagenesis, ►DNA ligases, ►NA-PK, ►PCNA, ►p53, ►p21, ►xeroderma pigmentosum, ►ataxia telangiectasia, ►Fanconi anemia, ►Bloom syndrome, ►Cockayne syndrome, ►colorectal cancer, ►aging, ►RAD50, ►RAD28, ►Ku, ►NHEJ, ►TRCF, ►retrotransposons, ►retroposons, ►Ty, ►mating type determination in yeast, ►chromatin assembly factor, ►preferential repair, ►alkyltransferases, ►proofreading, ►postmeiotic segregation, ►photoreactivation, ►Mer⁻ phenotype, ►Mex, ►chromatography, ►capillary electrophoresis, ►laser, ►SNIPS, ►male recombination, ►HEI, ►UMU, ►translesion, ►SSB, ►RecA, ►DNA polymerases, ►Gy, ►mtDNA, ►XRCC, ►methylguanine-O⁶-methyltransferase, ►unscheduled DNA synthesis, ►PARP, ►RNA repair, ►SSA; Aravind L et al 1999 *Nucleic Acids Res* 27:1223; Kunkel TA, Bebenek K 2000 *Annu Rev Biochem* 69:497; Sutton MD, Walker GC 2001 *Proc Natl Acad Sci USA* 98:8342; Wood RD et al 2001 *Science* 291:1284; Friedberg EC et al 2002 *Science* 296:1627; Rattray AJ, Strathern JN 2003 *Annu Rev Genet* 37:31; Barnes DE, Lindahl T 2004 *Annu Rev Genet* 38:445, DNA double-strand repair: Wyman C, Kanaar R 2006 *Annu Rev Genet* 40:363, break and disease: McKinnon PJ, Caldecott K 2007 *Annu Rev Genomics Hum Genet* 8:37.

DNA Replication, Eukaryotes: The mechanism of replication in prokaryotes is better understood because more simple in vitro assay systems are available for the smaller DNAs. In yeast, the replicational origins are called ARS (*autonomously replicating sequences*). Although the genome of the eukaryote, *Saccharomyces cerevisiae* is only about 4 times larger than that of the prokaryote *E. coli*, the former has 400 replicational origins, each including about 300 bp. The yeast ARS are not identical with each other yet they have a short core sequence that is about 11 repeating A = T units. The single replicon of *E. coli* is over 4,000 kb but the yeast replicons are only about 40 kb. The speed of replication in yeast is about 3.6 kb/min but in *E. coli* it is almost 14 times as fast. In the large amphibian genome, it proceeds at a speed of about 1/7 of that of the yeast. If the replication of the toad DNA proceeds only 500 bp/min, it would take more than 20 years to complete an S phase when actually at the gastrula stage it takes about 4 to 5 h because the large genome relies on more than 15,000 replicons. Replication in eukaryotes just like in *E. coli*, proceeds bidirectionally and electron-microscopic examination detects a large number of replication “bubbles” or replication “eyes” that are actually the replicational origins. As the replication within a bubble nears completion the neighboring bubbles coalesce as replication is completed along the length of the chromosome (see Fig. [D77](#)). The molecular structure and function of the eukaryotic replication fork is best understood in the eukaryotic SV40 virus that has a 5,243-bp chromosome with nucleosomal organization.

Human and other mammalian cellular fractions combine with the large T antigen of SV40 and in a plasmid replicate the viral genome, indicating the similarities of the interchangeable elements of the systems. In the presence of ATP, a double hexamer of the viral T antigen (which is an initiator and a DNA helicase) binds to the viral origin and modifies it. This protein–DNA complex then binds the *cellular replication protein A* (RPA, subunits 70, 34 and

11 kDa). RPA/RFA/HSSB is a single-strand binding protein (SSB) similar in function to the helix-destabilizing proteins and in cooperation with the helicases assists in unwinding of the DNA duplex. The T antigen–RPA complex then binds eukaryotic *DNA polymerase α* (in humans with subunits p180 [polymerase], p70 [assembles the primosome], p58 [stabilizer] and p48 [primase]) with RNA and DNA polymerase functions. The sizes of these subunits may be different in other eukaryotes. (Pol α -primase functions may be inhibited by kinase cyclin A-CDK2. In the human ataxia telangiectasia the phosphorylation may be hindered.) This enzyme (pol α) then generates an RNA–DNA primer at the replicational origin. Initiation of replication in mammalian (and presumably other eukaryotic cells) cells requires specific DNA sequences. The *cellular replication factor C* (RFC, subunits 140, 40, 38, 37, 36-kDa) binds to the 3'-end of the new DNA and brings to the growing point the *proliferating cell nuclear antigen* (PCNA, 29-36-kDa) and DNA-polymerase δ (pol δ , catalytic subunit 125-kDa, plus another 48-kDa subunit) then pol α is replaced by pol δ aggregate proceeds in elongating the leading strand. On the lagging strand pol α /primase complex remains active at the initiation of the Okazaki fragments but after a *switch* the RCF/PCN/pol δ complex elongates also this strand. The elongation of the two strands is a coordinated process. After the Okazaki fragments are completed *RNase H* and 5'→3' *exonuclease MF1* (Fen1 and Dna2 helicase) remove the RNA primer and DNA ligase binds the ends of the Okazaki fragments into a continuous strand. Eukaryotic replication also utilizes topoisomerases in a somewhat similar fashion to *E. coli*. When the replication fork encounters transcription initiation complexes, both in yeast (eukaryote) and prokaryotes (T4 page, *E. coli* bacterium) the progress of replication transiently slows down. Actually, DNA replication depends on the cooperation of a multitude of proteins forming higher orders of domains (factories). An experimental study in mouse cells detected about 22 sets of domains of DNA replication. The replication domains are distinct from the 16 higher order transcriptional domains. The late-firing origins of replication are regulated during S phase also by the Mec1 and Rad53 proteins of yeast. The majority of replication models assume that the replication factories move along the DNA. Alternative models suggest that the polymerases are in a fixed position within the factories and rather the DNA moves along and rotates during the process of replication. ► [replication fork](#), ► [replisome](#), ► [clamp-loader](#), ► [DNA replication prokaryotes](#), ► [processivity](#), ► [replication machine](#), ► [SBD](#), ► [DNA replication mitochondria](#), ► [replication during the cell cycle](#), ► [cell](#)

The dashed lines show the new, bidirectionally synthesized DNA within the “eyes”. O = origin, T = terminus. Eventually the multiple replication bubbles coalesce. (Redrawn after Huberman JA, Riggs AD 1968 J Mol Biol 32:327)

DNA Replication, Mitochondria: The mammalian mitochondrial DNA is a very short duplex circle (16.5 kbp). In mouse it has two origins of replication, *ori-H* and *ori-L*. Before replication at the *ori-H* site, a displacement loop is formed of the H-strand, apparently to make room for the unidirectional replication. When the H strand loop is about 2/3 complete, replication of the L strand begins. The completion of the replication requires 2 h as it proceeds 270 base/min, i.e., more than two orders of magnitude slower than the process in the *E. coli* chromosome. RNA transcribed on the L strand initiates priming. Replication and transcription appear to be primed by the same process. The transition to L (light)-strand synthesis in human mtDNA is at

the template GGCCG. In the larger mitochondrial DNAs (e.g., in maize the T mtDNA is 540-kbp and N mtDNA is 700-kbp) more *ori* sites are used. The 80-kbp yeast mtDNA has at least seven replicational origins. At the latter, there are 3 shorter G=C rich regions, interrupted by 2 longer A=T rich sequences. In the DNA, ribonucleotides are found, probably leftovers from the RNA primer. The principal replicase enzyme is DNA polymerase γ (180 to 300-kDa) has a very low rate of error (10^{-6}) and this accounts for its high fidelity of replication. Nevertheless, mitochondria accumulate mutations at a higher rate than the nucleus probably because of the high ROS activity. [Note that this is not identical with the γ subunit (52-kDa) of prokaryotic DNA polymerase III coded for by *E. coli* gene *dnaX*]. The *Drosophila* mtDNA does not display D loops. The mtDNA may be divided into the daughter nucleoids either by pinching it off into two approximately equal pieces during the division of the nucleoid (*Physarum*), or, the nucleoid divides into two equal parts at the beginning of splitting of the organelle (*Paramecium*) or the nucleoid divides prior to the beginning of division of the organelle (*Nitella*). Another method of division is that the approximately 30 small mitochondria fuse into a long mitochondrion during the G1 phase of the cell cycle following mtDNA replication. Subsequently, the large mitochondrion divides into two and then fragments further into spherical nucleoids (*Saccharomyces*). Within each nucleoid the number of mtDNA molecules may vary: 3–9 in yeast, 32 in the *Physarum* plasmodium or 2–6 in the mouse nucleoids. The number of mtDNA copies/cell may show substantial variations (≈ 1000 to ≥ 8000). In some fungi (*Candida*), the catenated mtDNA molecules may contain 7 units in a linear array. Most commonly, the mtDNA appears as covalently closed circles yet in some cases (e.g., malignancy), two monomers may be catenated in a double circle or may be double-length chains. The 50 kbp mtDNA of *Tetrahymena* is also linear whereas in the *Paramecia* kinetoplasts mini- and maxicircles occur. ▶DNA replication, ▶DNA polymerases [γ], ▶MRP, ▶CSB, ▶kinetoplast, ▶nucleoid, ▶D loop, ▶R loop, ▶plasmodium, ▶polymerase, ▶catenate, ▶mitochondrial genetics, ▶error in replication, ▶ROS, ▶mitochondrial-control regions; Moraes CT 2001 Trends Genet 17:199; Clayton DA 2000 Hum Reprod 15(2):11; Lecrenier N, Foury F 2000 Gene 246:37; Maier D et al 2001 Mol Biol Cell 12:824; Gensler S et al 2001 Nucleic Acids Res 29:3657; Shadel GS, Clayton DA 1997 Annu Rev Biochem 66:409.

DNA Replication, Prokaryotes: The genetic material must be faithfully replicated to assure heredity.

Unlike in eukaryotes, pyrimidine deoxyribonucleotides are synthesized from ribonucleotide diphosphates rather than triphosphates. The replication takes place in a semi-conservative manner ► **semi-conservative replication**. Although the basic system of the process is very similar from viruses to eukaryotes, variations exist in the mode the final product is made. **Viral DNA REPLICATION**—Some viruses (ϕ X174, G4, M13, fd) contain single-stranded viral DNA (V DNA) and thus the genetic material must be replicated via a complementary strand (C DNA) in the intermediate double-stranded step, the replicative form (RF). All types of DNAs require a replication *origin* (*ori*) to begin the process. A common feature of the origins is that they are rich in A = T to facilitate strand separation required for the semiconservative replication. Not uncommonly in the leading strand there is a prevalence of G over C and T over A in prokaryotes and also in mammals (Touchon M 2005 Proc Natl Acad Sci USA 102:9836). The initiation of replication in the filamentous phage fdV DNA proceeds in opposite direction to the C DNA in the RF from closeby points. In the G4 phage the replicational origins of the V and C strands are widely separated and in its close relative, ϕ X174 there is one origin for the V strand but multiple origins for the C strand. The replication of the about 15 times larger duplex DNA of phage T7 proceeds bidirectionally \leftrightarrow from the origin and so does the *E. coli* duplex DNA that is about 800 times larger.

Since the DNA single strands run antiparallel, simultaneous semiconservative replication has some special requirements (see Fig. D78). This problem is met in a simple way by the 36-kb DNA of adenoviruses: first the replication starts at one of the 3'-ends and when it is completed then the other strand is copied using as template the other OH-end. Here

each 5'-end cytidylic residue of the DNA is bound to a 55 kDa terminal protein. Then an 80-kDa viral protein displaces the end protein and uses the terminal deoxycytidylic acid as the beginning nucleotide template to lay down the first guanosinephosphate.

The 80-kDa protein binds to nucleotides 9 to 18 at the end, and to the next 30 nucleotides host-nuclear-protein factor I is attached. Since the 80-kDa protein had already formed a complex with the polymerase, replication can now proceed.

Replication in *E. coli*—The size of the replicational unit, the *replicon*, in *E. coli* is thus the whole genome (4.7×10^6 bp) whereas in mouse the average length of the about 2,500 replicons is about 150 kb. Despite the large number of replicons in higher eukaryotes the pace of replication is much slower. In *E. coli* about 50 kb/min, but in mouse about 2.2 bp/min.

The single origin in *E. coli* is in the *oriC* locus and the two forks must meet at about half way in the circular DNA. At about 100-kb from this meeting point there are the *ter* (termination) regions of about 23-bp length; *terD* and *terA* signal termination on one of the branches of the fork and *terC* and *terB* on the other. The protein coded by the *tus* gene recognizes the terminators and halts replication after the replication forks passed the *ter* sites. DNA synthesis can be started only if appropriate hydroxyl ends are available because this is a requirement of all DNA polymerases known. In *E. coli* the hexameric *helicase* proteins (330-kDa) are required to unwind the two strands and generate the Y form (see Fig. D79).

This process uses energy liberated by hydrolysis of ATP to ADP. Single-strand binding (SSB) helix-stabilizing proteins that make the bases free to be copied on both old strands assist the unwinding. The unwinding removes the negative supercoiling and may even reverse the original coiling into positive supercoiling. This process has limitations and the tension must be relieved by making single-strand cuts in the still unwound duplex. This nicking is carried out by topoisomerases (swivelases). DNA *topoisomerase type I* enzymes make a single cut in one strand of the helix and then permit the nicked strand to rotate once around the intact strand and then resealing the free ends and relieving negative supercoiling. *Topoisomerases type II* can cut and rejoin both strands of the duplex ahead of the fork and thus remove both negative and positive supercoiling. The latter group of enzymes includes *gyrases*, and can make double cuts and convert positively, supercoiled sections to negatively supercoiled ones. Type II *topoisomerases* can also convert catenated molecules OO into decatenated ones by permitting one duplex ring to slip out from the other \Rightarrow O O. At the bifurcation, one of the templates runs 5' \rightarrow 3' and the other 3' \leftarrow 5' (see Fig. D80).

Figure D78. Replication of single-stranded DNA. Broad outline of replication of single-stranded a nucleic acid molecule via a replicational intermediate double-stranded structure. (From August JT et al 1968 Cold Spring Harbor Symp Quant Biol 33:73)

D

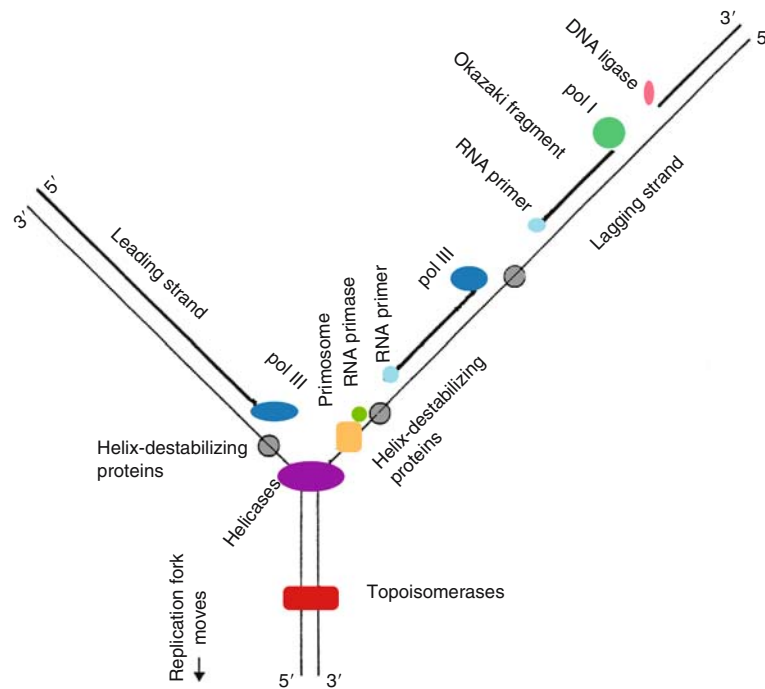

Figure D79. Replication fork. A broad overview of prokaryotic replication fork

Figure D80. Bidirectional replication

It is simple to proceed with replication of the old strand that faces the fork with its 5'-end because its complementary new strand can be elongated by adding bases to the 3'-OH terminus.

This is called the *leading strand* (left branch of the fork in the diagram). While DNA synthesis (the new strand is shown by the heavier line) is going on, the strands at the fork must be kept separated by the *helix destabilizing proteins* (also called SSB, tetrameric single-strand binding proteins of 74 kDa, shown as small circles). The principal enzyme of replication is *DNA polymerase III* holoenzyme (clamp-loader, 10 to 20 copies per cell). The α subunit of the enzyme (encoded by gene *polC*) carries out polymerization (chain extension) at the 3'-end of both *leading* and

lagging strands (right branch of diagram). The ϵ subunit (gene *dnaQ*) is endowed with a 3' to 5' exonuclease function that reduces errors to 5×10^{-9} from 7×10^{-6} . The two (α and ϵ) together with θ , represent the *pol III core*. The β subunit (gene *dnaN*) apparently keeps the holoenzyme attached to the DNA. Additional polypeptide chains (γ , δ , δ' , ψ , τ and χ) are also part of the huge holoenzyme (≈ 1 MDa).

The holoenzyme may be assembled in different ways under the control of gene *dnaX* products γ and τ . The lagging strand is synthesized in pieces (Okazaki fragments of 1 to 2 kb) because of the lack of a 3'-OH terminus to elongate a continuous strand starting from the base of the fork. Actually, even the leading strand is replicated in a discontinuous manner but it has fewer initiation sites than the lagging strand. The lagging strand requires a primer to be initiated. For primer a short RNA sequence is used. The primosome is a protein complex of helicases (*dnaB*, *dnaC* gene products), pre-priming protein (66-kDa, *dnaT* gene product), *priA* gene product (82-kDa monomer) recognizes primer assembly site and displaces the helix-destabilizing protein, and primase (60-kDa monomer product of gene *dnaG*). The primosome wraps around the DNA Strands. Although this complex is shown only at the base of the lagging strand in the diagram it probably moves along to other locations as its role requires. Since the

lagging strand is synthesized in pieces (Okazaki fragments) that carry RNA at the initiation region (5'), there is a need for other functions. DNA polymerase I (109-kDa monomer product of gene *polA*) serves triple roles. The larger C-terminal domain (68-kDa Klenow fragment, when cleaved by subtilisin) possesses a 5' to 3' polymerase and a 3' to 5' exonuclease functions. It can elongate the 3'-OH DNA or RNA termini by adding 5' nucleotidyl phosphates and can slice off nucleotides in the 3' to 5' direction. The elongation of the new DNA is contingent on the nutritional status of the cell and it is controlled by (p) ppGpp nucleotides (magic spot). Its N-terminal domain (35-kDa) is a 5' to 3' exonuclease, and activity blocked during the polymerization reaction. Thus, pol I can simultaneously extend the Okazaki fragment's 3'-OH end and remove the primer RNA at the 5'-end, and it is capable of the replacement replication (nick translation) that is just needed for making the lagging strand continuous. The 3' to 5' exonucleolytic activity has also the important function of "editing". If it finds "spelling errors" during synthesis, it removes the mismatched base and replaces it with the correct one. Its N-terminal domain reduces replicational errors from 10⁻⁵ to 10⁻⁷ that is about the average spontaneous mutation rate in bacteria. After the Okazaki fragments reach full length they are joined by DNA ligase, an E. Coli enzyme that attaches adjacent 5'-phosphoryl and 3'-OH ends of nucleotide chains in the presence of NAD⁺ (nicotinamide adenine dinucleotide). Most of the details of the information on DNA replication was obtained in in vitro systems where the single components can be added or withdrawn and the role can be established without the complications of the in vivo each chromosomal analyses. In E coli the transcriptionally most active genes are operating in the leading strand. In *Caulobacter crescentus* each chromosomal locus occupies a specific address arrayed linearly along the longitudinal axis of the cell. During replication, these are moved in chronological order to the final subcellular site (Viollier PH et al 2004 Proc Natl Acad Sci USA 101:9257) rolling circle replication and (theta) replication, ▶steric-exclusion model, ▶replication fork, ▶replication machine, ▶magic spot, ▶nucleoid, ▶RNA replication in viruses, ▶DNA chemical synthesis, ▶replication speed, ▶processivity, ▶Okazaki fragments; Wawrzynów A, Zylicz M 1997 In Gething M-J (ed) Guidebook to Molecular Chaperones and Protein Folding Catalysts, Oxford Univ. Press, New York, p. 481; Nossal NG et al 2001 Molecular Cell 7:31; Postow L et al 2001 Proc Natl Acad Sci USA 98:8219; Johnson A, O'Donnell M 2005 Annu Rev Biochem 74:283; polarity of termination: Mulcair MD et al 2006 Cell 125:1309.

DNA Replication Types: These are distinguished as type I and type II (see Fig. D81):

Figure D81. Replication types

DNA-RNA Hybrid: DNA is annealed with RNA in a double helix. ▶annealing

DNA, 7S: It is found in the mitochondria where it facilitates the synthesis of the heavy strand of the mtDNA. In mammals, mtDNA replication proceeds from two promoters the light strand and the heavy strand promoter, respectively. In this region an arrested H strand DNA, the 7S DNA is hybridized to the parental circular mtDNA and forms there a triplex with the displaced replication loop. This 7S DNA is primed by a 7S RNA derived from the light strand DNA. ▶mtDNA, ▶RNA 7S; Lee DY, Clayton DA 1998 J Biol Chem 273:30614; Gensler S et al 2001 Nucleic Acids Res 29:3657.

DNA Sequence Information: (see Fig. D82) ▶databases, ▶Nucleotide sequencing collaboration: <http://www.insdc.org/>, <http://www.ebi.ac.uk/embl/>, about many different species including extinct ones: <http://www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html>.

DNA Sequencing: It determines the order of nucleotides in DNA fragments. Two procedures have been most widely used: the protocol of Maxam and Gilbert (M&G; see diagram) and one or another modification of the method of Sanger and co-workers. The M&G method can sequence both single and double-stranded DNA.

The P³² end-labeled DNA sample is divided into five aliquots and by different, limited chemical breakage at one or two of the four bases, unique sets of labeled fragments are produced (G, G + A, A + C, C, C + T). From the five batches, fragments are then separated according to length in five lanes in

D

Since one end of each fragment in each batch terminates by the same nucleotide(s), according to the breakage mechanism (see figure and box) and in each batch these ends are specific, the sequence of the bases, in the different length fragments, can be read directly from the film of the gel (see Fig. D83).

Figure D83. Because no band appears in the **A > C** lane corresponding in position in the **G + A** lane or in the **C** lane corresponding to the **C + T** lane the sequence must be **GTCATAGCA** (read from bottom to top). The maxam gilbert method can sequence both single- and double-strand dnas, and the sequence can be read directly as illustrated below

By the *Sanger method* single-stranded DNA is sequenced that has been cloned in M13 (or related) phage vectors (see Fig. D84). A chosen DNA fragment is then replicated in the presence of appropriate primer, α - P^{32} -dATP, limited supply of the four normal deoxyribonucleotide triphosphates and the large subunit of DNA polymerase I (Klenow fragment), or mainly Taq or phage T7 polymerases.

In addition to these common components in four separate vessels, the dideoxy analogs of the four nucleotides (dideoxyATP, dideoxyTTP, dideoxyGTP, dideoxyCTP) are added. These analogs when incorporated into the growing nucleotide chain stop further elongation because they do not have OH at the 3' position where the new nucleotides normally attach during replication. As a result, the chain growth stops and the position of this nucleotide in the chain is marked. The fragments generated by this stopped replication procedures are separated by electrophoresis as described in the M&G procedure and from the results of the sequencing gel, the base sequences can be read directly. Another method called "sequencing-by synthesis" uses iterative addition to the template the four deoxynucleotide triphosphates, and as the DNA polymerase incorporates the complementary nucleotide monophosphate the liberated pyrophosphate is determined. Actually, after addition the nucleotides are enzymatically degraded in the sequence of incorporation. The detection is made possible by a sulfurylase reaction coupled with luciferase. In recent years, great technical advances were made in DNA sequencing by using laboratory equipment and computer technology, and megabase-size DNA stretches can be sequenced in much shorter time. A large number of viral, several prokaryotic, a score of eukaryote (*Saccharomyces*, *Caenorhabditis*, *Drosophila*) genomes have been entirely sequenced and several others nearing completion. The average estimated error rate is $1-3 \times 10^{-3}$ base. The sequencing of DNAs facilitates the understanding of how

INSERT INTO A CLONING SITE (CONTAINING THE *Lac* GENE) OF THE SINGLE-STRANDED M13 PHAGE. THE INSERTION INACTIVATES *Lac* IN THE PHAGE AND INFECT *Lac*⁻ BACTERIA. THE TRANSFORMANTS DO NOT PRODUCE COLORED PLAQUES ON Xgal MEDIUM.

TO FOUR TUBES, EACH, ADD THE SEQUENCING VECTOR (M13), ³²P-DEOXYRIBOADENOSINE TRIPHOSPHATE, THE NORMAL DEOXYNUCLEOTIDE TRIPHOSPHATES AND A DNA POLYMERASE (EITHER THE KLENOW FRAGMENT OR SEQUENASE) AND IN EACH OF THE FOUR TUBES ADD ALSO ONE OF EACH OF THE FOUR TYPES OF DIDEOXYRIBONUCLEOTIDES:

THE DIDEOXYNUCLEOTIDES ARE INCORPORATED IN PLACE OF THE NORMAL NUCLEOTIDES BUT LACKING THE 3'-OH END, THE CHAIN GROWTH STOPS. THEREFORE, THE SYNTHESIZED FRAGMENTS WILL TERMINATE EITHER WITH AN A or T or G or C, RESPECTIVELY. SINCE NORMAL NUCLEOTIDES ARE ALSO PRESENT, FRAGMENTS OF DIFFERENT LENGTH WILL BE GENERATED ON THE INSERT TEMPLATE ACCORDING TO THE CHANCE WHETHER NORMAL OR BLOCKING NUCLEOTIDES WILL BE INCORPORATED BY THE POLYMERASE. THE FRAGMENTS ARE THEN SEPARATED BY LENGTH BY POLYACRYLAMIDE GEL ELECTROPHORESIS. THE RADIOACTIVE dATP MARKS ONE END OF THE FRAGMENTS AND THEY CAN BE DETECTED IN THE GEL BY AUTORADIOGRAPHY. THE RESULTS MAY BE AS DIAGRAMMED:

THUS THE NUCLEOTIDE SEQUENCE CAN BE READ FROM THE LAST BASE OF FRAGMENT NUMBER 1 TO FRAGMENT NUMBER 9: G C A C T G C A T

THE START OF THE RUN IS AT THE TOP AND THE LONGER IS A FRAGMENT THE SHORTER THE DISTANCE IT MOVES IN THE ELECTRIC FIELD OF THE GEL

Figure D84. Sanger method of DNA sequencing

biological systems work. It opens new approaches to study interacting proteins, facilitates more efficient design of drugs, decipher the mechanisms of cancer and other diseases, provides new tools for forensic analyses, evolutionary and archeological research and it even may identify biological warfare agents. The Sanger method is applicable to fmole DNA samples in a nanoliter-scale microfabricated bioprocessor at 99% accuracy (Blazej RG et al 2006 Proc Natl Acad Sci USA 103:7240). ▶DNA sequencing automated, ▶pyrosequencing, ▶nucleic acid chain growth, ▶sulfurylase, ▶luciferin, ▶BLAST, ▶BLASTX, ▶FASTA, ▶BLOSUM, ▶databases, ▶evolutionary distance, ▶array hybridization, ▶DNA chips, ▶clone validation, ▶computerization of DNA and protein sequence data; Methods in Enzymology 59 & 65; Marziali A, Akeson M 2001 Annu Rev Biomed Eng 3:195; Green ED 2001 Nature Rev Genet 2:573, see diagram for an outline of the

most widely used dideoxynucleotide method of Sanger et al.

The genome projects use either one or the other of the two automated sequencing procedures for large-scale sequence determinations. The hierarchical shotgun sequencing (HS) breaks up the (human) genome into overlapping BAC clones, sequences them and then reassemble them as merging clones. This procedure was used by the Human Genome Project. The Whole-genome shotgun sequencing (WGS) sequences the entire genome and then reassembles the entire collection into contigs and scaffolds. This procedure was designed and used by the Celera biotechnology firm. The two procedures are discussed by Waterson RH et al 2002 Proc Natl Acad Sci USA 99:3712.

A newer method uses four-color DNA sequencing by synthesis on a chip. It employs four photo-cleavable fluorescent nucleotide analogs attached

though 2-nitrobenzyl linker to the 5 position of the pyrimidines and to the 7 position of the purines. The incorporated nucleotides are irradiated then by ~355 nm laser beam for 10 s. Afterward, sequencing by synthesis reaction was carried out a self-priming template on the chip, immobilized by azide-alkyne cycloaddition. The template was generated by PCR, using azido-labeled primer and ligated to the immobilized DNA. Each cycle of this procedure permitted the identification the sequence of 12 continuous nucleotides and then the fluorophores are cleaved off by near-UV. The procedure may be extended to longer tracts of DNA (Seo TS et al 2005 Proc Natl Acad Sci USA 102: 5926). It has been reported that another highly accurate procedure uses epifluorescence microscopy and nonelectrophoretic method. Short DNA fragments are amplified on 1- μ m beads by polymerase chain reaction (PTPCR) and then sequenced at about 1/9th of the cost of the conventional (Sanger) method (Shendure J et al 2005 Science 309:1728). Combination of chromatin immunoprecipitation (ChIP) with massively parallel sequencing permits the identification of specific DNA sequences under different epigenetic conditions (Robertson G et al 2007 Nature Methods 4:651).

►sequatron, ►DNA chips, ►shotgun sequencing, ►genome projects, ►computerization of DNA and protein sequence data, ►contig, ►scaffold, ►pyrosequencing, ►bisulfite reaction, ►massively parallel signature sequencing, ►deep sequencing, ►DNA fingerprinting; some newer procedures' survey: Marziali A, Akeson M 2001 Annu Rev Biomed Eng 3:195; history of progress: Venter JC et al 2003 Nature Genet 33 (Suppl.):219, advanced technologies: Shendure J et al 2004 Nature Rev Genet 5:335, <http://www.sequenceanalysis.com>.

Convenient identification of nucleotide sequences within specific DNA segments is relevant to many biological problems including developmental processes and medicine. Incorporation of a complementary nucleotide into self-primed single-strand DNA attached to the surface of a gold electrode evokes an electrode surface charge perturbation. Such an event is detectable by a voltage-clamp amplifier. It is supposed that the electrode detects proton removal from the 3'hydroxyl group of DNA during the formation of phosphodiester bond when complementary base is provided. Such a method is rapid and does not require special reagents (Pourman N et al 2006 Proc Natl Acad Sci USA 103:6466, DN sequence and physico-chemical property analysis tool: <http://gna.web.gbf.de/FeatureScanHome.htm>).

DNA Sequencing, Automated: The nucleotide sequences on the X-ray film obtained by autoradiography can be read directly or can be scanned with aid of computer

Figure D85. The peaks (in four colors) correspond to the pattern of a sequencing gel. (**Note** the scan is not of the gel shown below it!). The laser scanner feeds to the computer the information according to color that corresponds to specific bases of the DNA

programs (see Fig. D85). The computer can be used also to search for particular sequences, transcription signals, homeoboxes, termination signals and any other type of conserved elements.

In addition, through computer connections to DNA databases, homologies to previously determined sequences can be identified. By the most efficient methods (by year 2000), more than Mb DNA can be daily sequenced at a cost less than \$0.50 per nucleotide in a finished sequence. In recent years, the cost has been reduced and the latest techniques permit a further substantial cost reduction. The genome projects used either a whole-genome shotgun method (Celera Genomics) or 150-kb clones in bacterial artificial chromosomes (International Human Genome Sequencing Consortium).

High-throughput technology reduced the cost to \$1.00 per raw kilobase by 2005. Currently developing systems by using pyrosequencing and sequencing-by-synthesis technologies may drive down the cost to \$1,000 for a 9-billion bp mammalian genome (Service RF 2006 Science 311:1544). In 2007, the sequencing of the whole genome of James Watson cost about \$1,000,000 and was completed in a few months.

Nucleoside triphosphates attached to a fluorophore can be incorporated into DNA through UV photocleavable 2-nitrobenzyl linkers. Such a procedure holds promise for an efficient automated sequencing by synthesis similarly to the Sanger method (Li Z et al 2003 Proc Natl Acad Sci USA 100:414). For great efficiency and scalable, a highly parallel system with raw throughput significantly greater than that of state-of-the-art capillary electrophoresis instruments have been developed.

The apparatus uses a novel fibre-optic slide of individual wells and is able to sequence 25 million bases, at 99% or better accuracy, in 1, 4-h run. This method can achieve an approximately 100-fold increase in throughput over current Sanger sequencing technology. An emulsion method for DNA amplification and an instrument for sequencing by

synthesis using a pyrosequencing protocol optimized for solid support and picoliter-scale volumes were used (Margulies M et al 2005 Nature [Lond] 437:376, note corrigendum Nature [Lond] 441:120). The latter method proved useful for such difficult tasks as the sequencing of the ancient DNA of Neanderthal bones. ▶DNA sequencing, ▶Bermuda standard, ▶shotgun sequencing, ▶pyrosequencing, ▶nanopore technology, ▶capillary electrophoresis, ▶polymerase chain reaction, ▶PTPCR, ▶BAC, ▶MALDI/TOF/MS; Meldrum DR 2001 Science 292:515; Markel S, León D 2003 Sequence Analysis in a Nutshell: A Guide to Common Tools and Databases. O'Reilly Press, Sebastopol, CA.

DNA Shuffling: It is the in vitro homologous recombination in pools of randomly fragmented genes, and reassembly by the polymerase chain reaction in order to test the consequences of the new sequences as evolutionary changes. Such a process may increase the efficiency of genes by hundreds of folds if the DNA sequences are derived from different bacterial or viral species. Shuffling within DNA sequences from one species may also result in several-fold increases in enzyme efficiency. In bacteria, extensive reorganization of the genes may contribute to variable expression (Cardeno-Tarraga AM et al 2005 Science 307:1463). ▶localized mutagenesis, ▶RCR-based mutagenesis, ▶protein engineering; Moore GL et al 2001 Proc Natl Acad Sci USA 98:326; Zhang Y-X et al 2002 Nature [Lond] 415:644.

DNA Silencing: ▶silencer

DNA Splicing: ▶splicing, ▶splicing junction

DNA Structure: ▶Watson and Crick model

DNA Subtraction: ▶genomic subtraction

DNA Supercoiling: ▶supercoiling of DNA

DNA Synthesis: ▶DNA replication, ▶DNA chemical synthesis

DNA Synthesis, Meiosis: During meiosis there is no DNA synthesis, except that may be needed for genetic repair. Before meiosis, synthesis brings the level of DNA in the meiocytes to 4 C level. After the reductional division each cell has 2 C amount of DNA and at the end of meiosis there is 1 C amount in each of the four gametes. ▶C amount DNA

DNA Thermal Stability: Heat may disrupt the hydrogen bonds between the two strands of DNA. The stability depends on the base composition since G≡C are linked by 3 hydrogen bonds whereas A = T by only 2. Generally, at temperatures exceeding 60°C denaturation may begin and upon prolonged exposure to 100°C it is completed. The resulting single strands

have higher UV absorption at 260-nm wavelength than the duplexes (hyperchromicity). ▶DNA denaturation, ▶denaturation, ▶hyperchromicity

DNA Topoisomerases: They are capable of nicking and reclosing single strands of (Type I) or causing scission in both strands and rejoining the cuts (Type II). These enzymes are ubiquitous from bacteria to eukaryotes and have roles in relaxing superhelical configuration, replication, transcription, recombination and repair. (mentioned items under separate entries; Huang WM 1996 Annu Rev Genet 30:79; Champoux JJ 2001 Annu Rev Biochem 70:369).

DNA Tracking: Following the path of the DNA such as the movement of a polymerase along the template after the initiation of transcription or replication.

DNA Translocase: An ATP-driven motor protein complex mediating replication, recombination and DNA transfer between cells. In *E. coli* it (FtsK) may move rapidly (5 kb/s) along the DNA in two directions (Pease PJ et al 2005 Science 307:586).

DNA Transport: It is concerned with segregation of the chromosomes, bacterial conjugation and chromosome transfer, phage infection and assembly into phage particles, transformation etc. DNA is generally transferred in single-stranded form, except in bacteriophages that move across bacterial septa. In bacteria, the SpoIII-like protein family is the most important instrument of the processes. ▶conjugation, ▶infection, ▶phage life cycle, ▶transformation, ▶pilus; Errington J et al 2001 Nature Rev Mol Cell Biol 2:538; Chen I et al 2005 Science 310:1456.

DNA Transposition: ▶transposition

DNA Tumor Virus: It may be integrated into the animal host DNA. The Papovavirus family consists of a variety of types and may be responsible for warts and carcinomas (see Fig. D86). The Hepadnaviruses (hepatitis-B) are responsible for liver carcinomas. The Herpes viruses (Epstein-Barr virus) may cause cancerous transformation of the lymphocytes (Burkitt's lymphoma, and nasopharyngeal cancer). Several RNA viruses belong to the retrovirus groups and may be transcribed into DNA and activate cancerous growth. See mentioned terms under entries; ▶isometric phage

Figure D86. Adenovirus, facultative DNA tumor virus

DNA Twist: The number of base pairs per turn of the double helix. DNA-binding proteins (repressors, histones of the nucleosomes, remodeling of chromatin) can affect the winding of the molecule and alter expression of genes. Nicks of one strand reduces the torsion. ▶DNA bending; Havas K et al 2000 Cell 103:1133.

D

DNA Types: see table D6. ▶xDNA

DNA Typing: determination of the individual specificity of a DNA sample (see Table D6). ▶DNA fingerprinting, ▶DNA sequencing, ▶microarray, ▶multi-locus sequence typing; Burns MA et al 1998 Science 282:484.

DNA, Ultraviolet Absorption: The maximal absorption is at about 260 nm but the solvent and pH may influence the maximum. The maximal absorption of polycytidylic acid is between 270 and 280 nm whereas that of polyguanylic acid may vary between 250–290 nm, depending on the pH. Single-stranded molecules have increased absorption relative to double-stranded DNA. DNA isolated from plant or animal tissues generally has 280/260 \approx 2 absorption ratios. The OD₂₆₀ of 1 corresponds to about 50 μ g/mL double-stranded and 40 μ g/mL single stranded DNA at about pH 8 in TE buffer. ▶O.D., ▶TE buffer, ▶buffer, ▶UV, ▶cyclobutane dimer, ▶physical mutagens

DNA, Unique: DNA sequences that occur only in single copies in the genetic material.

DNA Uptake Sequences (DUS): The genomes of certain bacterial species (but not *E. coli* K12) contain 9-10-mer base sequences, 5'-GCCGTCTGAA-3' repeated in ~1900 copies in *Neisserias* or 5'-AAGTGCGGT-3' sequences in *Haemophilus influenzae* (repeated 1,471 times) and in *Actinobacillus actinomycetemcomitans*. These species are naturally competent for

transformation. Besides, their protein-coding gene's expression is more stable and have better regulated phase variation and better stress responses and DNA repair, recombination, restriction-modification, etc. ▶oligodeoxyribonucleotide gated channel, ▶phase variation, ▶competence of bacteria, ▶DNA repair, ▶restriction-modification; Davidsen T et al 2004 Nucleic Acids Res 32:1050.

DNA Vaccines: ▶immunization genetic, ▶vaccines

DnaA: The DNA replication initiation protein in *E. coli*. It binds to a 9mer consensus the DnaA-box (5'-TT (A/T)TNCACA) and if it complexes with ATP it binds to the ATP-Dna-box (5'-AGatct). ▶oriC, ▶DnaB

DNAase: ▶DNase

DnaB: A hexameric DNA helicase involved in bacterial replication by polymerase III. Besides being a helicase, it regulates the synthesis of the primer and a factor of processivity. ▶DNA replication in prokaryotes, ▶O-some, ▶processivity, ▶DnaA, ▶oriC; Carr KM, Kaguni JM 2001 J Biol Chem 276:44919.

transcription of Hsp70, the complex may separate the heatshock-specific σ^{32} subunit from the RNA polymerase and reactivates the heat aggregated and thus inactivated regular σ^{70} subunit. ▶chaperones, ▶HSP, ▶Hsp70, ▶DnaK, ▶GRP, ▶Rep, ▶ σ^{70} , ▶CbpA, ▶RcsG; Rüdiger S et al 2001 EMBO J 20:1042.

DnaK: An *E. coli* chaperone protein of the Hsp70 family with high homology to eukaryotic Hsps. In cooperation with DnaJ and GroE it carries out the main functions of controlling heat responses, protein folding, transport and degradation in concert with proteases, initiation of bacterial, plasmid and phage replication, flagella synthesis, etc. DnaK synthesis is regulated by a specific σ^{32} subunit a bacterial RNA polymerase. Severe oxidative damage inactivates DnaK and activates the redox-regulated Hsp33 chaperone. Upon return to non-stress conditions Hsp33 is inactivated and DnaK is reactivated to protein folding function (Winter J et al 2005 Mol Cell 17:381). ▶chaperones, ▶Hsp70, ▶GroEL, ▶flagellum, ▶RNA polymerase, ▶ σ , ▶Ydj1, ▶Sis1, ▶Zuotin, ▶Anj1, ▶Ldj, ▶Tid50, ▶Hdj2, ▶HsJ1, ▶auxilin, ▶Mtl1, ▶Hip, ▶trigger factor, ▶translcon; Kedzierska S, Matuszewska E 2001 FEMS Microbiol Lett 204:355.

DNA-PK (DNA-dependent protein kinase, 8q11): A phosphatidyl inositol kinase family (PI[3]K) protein has a role in transcription, replication, immunoglobulin gene switching, cancer and DNA repair. In cells deficient in DNA-PK non-homologous end-joining is preferred whereas homologous recombination is reduced (Convery E et al 2005 Proc Natl Acad Sci USA 102:1345).

The sequence-specific enzyme complex works only when it is in cis-position to the site of phosphorylation. The Ku autoantigen, a transcription factor, attracts DNA-PK to specific DNA sequences. Ku binds to a specific negative regulatory element (NRE1) — in the long terminal repeat—and keeps in check inappropriate expression of the glucocorticoid-induced transcription of mouse mammary tumor virus (MMTV). Ku can bind also to other DNA sites although it displays preference to DNA ends and to the MMTV glucocorticoid receptor and octamer transcription factor 1 (Oct-1). DNA-PK phosphorylates in vitro glutathione S-transferase-Oct-1 fusion protein and the glucocorticoid receptor. Phosphorylation by DNA-PK was contingent on the presence of the glucocorticoid receptor and Oct-1 binding sites. DNA-PK is required also for immunoglobulin (V[J]D) recombination and activation of innate immunity. DNA-PK mediates also the binding of p53 protein to the DNA and thus, may or may not play a role in the mammalian DNA damage control pathway. DNA-PK also functions as an RNA-dependent protein kinase and regulates RNA

processing and transport (Zhang S et al 2004 Nucleic Acids Res 32:1). ▶mouse mammary tumor virus, ▶Oct-1, ▶autoantigen, ▶p350, ▶Ku, ▶immunoglobulins, ▶RAG, ▶XRCC4, ▶p53, ▶ligase DNA, ▶non-homologous end-joining, ▶double-strand break, ▶PIK, ▶innate immunity; Smith GCM; Jackson SP 1999 Genes Dev 23:916; Bryntesson F et al 2001 Radiat Res 156:167; Chechlacz M et al 2001 J Neurochem 78:141; Goiytisolo FA et al 2001 Mol Cell Biol 21:3642; Soubeyrand S et al 2001 Proc Natl Acad Sci USA 98:9605; Mårtensson S, Hammersten O 2002 J Biol Chem 277:3020; DNA-PK structure: Rivera-Calzada A et al 2005 Structure 13:243.

DNase: Enzymes degrading DNA. ▶restriction enzymes, ▶endonuclease, ▶exonuclease, ▶DNA polymerases

DNase-Free RNase: It may be prepared by different procedures such as affinity chromatography on agarose 5'(4-aminophenylphosphoryl)-uridine-2'(3')-phosphate, by adsorption on Macaloid, by heating in the presence of iodoacetate. Commercially available preparations so labeled may not always be trustworthy. ▶RNase-free DNase, ▶DNase, ▶RNase, ▶Macaloid

DNase Hypersensitive Site (HSS/DHS): In the DNA, HSS is very easily attacked by nucleases probably because they are unprotected by proteins (histones); their presence correlates with expression of adjacent genes. The generation of hypersensitive sites alters the nucleosomal structure of the chromatin. Hypersensitive sites are located in the vicinity of promoters or a promoter and enhancer, suppressors and insulators. Computational method were developed to detect common DNA structural motifs in a large collection of HSSs that are found in the ENCODE regions of the human genome. HSSs have common DNA structural motifs that show no apparent sequence consensus. One such structural motif is much more highly enriched in experimentally identified HSSs that are in CpG islands and near transcription start sites (TSSs), compared to HSSs not in CpG islands and farther from TSSs, suggesting that DNA structural motifs may participate in the formation of functional regulatory elements (Greenbaum JA et al 2007 Genome Res 17:940). By cloning HSS sequences, regulatory systems can be identified globally and in various tissues, developmental stages and disease susceptibility. ▶IN11, ▶integrase, ▶promoter, ▶enhancer, ▶nucleosome, ▶antitrypsin, ▶chromatin remodeling; Crawford GE et al 2004 Proc Natl Acad Sci USA 101:992, <http://www.gene-regulation.com/>.

DNA-Templated Organic Synthesis and Selection

(DTS): DNA-templated synthesis generates labeled libraries for screening small synthetic compounds, macrocycles. The DNA-macrocyclic conjugates were screened for protein affinity. The procedure is sensitive for detection of small biological molecules. The procedures enable selection of libraries of 10^6 peptides for therapeutic or chemical applications. (Gartner ZJ et al 2004 Science 305:1601; Halpin DRT, Harbury PB 2004 PLoS Biol 2(7):e17). ▶[macrocycle](#)

DnaX: is one of 10 different subunits of the prokaryotic DNA polymerase holoenzyme. ▶[DNA replication in prokaryotes](#); Song M-S, McHenry CS 2001 J Biol Chem 276:48709.

DNA-Zymes (DNA enzymes, deoxyribozymes): These are catalytic single-strand DNA molecules that have been isolated in the laboratory by in vitro selection in random oligonucleotide pools (see Fig. D87). They are thus not “natural enzymes” unlike ribozymes. They can cleave and make phosphoester bonds and also catalyze other reactions (porphyrin metallation). They do not have the 2'-hydroxyl group of RNA yet can carry out the reactions very effectively. The so called 10–23 DNA-zyme digests a specific motif of nucleotide sequences. The 15-nucleotide catalytic core of this DNA-zyme is flanked by two substrate recognition sequences that bind to complementary RNA by hydrogen bonds. It cleaves the phosphodiester bonds between unpaired purines and pyrimidines and generates 2',3'-cyclic phosphate and 5'-hydroxyl ends. A DNA-zyme-based catalytic beacon can detect uranium oxide (UO_2^{2+}) in < 2 min at ambient temperatures with 11 parts-per-trillion (45 pM) sensitivity and > 1-million-fold selectivity over any other metal ions (Liu J et al 2007 Proc Natl Acad Sci USA 104:2056) although similar methods also exist for the detection of Pb^{2+} . Such methods have application for the detection of metal pollution and for medicine. ▶[ribozyme](#), ▶[phytoremediation](#), ▶[soil remediation](#); Breaker RR 2000 Science 290:2095. Dog (*Canis familiaris*, $2n = 78$, ~2.5 Gb/genome): Molecular data indicate its origin from wolves. Because of the high diversity in the mtDNA in both species, dogs apparently originated by more than a single event of divergence although the difference between dog and gray wolf DNA is only 0.2%. Dogs

and wolves are not isolated sexually. Dogs have been domesticated about 15,000 years ago and over 350 to 1,000 different breeds may exist. Among 85 domestic pure-breeds, about 99% of the individual animals could be identified correctly to breed on the basis of microsatellite genotypes (Parker HG et al 2004 Science 304:1160). A high-quality draft of the genome sequence became available by 2005 (Lindblad-Toh K et al Nature [Lond] 438:803). The major conclusions about the dog genome and its comparison with other mammalian genomes indicate that the average transposons insertion rate is lowest in dogs, deletion rate is highest in mouse and the lowest nucleotide substitution rate is in humans (see

Figure D89. Total length (Mb) of aligned and unique sequences in euchromatin. Overlapping portions are orthologous ancestral sequences. Lineage-specific interspersed repeats are shown in larger fonts and in purple color (After Lindblad K et al. 2005 Nature [Lond] 438: 803)

Fig. D89). About 5.3% of the functional elements in dogs and humans underwent purifying selection. Most of these elements are also preserved in mouse, indicating common sequences across mammalian genomes. Half of the highly preserved non-coding sequences are clustered in about 200 gene-poor regions, including transcription factors or axon guidance receptors. Linkage disequilibrium (LD) within breeds of dogs includes several megabases but among different breeds, LD extends only to tens of kilobases. The patterns of LD display two principal bottlenecks; one indicates early domestication and the other reflects recent breeding events. Haplotypes within breeds are long and include 3–5 alleles per locus. Some may involve 100 kb and may be shared to a variable extent across breeds. SNP frequency within breeds is about 1/900 bp and among breeds about 1/1,500. Functionally related genes reveal evolutionary patterns in dogs and humans. The sequence information permits construction of evolutionary trees.

Body size variations are larger in dogs than in other terrestrial mammals and it is under the control of a major QTL in chromosome 15. Near this QTL there is a *IGF1* (insulin-like growth factor) single-nucleotide polymorphism locus, which is common to all small breeds and nearly absent from giant breeds, suggesting that the same causal sequence variant is a major contributor to body size in all small dogs (Sutter NB et al 2007 Science 316:112) (see Fig. D90).

Figure D90. Dog breeds show great variation in size, color and morphology. Top left to right: English Bulldog, Poodle, Italian Greyhound. Below left to right: hungarian Puli, Dachshund, Hungarian Vizsla

D

About 370, mainly recessive genetic diseases have been identified by 1999 and many of them (~58%) have homologs in humans. In 2005, cloning of two Afghan hounds by nuclear transfer from adult skin cells into oocytes that had matured in vivo has been reported (Lee BC et al 2005 Nature [Lond] 436:641). The validity of this paper has been questioned after the same laboratory fabricated reports on human cloning for the purpose of stem cell production ►stem cells. Further investigation confirmed, however, the validity of this paper (Cyranowski D 2006 Nature [Lond] 439:123). ►microsatellite, ►prairie dog, ►insulin-like growth factors, ►QTL, ►Waardenburg syndrome; Ostrander EA et al 2000 Trends Genet 16:117; Breen M et al 2001 Genome Res 11:1784; Savolainen P et al 2002 Science 298:1610; A 3;270 radiation hybrid map: Guyon R et al 2003 Proc Natl Acad Sci USA 100:5296; review of dog genetics; human disease homologs: Sutter NB, Ostrander EA 2004 Nature Rev Genet 5:900; genome sequence: Kirkness EF et al 2003 Science 301:1898; wolf; fox.

Dog Rose: ►*Rosa canina*

DOGS: (dioctadecylamidoglycylspermine): A lipopolyamine used for delivering exogenous DNA into cells. ►liposomes

Dollo Parsimony: It posits that it is harder to acquire a new feature during evolution than to lose it. It is named after the Belgian evolutionist Louis Dollo who in 1893, apparently, first announced the principle as “An organism is unable to return, even partially, to a previous stage already realized in the ranks of its ancestors”. Farris and Felsenstein mathematically defined this law about a century later. (Felsenstein J 1979 Systematic Zool 28:49)

Dolly: ►nuclear transplantation

Dolphins: *Lissodelphis borealis* 2n = 44; *Orcinus orca* and other species are 2n = 44.

Dolycephaly: The head being abnormally long. It is a characteristic of several hereditary diseases.

Domain: The defined segments of proteins (with a characteristic tertiary structure that folds independently and usually represents specific functional properties), or cellular structures (chromosomes), e.g., DNA binding domain of transcription factors. DNA sequence units or exons are also considered as domains. Shared domains of macromolecules reveal evolutionary histories among organisms. It appears that the majority of eukaryotic proteins consist of two or more domains. Some domains may be shared among several different proteins of different functions. Hidden Markov model-based statistics are used for domain recognition. Protein domain contents allow reasonably good inferences on phylogenesis (Yang S et al 2005

Proc Natl Acad Sci USA 102:373). ►domains of antibodies, ►exon, ►protein domains, ►genome domain, ►SMART, ►genetic network, ►hidden Markov model; Coin L et al 2003 Proc Natl Acad Sci USA 100:4516; <http://scop.mrc-lmb.cam.ac.uk/scop/>; <http://ekhidna.biocenter.helsinki.fi:9801/sqgraph/pairsdb>; conserved domains: <http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi>.

Domain Swapping: Generates from monomers of proteins dimeric structures (see Fig. D91). (Hohl M et al 2007 Nucleic Acids Res 35:3053)

Figure D91. Domain swapping

Domains of Antibodies: These are segments of light and heavy-chain polypeptides separable by chemical treatments. ►antibody

Dombrock System Blood (DO): About 64% of northern Europeans are Do(a⁺) blood type; it is coded in the short arm of human chromosome 1. ►blood groups

Domestication: The taming and breeding of animals under human supervision and for human use began in the Neolithic (stone) age, about 10,000 years ago. The evolution of the domesticated animal breeds was a gradual process. There is evidence for numerous MHC *DRB* alleles that are present in modern domestic mammals implying that substantial backcrossing with wild ancestors, either accidental or intentional, has been important in shaping the genetic diversity of our domesticates (Vilà C et al 2005 Trends Genet 21:214).

Cultivation of plants started at about the same time. Fig plants (*Ficus carica*) in the Jordan Valley were apparently domesticated about a thousand years earlier than cereals as indicated by archeological finding of carbonized fruits (Kislev ME et al 2006 Science 312:1372). An estimated 1200 genes of maize was affected by selection during evolution from teosinte (Wright SI et al 2005 Science 308:1310). ►major histocompatibility complex; Cowan CW, Watson J 1992 The Origins of Agriculture. Smithsonian Inst., Washington, DC; Salamini F et al 2002 Nature Rev Genet 3:429; morphological, genetic and archeological evidence for the course of domestication of plants and animals; Zeder MA et al 2006 Trends Genet 22:139.

Domestication Bottleneck: It reduces genetic variation relative to wild ancestors.

Dominance: The property of an allele to be expressed in a heterozygote (heterozygote) in the presence of any other allele at a gene locus. In the majority of species, dominant mutations are much less common than the recessive ones. In humans, however, the known dominant mutations seem to exceed the recessives but many traits cannot be classified to either group. One must keep also in mind that the term dominance was conceived before biochemical characterization of gene expression became feasible. Usually, at a finer level of analysis both the “dominant” and the “recessive” alleles are expressed in the heterozygotes. The degree of dominance is sometimes expressed as the *coefficient of dominance*. In human or larger mammal pedigrees, because of few offsprings, it may be difficult to distinguish between dominant and recessive pattern of inheritance. The probabilities can, however, be analyzed statistically. Let us assume that 8 affected males have 6 affected female offspring and 5 unaffected male progeny. For non-dominant inheritance we would expect the probability to be $(0.5)^6 + (0.5)^5 = (0.5)^{11} \approx 0.00049$ (1/2048). One must also consider the problems of penetrance and environmental factors. ▶codominance, ▶semidominance, ▶dominance reversal, ▶penetrance

Dominance, Evolution of: R.A Fisher suggested in the 1930s that dominance evolves through the acquisition of modifier mutations that convert gradually the original recessive mutations into dominant ones. The basis of this idea was that under feral conditions the majority of alleles are dominant while the majority of new mutations are recessive. Sewall Wright (1934), J.B.S. Haldane (1930) and H.J. Muller (1932) hypothesized that dominance occurs by mutation as such and the rare advantageous dominant ones have the selective advantage of masking the deleterious recessive alleles in the populations. According to the molecular evidence since then, the majority of the mutations (except the loss of genes) show codominance when their function can be determined with greater precision. The development of dominance has been attributed to the control of processes regulating metabolic pathways, to the “flux” by changes in activities of controlled enzymes, by the changes in enzyme concentration and in enzyme kinetics ▶dominance, ▶co-dominance; Bourguet D 1999 Heredity 83:1; Hurst LD, Randerson JP 2000 J Theor Biol 205:641; Bagheri HC, Wagner GP 2004 Genetics 168:1713.

Dominance Hypothesis: It attributes the superior value of hybrids (hybrid vigor, heterosis) to the accumulation of favorable dominant genes. ▶hybrid vigor, ▶overdominance, ▶superdominance; Rédei GP 1982 Cereal Res Commun 10:5.

Dominance Reversal: A change of environment or developmental stage may alter and reverse the dominance–recessivity relationship of alleles (see Table D7). The *co* (*CONSTANS*) mutation flowers earlier than the Columbia wild type but under long daily illuminations, its onset of flowering was delayed. The F1 hybrid was dominant at short days but recessive at long days. The transcription of this gene was regulated by the FLAVIN-BINDING, KELCH REPEAT, F-BOX protein (FKF1). This protein controls the cycling Dof transcription factor (CDF1). FKF1 seems to determine the daily expression of *CO* in part by degrading a repressor (CDF1) of *CO* transcription, depending on the length of daily illumination (Imaizumi T et al 2005 Science 309:293). ▶epistasis, ▶conditional lethal genes, ▶temperature-sensitive mutation, ▶dominance, ▶F-Box; Shiffriss O 1947 Amer Soc Hort Sci 50:330.

Table D7 Reversal of dominance in flowering of *Arabidopsis*

| | Short Days | Long Days |
|------------------|------------|------------|
| wild | 27.4±0.72 | 11.1±0.48c |
| <i>co</i> | 20.0±0.54 | 15.7±0.03 |
| <i>co</i> × wild | 21.0±0.52 | 9.8±0.15 |

(From Rédei, G.P. 1962 Genetics 47:443)

Dominance Theory: ▶dominance hypothesis

Dominance Variance: (in quantitative genetics) This occurs due to the expression of dominant alleles. ▶genetic variances, ▶additive genes

Dominant Allele: It is expressed fully in a diploid (polyploid) even in the presence of recessive allele(s). ▶dominance, ▶semi-dominant

Dominant Individual: Occupying a higher rank in an animal society and better access to food and mates than the rest of the individuals.

Dominant Lethal Assays in Genetic Toxicology: Generally, rodents are treated with mutagens during various stages of spermatogenesis. Subsequently they are mated with untreated females. After about two weeks of pregnancy the females are sacrificed and the number of lethal implantations are classified and counted. ▶bioassays in genetic toxicology, ▶implantation, ▶autosomal dominant mutation

Dominant Negative (dominant-negative): The inhibition of the activity of a normal (wild type) protein when its subunits are mixed with mutant polypeptide

subunits, which alter the conformation and thus render it inactive. ▶ [conformation correction](#), ▶ [allelic complementation](#), ▶ [tetralogue](#), ▶ [RET oncogene](#), ▶ [osteogenesis imperfecta](#), ▶ [Marfan syndrome](#), ▶ [Denys-Drash syndrome](#), ▶ [gain-of-function mutation](#)

D

Donkey: *Equus asinus* 2n = 62. The domestication apparently took place in northern Africa and from more than a single progenitor race of the wild (see Fig. D92). Although in the Western world donkeys are neglected animals today, in medieval times (and in the underdeveloped world even today) they had/have prominent role. The illustration is adopted from the mid-fourteenth century *Biblia Pauperum*. ▶ [hinny](#), ▶ [mule](#); Beja-Pereira A et al 2004 Science 304:1781.

Figure D92. Donkey in a medieval codex

Donohue Syndrome (Leprechaunism, 19p13.2): It is a defect in the insulin receptor. Growth retardation, face anomalies, protuberant ears, abdomen, genitalia, hand, feet enlargement, excessive hair on skin, acanthosis nigricans, hepatocyte vacuolization. ▶ [insulin](#), ▶ [insulin receptor protein](#), ▶ [dwarfism](#)

Donor: A donor provides genetic material (F^+) to the recipient (F^-) by bacterial conjugation or any other means of genetic transfer (including eukaryotes). Blood type O that is acceptable to any individual with other alleles of the ABO blood group or other antigenic substances compatible to other serotype is also called a (universal) donor. ▶ [conjugation](#), ▶ [ABO blood group](#), ▶ [serotype](#)

Donor Site: The original position in the DNA (map) of a non-replicative transposable element from where it may move to another position within the genome, to the *recipient site*. ▶ [transposable elements](#)

Donor Splicing Site: ▶ [introns](#)

Dopa: 3,4-dihydroxyphenylalanine, an intermediate in melanin synthesis; the derivative dopa-mine is a neurotransmitter. ▶ [neurotransmitter](#), ▶ [phenylalanine](#)

Dopamine: A catecholamine formed by decarboxylation of dopa and it is a precursor of epinephrine, norepinephrine and melanine. Dopamine hydroxylase converts dopamine into epinephrine (see Fig. D93). Dopaminergic means an activation or site of effect by dopamine. Regulation of dopamine D2 class receptors involves Akt protein kinase, arrestin $\beta 2$ and protein phosphatase 2A (Beaulieu J-M et al 2005 Cell 122:261). ▶ [dopa](#), ▶ [animal hormones](#), ▶ [neurotransmitter](#), ▶ [DARPP](#), ▶ [memory](#), ▶ [Akt](#), ▶ [arrestin](#), ▶ [phosphatases](#), ▶ [Parkinson disease](#)

Figure D93. Dopamine

Dope: ▶ [lipids cationic](#)

Doping Nucleotides: Process in which a short nucleotide string is synthesized where some codons in the first strand have any of the four natural nucleotides and at the third position they have either G or C. In the second strand at the positions corresponding to the above named codons there will be inosines. The rest of the codons correspond to the usual amino acids. When such an insert is added to a vector, a variety of random mutations may occur in the protein domain coded by the sequence and yields a library of proteins with different amino acids at critical regions. ▶ [directed mutation](#), ▶ [protein engineering](#), ▶ [hypoxanthine](#) [for inosine]; Balint RF Larrick JW 1993 Gene 137:109; Hutchison CA et al 1986 Proc Natl Acad Sci USA 83:710.

DOP-PCR (degenerate oligonucleotide-primed polymerase chain reaction): DOP-PCR amplifies short chromosomal sequence and thus facilitates the detection (by fluorescence) of chromosome copy number in aneuploidy cancer cells. ▶ [FISH](#), ▶ [PCR](#); Tsubosa Y et al 2005 Cancer Genet Cytogenet 158:156.

Doppelgänger: ▶ [prion](#)

Dorfin: An RNA-finger ubiquitin ligase protein. ▶ [RNA finger](#)

Dormancy: A state of low metabolic activity. In plants seed dormancy requires the hormone abscisic acid whereas gibberellic acid relieves dormancy. Two basic-helix-loop-helix proteins seem to suppress germination of seeds (Tsiantis M 2006 Curr Biol 16 (1):R25). ▶ [plant hormones](#), ▶ [DNA binding protein domains](#); Alonso-Blanco C et al 2003 Genetics 164:711.

Dorsal: Relating to the back position of a body or upper surface of a structure or organ. Dorsal–ventral cell fate specification in the *Drosophila* embryo is initiated by *Dorsal* and is partly under the control of an autoproteolysis cascade determined by genes *GD*, *Snk*, *Ea* and the nerve growth factor ligand Spätzle (Dissing M et al 2001 EMBO J 20:2387). *Dorsal* represses the Zen (*zerknüllt*) homeobox by a 600 bp *ventral repression element* (VRE) containing 4 *Dorsal*-binding sites. There are 15 regions in the *Drosophila* genome that contain three or more binding sites within up to 400-bp sequences (Markstein M et al 2002 Proc Natl Acad Sci USA 99:763). About 100 genes mediate the dorsal–ventral nuclear gradient in *Drosophila* (Levine M, Davidson EH 2005 Proc Natl Acad Sci USA 102:4936; Biemar F et al 2006 Proc Natl Acad Sci USA 103:12763)

Dorsal Closure: Dorsal closure after gastrulation of the embryo establishes the dorsal ectoderm by stretching—without proliferation—the lateral ectoderm over a transient epithelial structure (amnioserosa). This is a complex process, mediated by the products of several known genes in *Drosophila*.

Dorsal Lip: ►blastopore

Dorsalization: The formation of dorsal elements is preferentially enhanced at the expense of ventral development during morphogenesis and embryo development. ►morphogenesis

Dorso-ventral: Back-abdomen directional arrangement of anatomical structures. (Stathopoulos A et al 2002 Cell 111:687)

Dosage Compensation: A single dose of a gene has the same phenotypic effect as two or more. Examples for this abound in X-chromosome-linked genes where the phenotype for such genes is practically identical in the XY males and XX females or in the WZ females and ZZ males or XO males and XX females. Such dosage compensation may occur with various doses of the X-chromosome and to some extent, it may occur in various aneuploids. MSL (male-specific lethal, *msl-1* 2.53.3, *msl-2* 2.90) and MLE (maleless, *mle-2*.55.2) proteins appear to be involved in dosage compensation in *Drosophila* by hypertranscription in the single male X chromosome. The MSL1 protein binds to more than 700 locations in the X chromosome and cover more than half of the genes. High level of dosage compensation involves the most essential genes. The binding favors the 3'-end of the transcription units and exons and coding sequences (Gilfillan GD et al 2006 Genes & Development 20:858). The MSL effect is also global not just directed to specific sites (Legube G et al 2006 Genes & Development 20:871). MSL is responsible for the

presence of a monoacetylated histone H4 in the male X chromosome of *Drosophila* and this results in remodeling of the active chromatin (Sass GL et al 2003 Proc Natl Acad Sci USA 100:8287). MOF, a histone H4 lysine 16-specific acetyl transferase protein interacts with the MSL and with several components of the nuclear pore complex (Mendjan S et al 2006 Mol Cell 21:811). MLE also seems to attach to the male X-chromosome two non-coding RNA (roX1, roX2) that may upregulate the transcription of genes in the X. In mammals, however, the non-coding Xist RNA mediates X-chromosomal inactivation in the female. *Sex lethal* (*sxl*, 1-19.2, with many different alleles), controls both sexual dimorphism and dosage compensation through its 39-kDa-protein product and promotes alternative splicing of *msl-2* RNA transcripts. Females with X:A (sex chromosome:autosome) ratio of 1 synthesize this protein and permit the transcription of both X-chromosomes. Males of X:A of 0.5 do not make the SXL protein and increase the expression of the majority of the X-linked genes. SXL permits the normal transcription of *Sxl* and *tra* in the females but in males, it inserts stop codons into these two transcripts. There are binding sites for SXL in the 3' untranslated region (UTR) in the *msl-1* transcripts and these may cause down-regulation in the females. There are both 5' and 3' UTR binding sites in the *msl-2* transcripts in the females and thus other potentials for regulation. Msl-2 seems to be the main target and instrument of X-regulation. The SXL protein is suspected to have another function, down-regulating some X-chromosomal genes in the female flies. In the hermaphroditic XX females of *Caenorhabditis*, X-chromosomal genes are expressed at about the same level as in the normal XO males (hypotranscription; Meyer BJ 2000 Trends Genet 16:247). In *Drosophila*, the single X-chromosome is hypertranscribed to achieve dosage compensation. In mammals, only one of the two or more X-chromosomes remains active. Some of the (*sdc*) genes affect both sex determination and dosage compensation. In the males XOL1 prevent the assembly of the dosage compensation complex in contrast to the XX females (hermaphrodites) where it activates the assembly. In *Caenorhabditis* a 793-bp sequence recruits the dosage compensation complex to the X-chromosome and from one or more sites its effect spreads along the chromosome (Csankovszki G et al 2004 Science 303:1182). The *rex* recruitment elements occurring in promoters, exons and introns in the X-chromosome of *Caenorhabditis* control dosage compensation. Mutations in these elements may abolish dosage compensation (McDonel P et al 2006 Nature [Lond] 444:614). Other genes (dumpy series [*dpy*]) affect only dosage compensation. The DPY-27 protein is associated with

the X-chromosomes in the hermaphrodites of *Caenorhabditis*. DPY-27 like proteins are present in other organisms too and control chromosome condensation and segregation. The DPY-26 locus affects Dpy-27 and Dpy-30 proteins for dosage compensation and Sdc2 and Sdc3 for the coordination of dosage compensation and sex determination. SDC-1 is a 139-kDa protein with Zn fingers. This family of proteins has some structural features characteristic for motor proteins. SDC-3 regulates sex determination by its ATP-binding domain and a Zn finger-like domain seems to affect dosage compensation. Actually, both series are cooperating in reducing the level of X-chromosomal gene expression in the hermaphrodites. A more recently discovered gene, *Pof* (painting of the fourth chromosome) involves heterochromatinization of the X chromosome in *Drosophila busckii* when translocated from *D. melanogaster* where it is located in the fourth chromosome. In birds, observations on dosage compensation are not entirely unequivocal although some of the genes seem to follow the rules in mammals. Dosage compensation may be either by X-chromosomal inactivation or by imprinting (Reik W, Lewis A 2005 Nature Rev Genet 6:403). It has been suggested that X-chromosomal inactivation and imprinting might have evolved from a defense mechanisms that silences unpaired DNA (Huynh KD, Lee JT 2005 Nature Rev Genet 6:410).

DOTMA: ► [lipids cationic](#)

Dotted: ► [Dt gene](#)

Double-Blind Test: Neither the subjects nor the experimenter knows who received the treatment and who received the placebo. ► [placebo](#), ► [open-label trial](#)

Double Bridge: It is visible at anaphase I if four-strand recombination occurs in paracentric inversion heterozygotes or in the case of sister-chromatid exchange in ring chromosomes. ► [bridge](#), ► [inversion](#), ► [dicentric ring chromosome](#)

Double Cortex: Human Xq21.3-q24 brain defect of the thinner cortex and disorganized neurons resulting in mental retardation and seizures. ► [mental retardation](#), ► [seizures](#)

Doublecortin (DBX): DBX and doublecortin-like (Dclk) kinases control mitotic proteins associated with neuronal development and neuronal migration (Shu T et al 2006 Neuron 49:25; Koizumi H et al 2006 Neuron 49:55).

Double Cross Hybrids: These were extensively used for the commercial production of hybrid corn. The seed companies produced the seed of single crosses (1) and (2) and crossing the two single crosses according to the scheme yielded the seed for the farmers to produce corn for food, feed or industrial raw material (Fig. D95). Currently, most of the corn hybrids are single-crosses. ► [hybrid vigor](#), ► [heterosis](#), ► [cytoplasmic male sterility](#)

single cross (1) [A x B] x [C x D] single cross (2)
DOUBLE CROSS SEED ←

Figure D95. Derivation of Double Cross Hybrids

Double Crossing Over: A single recombination changes the synteny of linked markers (see Fig. D96). The frequency of double crossing over is expected to equal the product of the frequency of the single crossing overs. 2-strand double crossing over within

an inverted segment generally has no harmful effect in inversion heterozygotes and two normal and two inverted chromosomes are recovered in the gametes. 3-strand double crossing over within the inversion produces 1 acentric, 1 dicentric, 1 functional recombinant chromosome with a piece of the inverted segment and 1 functional (inverted or non-inverted chromosomes). 4-strand double crossing over within a paracentric inversion heterozygote leads to the formation of double bridges (two dicentric chromosomes) and two acentric fragments and most likely no viable gametes. In pericentric inversions bridges do not occur but the gametes receiving the exchange strands (except the two strand double cross overs) will be duplicated or deficient and most likely non-viable. Double crossing over in translocation heterozygotes, depending on their site, may damage most of the gametes and reduces the fertility below 50%. ► [crossing over](#), ► [inversion](#)

Double Dummy Trial: Clinical test where patients take two sets of medicine (experimental or placebo) for treatment A and treatment B and neither the patients nor the experimenter know who received A or B until the evaluation has been completed.

Double Exchange: ► [double crossing over](#)

Double Fertilization: It occurs in plants when one of the generative nucleuses of the pollen fuses with the haploid egg and gives rise to the zygote whereas the other fuses with the two polar nuclei and initiates the development of the triploid endosperm. In a *cdc2* mutant *Arabidopsis* the pollen tube contains only a single sperm and that fertilizes the egg, yet minimal endosperm (and mainly aborted seeds) developed indicating the transfer of a positive signal to the two nuclei of the future endosperm that normally is triploid after fertilization by the second sperm (Nowack MK et al 2006 Nature Genet 38:63). ► [gametophyte](#), ► [embryogenesis in plants](#), ► [heterofertilization](#), ► [semigamy](#), ► [apomixis](#), ► [polyembryony](#), ► [adventive embryony](#), ► [parthenocarp](#), ► [xenia](#), ► [metaxenia](#), ► [CDC2](#), ► [pollen tube](#)

Double Flowers: ► [flower differentiation](#), ► [petal](#), ► [Matthiola](#)

Double Helix: Two deoxyribonucleotide chains formed by phosphodiester linkages are joined in a helical arrangement through hydrogen bonding between bases

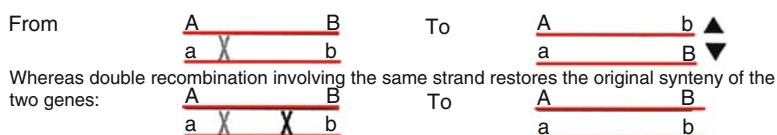

Figure D96. Double crossing over

as determined essentially by the Watson and Crick model (see Fig. D97). The two DNA strands form plectonemic coils (wound around each other) that can be partially and locally released during replication by the helicase and topoisomerase enzymes. ▶DNA types, ▶Watson and Crick model, ▶helicase, ▶topoisomerase, ▶plectonemic coils; Nature (2003) 421:395–453.

Double Heterozygote: Heterozygous at two gene loci.

Double Homozygote: Homozygous at two gene loci.

Double Infection: A bacterial cell may be infected with two different genotypes of the same or compatible bacteriophages and this may provide an opportunity for phage recombination. ▶multiplicity of infection

Double Lysogenic: A bacterium carrying a normal lambda phage, side-by-side with a λ dg. This lambda-defective-galactose phage lost a piece of its genetic material but acquired the bacterial *ga*⁺ gene and is thus capable of specialized transduction if another phage compensates for its defect. When such a phage is induced (to switch from prophage to vegetative phage) it produces a *high frequency lysate* and high *specialized transducing* ability. ▶transduction, ▶lysogen

Double Minutes (DMs): Extrachromosomally amplified chromatin containing a particular acentric chromosomal segment (gene). The homogeneously stained sites in the chromosomes indicate their incorporation. They occur frequently in cancer cells. ▶cancer, ▶homogeneously stained sites, ▶fragile sites, ▶YAC, ▶DM chromosome, ▶amplification; Zimonjic DB et al 2001 Cytogenet Cell Genet 93:114.

Double Muscling: ▶myostatin

Double Negative Cell: Lymphocytes in the thymus without CD4 or CD8 proteins.

Double PCR and Digestion: A procedure intended to enrich mutant DNA sequences in the amplified mtDNA. During the first PCR step both mutant and wild type DNA is amplified. Then a restriction endonuclease is applied which degrades the wild type but not the mutant DNA. A subsequent PCR step then amplifies the full-length mutant sequence. ▶polymerase chain reaction, ▶mtDNA

Double Positive Cell: It expresses both CD4 and CD8 proteins but may die within the thymus. ▶T cell, ▶lymphocytes

Double Reciprocal Plot: ▶Lineweaver-Burk plot

Double Recombination: Two recombinations in between two strands (chromatids, DNA) within a determined interval (see double crossing over). It is genetically detectable only if there are multiple markers in the chromosome.

Double Reduction: A chromatid segregation, which may occur when in a trisomic or tetrasomic individual recombination takes place between a gene and the corresponding centromere (see Fig. D98). Consequently, in a duplex, double recessive gametes are produced and e.g., an *AAa* individual produces *aa* gametes. The chromosome mechanism leading to double reduction in case of tetrasomy is represented at the entry *alpha parameter*. ▶trisomic analysis, ▶autopolyploid, ▶centromere mapping in higher eukaryotes, ▶alpha parameter

Figure D98. Double replacement targeting

Double Replacement Targeting: It can be used for the insertion very small changes within a gene locus. The procedure is suitable for the HPRT marker where both positive and negative selections are practical. The first replacement is followed by a second step with another vector homologous to the same target and carrying the negative selectable gene, which then screened. (Moore RC et al Biotechnology 1995 13:999; see diagram).

Double Restriction: The DNA is cleaved by two restriction enzymes. ▶restriction enzymes

Double Stranding: The sequencing of both strands of the DNA to minimize errors.

Double-Copy Vector: A transgene, including its promoter, is inserted into the 3'-LTR. After replication (since the 3'-LTR is the template for the 5'-LTR) the

transgene + promoter + the regular 5'-LTR promoter are present in the new construct that is expected to display high activity of the transgene because of the duplications. The transgene may be inserted in either forward or in reverse orientation. In the former case, it may slow down the expression from the downstream copy. In the reverse orientation this may not happen but the transgene may not find its own polyadenylation signal. Nevertheless, its stability may not suffer because the signal may be provided by adjacent cellular gene(s). ►retroviral vectors, ►SIN vectors; Wiznerowicz M et al 1997 Gene Ther 4:1061.

Doubled Haploid: A diploid line arising by doubling the chromosome number of a haploid. Therefore, they are expected to be homozygous at all gene loci until mutation occurs. ►haploid

Doubleisotrismic: In wheat, $20'' + (i + i)1'''$, $2n = 43$, [$''$ = disomic, $'''$ = trisomic, i = isochromosome]. ►disomic, ►trisomic, ►isochromosome

Doublemonoisosomic: In wheat, $20'' + i' + i'$, ($2n = 42$), [$''$ = disomic, $'$ = monosomic, i = isosomic]. ►disomic, ►monosomic, ►isosomic

Doublemonotelosomic: In wheat, $20'' + t' + t'$, $2n = 42$, [$''$ = disomic, $'$ = monosomic, t = telo-chromosome]. ►disomic, ►monosomic, ►telosome

Double-Strand Breaks (of the chromosomes): They occur frequently as a consequence of ionizing radiation of the nuclei, exposure to various chemicals (mutagens, carcinogens), free oxygen radicals, cellular enzymes, etc. Palindromic “at-risk sequence motifs” (ARMs), trinucleotide repeats, arrest of the cell cycle, meiotic recombination, mating type switch, intron homing may all cause such breaks. Double-strand breaks (and repair) are requisites for meiotic recombination or for any segmental interchange of the chromosomes. Apparently, when double-strand breaks occur the broken sites tend to congregate and thereby translocations are facilitated (Aten JA et al 2004 Science 303:92). In the budding yeast, mitochondrial DNA sequences may be incorporated into chromosomal DNA in the vicinity of the LTRs of retrotransposons.

The frequency of spontaneous DSB formation have been inferred from inviability, chromosome loss or cytogenetic phenotypes of cells lacking DNA repair proteins, some of which affect processes other than repair. These estimates range from 0.2–1 per genome replication in *Escherichia coli* and 50 per human genome (Vilenchik MM, Knudson AG 2003 Proc Natl Acad Sci USA 100:12871). Single-strand breaks occur 15–20 times more frequently. For repair of the breaks Ku70, Ku80, DNA-dependent protein kinase, XRCC4 and DNA ligase IV are required.

Double-strand breaks may be repaired by gene conversion. *E. coli* mutants in base excision repair because of defects in glycosylase activity are less susceptible to double-strand breaks but overproduction of glycosylases results in more DNA lesions. The DNA breaks occur when the glycosylase attempts to remove the damaged DNA. In higher eukaryote cells more than 8 double-strand breaks may occur daily. Double-strand breaks may be repaired by up to 20% efficiency with targeted oligonucleotides (Storici F et al 2003 Proc Natl Acad Sci USA 100:14994). In yeast histone H2A, phosphorylated at Ser129 is recruited to the site of the break and additional protein factors such as Arp4 and NuA4 and other chromatin remodeling proteins are also directed to the site for repair (Downs JA et al 2004 Mol Cell 16:979). Post-replicative break repair require the presence of cohesin along both arms of the chromosomes. DNA checkpoint kinases Mec1p and Tel1p phosphorylate histone H2AX and this generates a domain for cohesin binding and Mre1 and Scc2p enable binding (Ünal E et al 2004 Mol Cell 16:991). Proteasome subunit Sem1/DSS1 is also required for double-strand break repair by both homologous and non-homologous end joining repair (Krogan NJ et al 2004 Mol Cell 16:1027). Double-strand breaks are sensed in mammalian cells by the Mre11–Rad50–Nijmegen breakage syndrome 5 complex (MRN) and it recruits ataxia telangiectasia mutated (ATM) to the broken ends and cell cycle arrest, apoptosis and DNA repair are activated (Lee J-H, Paull TT 2005 Science 308:551).

RNA nucleotides complementary to DNA may serve as templates for repairing double-strand break in yeast using DNA polymerases α and δ (Storici F et al 2007 Nature [Lond] 447:338). ►palindrome, ►ROS, ►trinucleotide repeats, ►intron homing, ►chromosomal aberrations, ►chromosomal instability, ►end-joining, ►non-homologous end-joining, ►LTR, ►retrotransposon, ►Ku, ►PARP, ►X-ray repair, ►ATM, ►RAD50, ►RAD51, ►terminal deoxynucleotidyl transferase, ►DNA repair, ►glycosylases, ►DNA-PK, ►DNA ligases, ►Arp, ►NuA, ►chromatin remodeling, ►XRCC, ►X-ray caused chromosome breakage for illustration, ►V(D)J, ►gene conversion, ►Mac, ►Tel, ►histones, ►Mre, ►Scc, ►cohesin, ►Szostak model, ►mismatch repair, ►delitto perfetto, ►telomerase; Haber JE 2000 Trends Genet 16:259; Paques F, Haber JE 1999 Microbiol Mol Biol Rev 63:349; Blaisdell JO, Wallace SS 2001 Proc Natl Acad Sci USA 98:7426; Hopfner K-P et al 2002 Current Opin Struct Biol 12:115; double-strand break repair in human cells: O'Driscoll M, Jeggo PA 2006 Nature Rev Genet 7:45; Su TT 2006 Annu Rev Genet 40:187; double-strand break repair review: Downs JA et al 2007 Nature [Lond] 447:951.

Double-Strand-Break Repair Model of Recombination:

►Szostak model, ►double-strand breaks

Double-Strand RNA: ►RNA double-stranded

Doublestranding: The sequencing of both complementary strands of particular DNA stretch in order to minimize errors. ►compression in gels, ►base calling

Doublet: A double band in the salivary gland chromosome or a double band in an electrophoretic gel (see Fig. D99). Also, *Paramecia* that share a common endoplasm and a single macronucleus. ►salivary gland chromosomes, ►gel electrophoresis, ►*Paramecium*

Figure D99. Doublet

Double-Targeting Vector: It increases transformation efficiency by using selective CAR-specific adaptor proteins for special cells and specific promoters for transcription of the desired gene. Such an approach may enhance efficiency many folds. ►CAR, ►retroviral vectors, ►gene therapy

Doubletelotrisomic: In wheat, $20'' + (t+ t) + 1'''$, $2n = 43$, [$''$ = disomic, t = telochromosome, $'''$ = trisomic]. ►disomic, ►telosome, ►trisomic

Doubling Dose: The amount of a mutagen that doubles the spontaneous rate of mutation. Since mutation rate depends on the organisms, its genotype, developmental stage and environmental factors, the estimates arrived at by different investigators may not be identical. From mouse experiments it had been estimated that 1 R chronic ionizing radiation produces a mutation rate of 2.5×10^{-8} per locus per generation and the spontaneous rate was considered to be 1×10^{-6} , hence $(1 \times 10^{-6}) / (2.5 \times 10^{-8}) = 40$ R was assumed to be the doubling dose of ionizing radiation for humans too. Other estimates considered the doubling dose for recessive mutations 32 R and for dominant ones 20 R. More recently, the doubling dose for radiation has been estimated as 100 cGray (1 Rad). The majority of the data are systematically biased, depending on the genes used because the range of inducible mutations in mouse may vary within a range of about an order of magnitude and therefore, the samples used may not be true "average representatives". The doubling dose may have important meaning for the estimation of genetic radiation risks. Assuming that the average human dominant mutation rate is 10^{-5} to 10^{-6} , the chances

for the occurrence of a human dominant mutations at 100 R dose (1 R = ca. 93 erg/wet tissue) exposure may be 32×10^{-5} to 32×10^{-6} , i.e., 1/3,125 to 1/31,250. Actually, these estimates may not be very accurate but direct data cannot be readily obtained in human populations. Another problem is that the mutant gametes may not compete successfully and the absolute genetic damage may be much larger than these estimates. An additional problem is that in human populations the mating is random (or almost random) therefore homozygous recessives may not appear most of the time unless the marriages are consanguineous. Atomic radiations in Hiroshima and Nagasaki substantially increased the incidence of cancer and teratogenesis in the generation exposed, but an increase in human mutations in the following generation was not clearly detectable except by altered sex ratio. Based on the Hiroshima and Nagasaki human data of 31,500 children of parents exposed to the bombs within a 2-km range of the epicenter, James Neel estimated the doubling dose for low-level chronic radiation to be 3.4 to 4.4 Sv equivalent. On the basis of various mouse irradiation data the average doubling dose in mouse he estimated as 1.35 Gy. This latter figure was derived by pooling of recessive lethals (1.77), recessive visibles (3.89), dominant visibles (0.16), deletion or mutation of the dominant allele in male mice at 7 loci (0.44), protein loci (0.11), etc. studied in different mouse strains. The Chernobyl atomic power plant accident in 1986 has shown, however, genetic effects and increase in cancer caused by atomic radiation. A medical X-ray machine may deliver 0.04 to 1.0 rem (100 rem = 1 Sievert [Sv]) to the organ or structure routinely examined. Although the gonads are generally shielded during these examinations, some general risk remains, particularly for carcinogenic effects. Molecular techniques developed to detect mutations in DNA base and amino acid sequences have also been used to ascertain doubling doses. ►radiation effects, ►mutation in human populations, ►radiation hazard assessment, ►relative mutation risk, ►coefficient of inbreeding, ►atomic radiation, ►teratogenesis, ►RBE, ►Rem, ►Rad, ►Sievert, ►BERT, ►specific locus mutations assay, ►mutation detection; Sankaranarayanan K, Chakrobarty R 2000 Mutation Res 453:183.

Doubling Time: The time required for the completion of a cell division, measured in minutes, hours or days for specific cell types under defined conditions. ►cell cycle

Doubly Uniparental Inheritance: It is displayed by the mitochondria of some marine mollusks (*Mytilidae*). They have two types of mitochondria: one (F) is transmitted by the females to both female and male

offspring, and the other (M) is transmitted by the males only to the male offspring. ►mitochondria, ►uniparental inheritance, ►paternal leakage; Southerland B et al 1998 Genetics 148:341.

Douglas Fir (*Pseudotsuga menziesii*): Primarily a forest timber tree with $2n = 2x = 26$.

DOVAM-S (detection of virtually all mutations—single strand conformation polymorphism): A rapid method with very high efficiency. ►single-strand conformation polymorphism; Liu Q et al 1999 Biotechniques 26:932, 936, 940.

Dowex Resins: Ion exchangers and used also for gel filtration and chromatography. ►ion exchange resins, ►gel filtration, ►chromatography

Down Promoter: It slows down the rate of transcription.

Down-Regulation: decreasing activity by regulation. ►up-regulation, ►regulation of gene activity

Down's Syndrome: It is caused by primary trisomy or translocation of human chromosome 21 or 21q21–22.3. Robertsonian translocations occur in 5% of the patients, most commonly with 14q21q (Berend SA et al 2003 Am J Hum Genet 72:488). Older literature calls Down syndrome by the unfortunate term of *mongoloid idiocy*. The incidence of this condition varies from less than 1/1,000 at maternal age around 20 years to close to 100/1,000 live birth when the mother approaches menopause.

Trisomy 21 may affect only part of the body in a mosaic pattern. The transmission of disomic gametes is about 91% through the females and 9% through the males. The fertility of the afflicted persons is reduced (especially males) and the afflicted females is less than 50%. The most important phenotypic transmission risk by signs in humans involve a relaxation of the muscles (hypotonia) controlling the eyefold, protruding tongue, flat face, shorter than expected height, two third displays the

simian fold in the palm (see Fig. D100, Fig. D101), generally (but not always) reduced mental abilities (IQ 25 to 50 although with proper training they can learn to read and write and enjoy life and usually are quite sociable and affectionate.

This trisomy is associated with a series of other anomalies such as heart disease, susceptibility to megakaryoblastic leukemia. For leukemia and other tumors the SIM2 (Single Minded) gene encoding a basic helix-loop-helix motif within chromosome 21q22.2 is responsible. SIM1 in human chromosome 6q16.3-q21 is similar to SIM2. SIM2 exists in long and short forms due to alternative splicing (DeYoung MP et al 2003 Proc Natl Acad Sci USA 100:4760).

Prenatal cytological examination of fetal cells in the amniotic fluid and sampling chorionic villi may reveal if the fetus has this condition. Unfortunately, amniotic cells may display anomalies that do not occur in the normal cells of the fetus. There is a correlation between the low level of maternal α -fetoprotein (MSAFP) and fetal Down syndrome. The interpretation of the clinical analysis is further sharpened if unconjugated estriol (α -hydroxylation product of estradiol) and gonadotropin levels are also measured. Ultrasonic analysis may also indicate Down syndrome prenatally if heavy skin fold on the neck (nuchal translucency test, NT), excessive fluid accumulation, narrow small intestines or short bones are indicated. First-trimester NT screening for Down syndrome enables a significant number of women over age 35 to lower the risk for chromosome 21 trisomy several fold and avoid the risks of invasive testing (see Fig. D102). However, despite significant reductions in age-specific mid-trimester risks, a relatively high proportion of women over 35 years of age still opt for invasive testing (Caughey AB et al 2007 Prenatal Diagn 27(2):119). A newer, non-invasive technology is digital PCR SNP, which analyzes the fetal nucleic acids in maternal plasma. The use of digital PCR determines the allelic imbalance of a SNP on PLAC4 mRNA,

Figure D100. In a normal individual the palm creases do not go all the way from one side to the other (left). In Down syndrome and some other congenital disorders the typical Simian folds present. In addition, the hands may be shorter and the little finger crooked

Figure D101. Down's syndrome

Figure D102. Down's syndrome, Sweden 1968–1970

a placenta-expressed transcript on chromosome 21, in the maternal plasma of women bearing trisomy 21 fetuses. The procedure appears to be accurate (Lo YMD et al 2007 Proc Natl Acad Sci USA 104:13116). The recurrence risk of trisomy is very low unless the family has a history of non-disjunctions and heterozygous for translocations involving chromosome 21. In the expression of the bone characteristics of this trisomy, the ETS oncogene and transcription factor (human chromosome 21) may play the major role. The *DSCR1* (Down syndrome critical region) gene at 21q22.1-q22.2 encodes a proline-rich inhibitor of calcineurin protein phosphatase, which is highly expressed in the fetal brain and other organs (Fuentes JJ et al 2000 Hum Mol Genet 9:1681). The brain of DS individuals has fewer neurons and abnormal neuron differentiation. Apparently, several genes are overexpressed in the critical region of human chromosome 21 and the corresponding mouse region (Amano K et al 2004 Hum Mol Genet 13:1333). The expression of some chromosome 21 genes is however lower or are at normal level or highly variable among individuals (Yahya-Grayson EA et al 2007 Am J Hum Genet 81:475). In mouse, the human 21 chromosome genes are distributed among three chromosomes, 16, 21 and 22. In addition, the neurons become apoptotic earlier and predispose them to Alzheimer syndrome symptoms. These defects have been attributed to elevated levels of lipid peroxidation. The defects in the

nervous system are attributed also to *DYRK*, a dual-specificity tyrosine phosphate regulated kinase (Martinez de Lagran M et al 2004 Neurobiol Dis 15:132). Folate deficiency and hypomethylation due to defects in methylene tetrahydrofolate reductase and methylene synthase reductase may favor the nondisjunction involved. Many thousands of genes are involved in trisomy and even in smaller duplications, the number of genes can be several hundreds. Therefore, the precise molecular cause of the clinical symptoms is difficult to interpret (Vacik T et al 2005 Proc Natl Acad Sci USA 102:4500). Screening, using several tests, from the first trimester of pregnancy is highly effective (Malone FD et al 2005 New England J Med 353:2001). NFAT transcription factor is crucial for animal development. Two genes of mouse *DSCR1* (*Down syndrome critical regulator*, inhibitor of calcineurin) and *DYRK1A* (a nuclear serine/threonine kinase acting on GSK3) synergistically hinder the nuclear occupancy of NFATc transcription factors and this leads reduction in activation of NFAT-depending genes. This fact explains the cognitive deficits and muscular hypotonia and other symptoms of trisomy 21 (Arron JR et al 2006 Nature [Lond] 441:595). ▶nondisjunction, ▶trisomy, ▶trisomic analysis, ▶MSAFP, ▶I.Q., ▶amnion, ▶estradiol, ▶fetoprotein, ▶translocation, ▶prenatal diagnosis, ▶homocystinuria, ▶amniocentesis, ▶Alzheimer disease, ▶apoptosis, ▶triple test, ▶mongolism, ▶NFAT, ▶calcineurin, ▶GSK3, ▶PCR; Hassold PA, Jacobs PA 1984 Annu Rev Genet 18:69; Hunt PA, LeMaire-Adkins R 1998 Curr Top Dev Biol 37:359; Kahlem P, Yaspo M-L 2000 Gene Funct Dis 1:175; Epstein CJ 2001 In: Scriver JR et al (eds), The Metabolic and Molecular Bases of Inherited Disease, McGraw-Hill, New York, p. 1123; Gardiner K et al 2002 Genomics 79:833; Patterson D, Costa ACS 2005 Nature Rev Genet 6:137.

Downstream: In the direction of the 3' terminus of the polynucleotide; the nucleotide chain grows downstream because the nucleotides are added to the 3' OH end of the preceding one.

Downstream Box: A downstream enhancer of prokaryotic translation of mRNA. It appears that it is not acting by binding to the 16S rRNA (anti-downstream box) as previously suggested.

Downtag: ▶bar-code genetic

Doxorubicin (adriamycin): An antineoplastic agent, immunosuppressant, inhibitor of reverse transcriptase and suspected a carcinogen (see Fig. D103). A single recessive gene in chromosome 16 of mouse determines doxorubicin susceptibility and a modifier exist in chromosome 9. The susceptibility is correlated

with renal disease. (Zheng, Z et al 2005 Proc Natl Acad Sci USA 102:2502). ►angiogenesis

Figure D103. Doxorubicin hydrochloride

Doxycycline: An analog of tetracycline (see Fig. D104).
►tetracycline

Figure D104. Doxycycline

Doyme Honeycomb Retinal Dystrophy: ►macular degeneration

DP1: A transcription factor activated by MDM2.
►MDM2, ►E2F1

DPA (DNA pairing activity): A protein (120-kDa) that promotes the formation of heteroduplexes in yeast.
►recombination mechanisms eukaryotes

DPC4 (deleted in pancreatic cancer at human chromosome 18q21.1): A gene missing in about 50% of the pancreatic cancer cells. It is homologous to the *Drosophila* mad (many abnormal [imaginal] discs, 3–78.6) gene, member of the *dpp* (decapentaplegic) family, encoding a transforming signal related to TGF. ►morphogenesis in *Drosophila*, ►tumor suppressor genes, ►TGF, ►SMAD, ►imaginal disc

dpc also d.p.c. (days post coitum): The time after mating has taken place (in embryonic/fetal development).

DPE (downstream promoter element): ►core promoter, ►DSTF

dpm (disintegration per minute): The number of disintegrations per 1 g radioactive radium = 1 μ Ci = 2.2×10^6 dpm but usually about half as many counts

per minute (cpm) are shown in the equipment that generally work at about 50% efficiency. ►Curie

DPN (diphosphopyridine nucleotide): Current name NAD (nicotinamide adenine dinucleotide).

dpp (decapentaplegic): ►morphogenesis in *Drosophila* {17}

DPT: ►developmental therapeutics program

DQ Antigen: Antigen encoded by the DQ segment of the HLA complex. ►HLA

DR (death receptor): ►TRAIL, ►death domain, ►apoptosis

DR Antigen: Antigen encoded by the DR alleles of HLA. ►HLA

DRADA: A dsRNA-dependent adenosine deaminase; an RNA editing enzyme in mammals; the same as dsRAD. ►RNA editing, ►dsRNA

Draft Genome Sequence: An assembly of scaffolds into a nucleotide sequence map, which still has some gaps and other deficiencies. ►scaffolds in genome sequencing; Katsanis N et al 2001 Nature Genet 29:88; ►human genome

DRAP: ►DSTF

Dras: *Drosophila* homolog of *ras*. ►RAS oncogene

DRB (5,6-dichloro-1- β -D-ribofuranosylbenzimidazole): A potent inhibitor of eukaryotic mRNA synthesis in crude in vitro transcription system but not with purified polymerase II. ►transcript elongation, ►P-TEFb

DREAM (downstream-regulatory element antagonist modulator): A transcriptional repressor. When its calcium binding sites “EF-hands” are occupied by Ca^{2+} it comes off from the DRE element of the gene and transcription may be facilitated. ►CREB, ►calmodulin; Ledo F et al 2000 Mol Cell Biol 20:9120.

Dredging, Data: The finding tendencies within the set of data unforeseen at the outset. ►data mining

DRES: *Drosophila*-related expressed sequences.

DrFP583: A fluorescent protein that may change color from green to red after some elapse of time and may be used to monitor of gene expression in function of time. ►aequorin

Drift, Genetic: A change in gene frequencies caused by a sampling error in the gametic array of random mating populations. Such a change, due to chance, is most likely when the effective population size (the number of breeding individuals) is small. Genetic drift may occur repeatedly in a population and can cause substantial changes in the frequency of several

genes. The change does not reflect the adaptive value of the alleles involved. ►effective population size, ►founder principle, ►genetic drift, ►hitchhiking, ►mutation neutral, ►Muller's ratchet, ►antigenic drift, ►antigenic shift; Wright S 1921 *Genetics* 6:111; Pritchard JK 2001 *Am J Hum Genet* 69:124; Frost SD et al 2001 *Proc Natl Acad Sci USA* 98:6975.

D

Drip (ARC [activator required cofactor]): A transactivation complex of ~16 subunits in the chromatin. ►transactivator, ►chromatin; Taatjes DJ et al 2002 *Science* 295:1058.

DRIP (defective ribosomal products): About 30% of the proteins produced suffer translational error and chopped up by proteasomes, the quality control system of the cell. The amino acids are then recycled. Similar fate is waiting for some of the viral proteins forced upon the cells by the viral genetic material after infection. Aging cells may also be destroyed by apoptosis when their mission is completed. Viral proteins are disposed of mainly with the assistance of the major histocompatibility system class I (MHC I) that displays the peptide fragment of the surface of the cell. The MHC class II molecules similarly handle extracellular bacterial protein pieces. The MHC molecules reside inside the cells and the peptides are transported into the endoplasmic reticulum by TAP to meet the MHC system. The undesirable peptides are then loaded there onto the MHC molecules, which ferry them to the cell surface. The circulating T cells intercept the MHC—undesirable peptide complex and trigger an immune reaction. ►proteasome, ►apoptosis, ►MHC, ►TAP, ►T cell, ►immune system

Driver Excess Hybridization: ►subtractive cloning

DRK: A downstream receptor kinase of the *Drosophila* light signal transduction pathway. Its vertebrate homolog of GRB2 and it is equipped with SH2 and SH3 domains and it is frequently called a mediator protein in signal transduction. ►GRB2, ►SH2, ►SH3, ►signal transduction

Droe1: 24 kDa *Drosophila* mitochondrial homolog of GrpE. ►Grp

Drosha: Double-stranded RNA-specific type III RNase, and produces a precursor of miRNA with 5' phosphate and 2-nucleotide 3' overhang. For its activity, an RNA binding protein is also required (Tomari Y, Zamore PD 2005 *Current Biol* 15:R61). ►microRNA, ►mirtron; Elbashir SM et al 2001 *Genes Dev* 15:188.

Drosophila: Species of dipteran flies. Genetically most thoroughly studied is the cosmopolitan *D. melanogaster*, (n = 4). The species are reproductively isolated, i.e., they may intermate if the opposite sex

from the same species is not available but the F1 offspring is sterile. The sterile eggs may be recognized by the lack of filaments (see diagrammatic life cycle in Fig. D105). The size of the eggs is about 0.5 mm. Within less than a day, it hatches into the first instar stage larva. (The instar is a larval growth stage in between moltings). The larvae shed their cuticle by the process of molting. Three instar stages are distinguished. The larvae are very voracious feeders and reach a size of about 4.5-mm. The cuticle of the third instar darkens and hardens and becomes the puparium four days after hatching, and in another four days the metamorphosis completed and from the larva the imago (2-mm) emerges. (The imago is a fully differentiated adult form.) This adult type emerges by the process of eclosion through the anterior (fore) end of the pupa. Within a day its color darkens, the wings expand and the abdomen becomes rotund.

There is no further growth after emergence. Within two days the imagoes may be copulating after a mating courtship and may start laying eggs. The adult males live for about 33 days while the females die on the average after 26 days.

Sexing (determining the gender) of *Drosophila* can be made by looking at the metatarsal segment of the fore leg that carries a structure called *sex comb* in the male only (see Figs. D106 and D107). Sexing is possible also on the basis of the genitalia viewed from the ventral side of the abdomen. The abdominal segmentation is also different in the two sexes. After copulation the female stores the sperm in the spermatheca (located above the uterus) and in the uterus. Once the female had been mated it may keep the sperm for a long time, therefore for each genetically controlled mating generally virgin females are used. The eggs are fertilized just before laying. *Drosophila melanogaster* has XX (female) or XY, XO (male) sex chromosomes and three pairs of autosomes. The X-chromosome (chromosome 1) is acrocentric (has one arm) has a genetic length of about 73 map units; chromosomes 2, 3, and 4 have genetic lengths of about 110, 111 and 3 map units, respectively. The Y chromosome has the *KL* male fertility complex on the long arm and the *KS* male fertility complex on the short arm and no other "visible" genes. The X-chromosome contains the nucleolar organizer region in a tandem array of repeats at the *bb* (*bobbed*) locus, coding for the 5.8S, 18S and the 28S ribosomal RNAs. The polytenic X-chromosome is divided into 20 regions; first is at the tip and the 20th at the centromere. It displays about 1000 bands. The Y chromosome does not display polyteny. The second chromosome contains 20 sections in the left arm (21 at the tip and 40th at the centromere) including about 869 to 927 bands and the right arm starts at the centromere with section 41

Figure D105. The life cycle of *Drosophila*. The female deposits more than a hundred filamentous eggs (0.5 mm). The hatching maggots (instars) burrow into the food where they undergo two molts. The emerging larvae develop into pupae. The adults (imago) are about 2 mm long when they emerge from the pupal case. The average lifetime of the females is about 4 weeks; the males may live a little longer. The organs of the adults develop from the imaginal discs, present at the 1st instar stage. In the center (insert) the development of the germline is shown

Figure D106. The major areas of the body of *Drosophila melanogaster*. Surface appendages (bristles, hairs) and wing venation are not shown here. (see more at figures in morphogenesis in *Drosophila*)

and ends with section 60 at the other telomere including 1009 to 1152 bands depending on the classification of doublets and singlets. Chromosome 3 appears the longest. The left arm begins with

Figure D107. Sexing of the flies is by inspection of the sexcomb present only on the metatarsus of the fore-leg of the male and the genitalia, visible on the posterior ventral part of the abdomen. For examination, the flies are anesthetized for 5–10 min with ether or other suitable times and placed under the dissecting microscope

D

section 61 at the tip and section 80 at the centromere including 884 to 1032 bands. The right arm starts with section 81 at the centromere through section 100 at the other end, containing about 1147 to 1233 bands depending on the classification. Chromosome 4 is extremely short and does not display very clear polyteny and does not contain more than about 40 to 50 bands. It is divided into sections 101 and 102, proximally and distally to the centromere, respectively. Each section is further subdivided into A, B, C, D, E, F subsections by vertical lines positioned left to conspicuous bands. Within lettered subdivisions individual bands are numbered. The size of the nuclear genome is ca. 180 Mb and the circular mitochondrial genome contains 19,500 bp. The total euchromatin is ~121 Mb. The origin of replication of the mtDNA is within an AT rich tract. The replication of the first strand is completed before the replication of the 2nd strand begins. It codes for ribosomal RNA and 22 tRNAs. It encodes also cytochrome b, cytochrome c oxidase, two subunits of ATPase and for 7 subunits of the NADH reductase complex. These genes are crowded next to each other with very few nucleotides keeping them apart. They contain no introns. Translation is initiated with ATA, ATT and ATG codons. TAA is the most common termination codon. Codon TGA spells Try (tryptophan) rather than a stop like in the universal codon dictionary. ATA means Met rather than Ile, and AGA is a Ser codon rather than Arg. Codon usage is influenced by the predominance of AT pairs in this genome. "Infectious heredity" is also known in *Drosophilas*, caused by the (RNA) picornaviruses (DAV, DPV, DCV), and the vesicular stomatitis virus-like agent (sigma virus), and the sex-ratio (SR) condition (females do not produce male offspring) caused by spirochete-like protozoa. In *Drosophila melanogaster* more than 4,000 genes and 9,000 chromosomal rearrangements are more or less well characterized. The genome has been almost completely sequenced and more than 13,600 genes have been found yet substantially less than expected.

Alleles at a locus are generally distinguished by superscripts. Recessive alleles in a predominantly dominant allelic series are designated by capital letters but a superscript *r* is added, alternatively in a recessive series of alleles the dominant allele may be identified with lower case letters but with a *D* superscript their dominant expression is identified. The wild type alleles may be designated also by a (+) superscript, and an *rv* superscript and a number indicates revertants of recessive alleles.

Revertants of dominant mutations are considered deficiencies and are symbolized as *Df* with a distinguishing number, e.g., *Df*(1)1-*D1* is a deficiency of chromosome 1 (X-chromosome) and the latter part of

the symbol is explained by words. A number symbolizes alleles specifying the absence of a protein with an *n* superscript and possibly by a number. *Proteins* are frequently designated by three Roman capital letters. Loci moved to new locations by transposable elements are enclosed in brackets followed by the new site in parenthesis, e.g., [*ry*⁺] (*sd*) or [*Cp16*] (*52D*) indicates that the chorion protein gene was inserted by transformation into cytological site *52D*. *Mimics* (different loci but similar phenotype) are designated as e.g., *tu-1a*, *tu1b*, *tu-2* or by arbitrary numbers: *Sgs3*, *Sgs7* or by polytenic location *Act5C*, *Act42A* or by molecular weight *Hsp68*, *Hsp70* added to the letter symbols. *Modifier genes* such as suppressors or enhancers are symbolized with *e* or *E* and *Su* or *su* followed by the symbol of the gene acted upon in parenthesis, e.g., *su* (*lz*³⁴), suppressor of a *lozenge* allele. *Translocations* are symbolized with *T*, e.g., *T*(1;Y;3) indicates an X- and Y-chromosome interchange that may be followed by a number of other symbols. Chromosome rings are indicated as *R*(1)2 where *R* stands for ring, (1) for the X-chromosome and 2 for ring #2. *Inversions* are identified by *In* and additional specifications, e.g., *In* (2*L*)*Cy* indicates an inversion in the left arm of chromosome 2 involving the dominant wing mutation *Curly* or *In*(3*RL*) stands for a pericentric inversion of chromosome 3. Additional specifications may also be applied. *Transpositions* are defined as three-break rearrangements (two are needed for excision and one at the target site). *Tp*(3;1)*ry* designates the movement of a third chromosomal *rosy* allele to the X-chromosome.

Duplications are identified by *Dp* and additional information, e.g., *Dp* (1; 1)^{*y*^{bl}} designates a duplication in the X-chromosome containing the *yellow bristle* marker. When the duplication is a free fragment the designation is *Dp* (1;*f*) and it may further be specified by gene or band symbols added. *Dp*(1;1;1) indicates triplication. *Deficiencies* are defined by *Df*, irrespective whether a chromosomal segment or an entire chromosome (hypodiploid, 2*n* - 1) is involved, e.g., *Df* (2*R*) *vg* is a deficiency of the *vestigial* gene in the right arm of chromosome 2. Complex chromosomal rearrangements can also be symbolized but generally, they require detailed descriptions. Deviations from the euploid, normal chromosomes change the phenotypic sex because the balance of the sex chromosomes and autosomes affects sex in *Drosophila*.

The metafemales have the chromosomal constitution X/X/X;2/2;3/3;4/4, the triploid metafemales are X/X/X/X;2/2/2;3/3/3;4/4/4 (or 4/4 only). Metamales are X/Y;2/2/2;3/3/3;4/4/4. Intersexes may be X/X;2/2/2;3/3/3;4/4/4 with a Y chromosome either present or absent and the numbers of chromosome 4 may vary. Tetraploid females have been observed. Triploids are

X/X/X;2/2/2;3/3/3;4/4/4 (or the sex chromosomes may be either (X/X/X/Y or attached XX/X or XX/X/Y). Haploids of X;2;3;4 are known. Aneuploids nullo-X (Y/Y;2/2;3/3;4/4), nullo-X nullo-Y (0/0;2/2;3/3;4/4), tetra-four (X/X;2/2;3/3;4/4/4/4), triplo-4 (X/X;2/2;3/3; 4/4/4), haplo 4 (X/X;2/2;3/3;4), X0 male (X;2/2;3/3;4/4), XXY female (X/X/Y;2/2;3/3;4/4), XXYY female (X/X/Y/Y;2/2;3/3;4/4), XYY male (X/Y/Y;2/2;3/3;4/4) and YYYY male (either X/Y/Y/Y or attached XY/Y/Y plus normal autosomes) are also known. About 20% of the *Drosophila* genome consist of repeated sequences and display four satellite bands (1.672, 1.686, 1.688, 1.705) upon CsCl density gradient centrifugation [not amplified in the salivary glands]. Other repeated sequences, SINE (0.5 kbp) and LINE (5–7 kbp) 1572 transposable elements were identified. Detailed genetic information on 4,000 gene loci and 9,000 chromosomal aberration (including references) are described in THE GENOME OF DROSOPHILA by D.L. Lindsley and G.G. Zimm, 1992, Academic Press, San Diego, California. Upon sequencing the genome 13,676 genes were estimated in 2000. This number since has increased as the result of improved annotation. The total number of protein-coding genes appears to be ~14,000 (Yandell M et al 2005 Proc Natl Acad Sci USA 102:1566). The number of pseudogenes is small, 17. Some of the genes are overlapping. About 20% of the mRNAs are alternatively spliced. The *mdg4* gene generates 29 transcripts and *Dscam* more than 38,000. *Drosophila* because of its well-manipulated genome and abundance of mutations can be used even for modeling human diseases. A 63% of the predicted *Drosophila melanogaster* proteome has been cataloged (Brunner E et al 2007 Nature Biotechnol 25:576). ▶salivary gland chromosomes, ▶polytenic chromosomes, ▶fruit fly, ▶morphogenesis, ▶imaginal disk, ▶reproductive isolation, ▶instar, ▶molting, ▶puparium, ▶metamorphosis, ▶eclosion, ▶courtship, ▶virgin, ▶nucleolar organizer, ▶infectious heredity, ▶allele, ▶suppressor, ▶translocation, ▶inversion, ▶duplication, ▶deficiency, ▶triploid, ▶aneuploid, ▶tetraploid, ▶transposable elements, ▶P element, ▶hybrid dysgenesis, ▶SINE, ▶LINE; Adams MD et al 2000 Science 287:2185; Rubin GM, Lewis EB 2000 Science 287:2216; Celniker SE, Rubin GM 2003 Annu Rev Genomics Hum Genet 4:89; comprehensive information resources; Matthews KA et al 2005 Nature Rev Genet 6:179; or <http://flybase.org>; <http://flybase.bio.indiana.edu>, *Drosophila* gene homologs of human disease genes; <http://superfly.ucsd.edu/homophila>, tissue-specific genes; FlyAtlas, *Drosophila* genes/development: <http://www.sdbonline.org/fly/ai/main/1aahome.htm>, RNAi;

Drosopeterin: A bright red eye pigment in insects (*Drosophila*) and related pigments are common in other animals. The *se* (*sepia*) mutants of *Drosophila* (chromosome (3–26.0) accumulate a yellow pigment (a dihydropteridine) but unable to synthesize drosopeterin or iso-drosopeterin because of the defect in PDA (2-amino-4-oxo-6-acetyl-7,8-dihydro-3H,9H-pyr-imido[4,5,6]-[1,4] diazepin) synthetase. ▶pigmentation of animals; Wiederrecht GJ et al 1981 J Biol Chem 256:10399.

Drought Resistance: Soil moisture deficit is a common limiting factor of agricultural crop yield especially in arid regions. Reduced transpiration can conserve water and large root system may better utilize the water content of the soil. Overexpression of vacuolar H⁺-pyrophosphatase in transgenic tomato plants increased root mass, improved cation transport into roots and enhanced the recovery of the plants from episodes of water deficit under laboratory conditions (Park S et al 2005 Proc Natl Acad Sci USA 102:18830). The stress-responsive gene *SNAC1* of rice enhances drought resistance by 22–34% by controlling stomatal closing without reducing photosynthetic function (Hu H et al 2006 Proc Natl Acad Sci USA 103:12987). ▶stress tolerance, ▶salt tolerance

DRP (dynamin-related protein): DRP plays a major role in mitochondrial fission. ▶dynamin; Osteryung KW, Nunnari J 2003 Science 302:1698.

DRPLA: ▶dentatorubral-pallidoluysian atrophy

Drug Combinatorial Treatments: Many diseases are the end results of several genetic (QTL) or metabolic defects and in such cases the administration of more than a single drug is most effective without very detrimental side effects. In a mouse model human adenomatous polyposis (FAP), a non-steroid anti-inflammatory drug (sulindac) and an inhibitor of epidermal growth factor receptor (EKI-569) was quite effective (Torrence CJ et al 2000 Nature Med 6:974). Similarly, the amyotrophic lateral sclerosis model of mouse responded better to a combination of minocycline (lipid-soluble semisynthetic tetracycline) and creatine than either treatment alone (Zhang W et al 2003 Ann Neurol 53:267). Medicine cocktails successfully treat the stubborn cases of acquired immunodeficiency. A combination of ribonucleotide reductase inhibitors (trimidox) and didanosine (reverse transcriptase inhibitor) successfully inhibits retrovirus-induced splenomegaly, hypergammaglobulinemia, activated B-splenocytes and lost splenic structure in

mice (Mayhew CN et al 2005 Antiviral Res 65:13).

D

Drug Development: Genetic information can reveal the mechanisms of disease mechanism and its metabolic bases and can indicate potential targets for drug development. Model animals play important role in drug design and testing. Unfortunately, animal models may not always respond to drugs the same way or to the same extent as humans. Large scale and targeted mutagenesis and mutation testing in mice and other animals can reveal models for monogenic and complex human diseases. Tissue culture offers unique potentials for drug development because of ethical problems with human experimentation. According to estimates, there are about 3,000 human genetic alterations that can offer potential drug targets, i.e., are “druggable.” G-protein coupled receptors, various ion channels, kinases and phosphatases can be targeted, however without great specificity and precision serious side effects may be encountered in the patients because these molecules affect simultaneously multiple metabolic processes. Peptidomimetics (structurally modified, unnatural, peptides structurally modified molecules) and engineered antibodies with modified variable regions are newer types of potentially potent “drugs.”

Some genes may have substantial impact on the health of human population despite the fact of low penetrance and variable expressivity. In such cases, the precise mechanisms involved are difficult to validate and pose difficulties for drug development. Many human diseases are rather complex, e.g., schizophrenia, diabetes, heart diseases, cancer and a large number of diverse metabolic anomalies may be involved that are hard to clinically decipher and prescribe drugs for in an unambiguously helpful manner. An additional problem is that the majority of human diseases appear as syndromes based on defects of apparently unrelated genes, which affect complex genetic networks at different steps yet the phenotypic consequences can be quite similar. Different mutational sites in the same gene may respond to drugs as either agonists or antagonist of a process. Some of the drugs have multiple effects, some specifically alleviating one health problem and the same time aggravating another. Gain of function mutation in the proprotein convertase subtilisin gene (PCSK9, 1p34.1-p32) results in hypercholesterolemia by destruction of low-density lipoprotein receptor (Maxwell KN et al 2005 Proc Natl Acad Sci USA 102:2069) whereas loss-of-function mutations in PCSK9 lower the LDL cholesterol level by 40% (Cohen J et al Nature Genet 37:328). Thus,

mutations in the same gene can have different effects on the metabolism. The very simple hydrochlorothiazide drug can reduce hypertension is also a diuretic and may cause dizziness and other problems.

Protein defects may be targeted by interacting proteins or even with small molecules. Gene therapy and cancer gene therapy provide non-drug defense against disease. The advantages of these somatic treatments is that the therapeutic genes can be regulated at a natural, physiological level within the receiving organisms in contrast to drugs that are delivered in fixed quantities at ingestion. Therapeutic genes may also be equipped with special receptors, which may be subject to regulation by drugs.

In the *Drosophila* hybrid dysgenesis factor, the P element is being explored to study transgene responses to drugs. The proteome analysis and combinatorial chemistry open new avenues to design more effective medicine. The direct assays of side effects of potential drugs by biological means are difficult and time consuming. Efforts are being made to use toxicology assay chips for the early elimination of unsuitable compounds (Lee M-Y et al 2005 Proc Natl Acad Sci USA 102:983). Systems biology has special relevance to drug discovery, optimization and development of new pharmaceuticals (Butcher EC et al 2004 Nature Biotechnol 22:1253).

Drug Interaction: A very serious problem in medicine and it is not always easy to foresee how various simultaneous treatments may affect the intended cure. Some compounds may be buffering, activating or non-interacting with others. Natural food may also influence the uptake or metabolism of drugs

► **grapefruit**. These interactions can be represented in functional networks (Yeh P et al 2006 *Nature Genet* 38:489). In recent years, increased concerns developed for many drugs that had to be withdrawn from the markets after they were approved and widely used. The fifteenth century savant Paracelsus/Theophrastos of Hohenheim has already recognized that “poison is in everything, and nothing is without poison. The dosage makes it either a poison or a remedy.” ► **epistasis**, ► **multidrug resistance**, ► **multiple drug resistance**; 3D interactions; <http://bioserv.rpbs.jussieu.fr/cgi-bin/Frog>.

Drug, Personalized: ► **metabonomics**, ► **SADR**

Drug Resistance: In cancer therapy protein kinases appeared ideal targets. Unfortunately, resistance to these treatments appears (Daub H et al 2004 *Nature Rev Drug Discovery* 3:1001). The clearing of the drug from the target cells may cause resistance. This problem may be overcome by administering simultaneously the drug and appropriate antidrug-antibody. Genes that control absorption, distribution, metabolism and excretion may affect response to drugs (Carter TA et al 2005 *Proc Natl Acad Sci USA* 102:11011). A dynamic drug pool may be established by reversible dissociation of the drug and the antibody. The free drug may be gradually eliminated but the free drug pool is continuously replenished from the drug-antibody complex. If such a procedure is successful, it may provide a clinically useful technique to prolong appropriate drug level for a prolonged period (O’Hear CE, Foote J 2005 *Proc Natl Acad Sci USA* 102:40). Dominant drug-sensitive variants of poliovirus interfere with the growth of non-defective virions and may be useful for antiviral therapy with reduced risk of drug resistance (Crowder S, Kirkegaard K 2005 *Nature Genet* 37:701). ► **multiple drug resistance**, ► **resistance transfer factors**, ► **antimetabolite**; Gottesman MM 2002 *Annu Rev Med* 53:615.

Druggability: A molecular target, which can be altered in such a way that it may become a drug.

Drum Stick: ► **Barr body**

Ds: (*Dissociator*): A defective transposable element of maize that can move only when *Ac* provides the transposase function. Its name came from the observation that it was frequently associated with chromosome breakage. ► *Ac*, ► **controlling elements**, ► **transposable elements**

DSB: A double-strand break.

DsbA: A 21.1 kDa monomeric *E. coli* periplasmic protein with strong oxidizing ability. DsbB reoxidizes it. DsbC has similar function. DsbD and DsbE are

thiodisulfide reductases. ► **thioredoxin**, ► **glutaredoxin**, ► **PDI**

Dscam: A *Drosophila* gene, which regulates synaptic specificity of neurons by generating potentially more than 38,000 mRNA isoforms by alternative splicing (Chen BE et al 2006 *Cell* 125:607). ► **alternative splicing**, ► **synapse**

dsDNA: Double-stranded DNA (see Fig. D108).

Figure D108. dsDNA

DSE: Distal sequence element. ► **Hogness box**

DSIF: Regulatory dimeric (~14 and ~160 kDa subunits) protein of transcript elongation. It seems to be a target of DRB. The large subunit is homologous to the bacterial NusG. ► **transcript elongation**, ► **TEFb**, ► **DRB**, ► **NELF**, ► **nusA**; Renner DB et al 2001 *J Biol Chem* 276:42601.

DSP (dual specificity protein phosphatase): One of its active sites dephosphorylates serine, threonine, tyrosine in a protein whereas the deeper active site is specific only for tyrosine.

DsrA: A short (87 base) RNA with three stem-loop motifs modulating transcriptional regulators H-NS (inhibitory) and RpoS (stimulatory). One of the stem-loop binds and stabilizes RpoS mRNA and the second sequesters the H-NS mRNA. (Lease RA Belfort M 2000 *Mol Microbiol* 38:667)

dsRAD: ► **DRAD**

dsRNA: Double-stranded RNA. ► **RNA interference**

DSS (dosage-sensitive sex reversal): An approximately 160-kb duplication in the short arm of the X-chromosome upsets normal male gonad formation in XY individuals. Deletion of the same region however does not affect gonadal differentiation although the hypogonadism results in infertility. Defect in the *DAX-1* gene enhanced the expression in the expression of the aromatase enzyme encoded by the *Cyp19* gene of mice. This enzyme converts testosterone to estradiol in the Leydig cells. ► **sex reversal**, ► **sex determination**, ► **Wolffian duct**, ► **testosterone**, ► **estradiol**; Wang ZJ et al 2001 *Proc Natl Acad Sci USA* 98:7988.

DST1: The yeast gene encodes the 38-kDa strand transfer protein (STP α). ► **recombination mechanism**, ► **eukaryotes**

DST2: The yeast gene encodes the STP β protein (identical to Sep 1). ► **recombination mechanism** **eukaryotes**

DSTF (DPE-specific transcription factor): DSTF facilitates the transcription by DPE promoters and represses the TATA box-driven promoters by binding to the TBP of the transcription factor TFIID. DSTF activity is associated with a 43 kDa (NC) and a 22 kDa (Drap) proteins. ▶core promoter, ▶DPE, ▶NC, ▶Drap, ▶TBP, ▶TFIID; Kutach AK, Kadanaga JT 2000 Mol Cell Biol 20:4754.

dsx (*double sex*): Abnormal location 3–48.1; regulates sexual differentiation in somatic cells of *Drosophila melanogaster*. The null allele converts males and females into intersexes. ▶*Drosophila*, ▶sex determination; Erickson JW 2001 Developmental Cell 1:156.

DT40: A chicken cell line with as high as 10 to 100% homologous recombination in non-isogenic DNA without high selection pressure. It provides an opportunity of high efficiency gene transfer in vertebrate, including human cells. (Thompson LH, Schild D 2001 Mutation Res 477:131; <http://genetics.hpi.uni-hamburg.de/dt40.html>).

Dt Gene: It is actually a transposable element that may be situated in several locations in the maize genome (see Fig. D109). It causes the colorless *a1-m* allele to produce anthocyanin-containing dots in the triploid aleurone tissue, depending on the dosage of the *Dt* elements containing a transposase. It may also cause reversions to the *A* allele in the germline. *Dt*, like other transposable elements, induces also chromosome breakage and can newly arise through chromosomal breakage. The first *Dt* allele, *Dt1* was located to the initial position of the short arm of chromosome 9. *Dt2* (chromosome 6L-44), *Dt3* (7L), *Dt4* (4), *Dt5* (in the vicinity of *Dt1*) and *Dt6* (in the short arm of the chromosome 4) not far from the centromere were identified subsequently. ▶transposable elements; Brown JJ 1989 Mol Gen Genet 215:239.

Figure D109. *Dt* gene. Maize kernels *aaa* (left) and *aaa^m Dt Dt* (right) constitution. (Courtesy of M.G. Neuffer)

dTAF_{II}: ▶transcription factors

DTH (delayed types hypersensitivity): DTH may cause acute rejection of allografts and autoimmune reactions due to non-specific T cell responses. ▶autoimmune, ▶T cell, ▶hypersensitivity, ▶allograft; Jager D et al 2001 J Clin Path 54 [9]:669.

DTT (dithiotreitol, Cleland's reagent): A protective agent for SH groups. ▶mercaptoethanol

Dual-Gene Operons: Synthetic constructs carrying two selected structural genes driven by a single promoter. Within the operon and within the untranslated 5' and 3' regions various regulatory elements (restriction enzyme sites) can be placed. Hairpin structures at the 3'-end may protect against exonuclease attack and transcription termination. Such systems permit the analysis of the differential expression of both genes under various controlled conditions. ▶operon; Smolke CD, Keasling JD 2002 Biotechnol Bioeng 78:412.

Dual-Specificity Phosphatases: It recognize more than a single phosphorylated amino acid in a protein and have an important role in signal transduction pathways and differentiation/development, epigenesis. ▶serine/threonine kinase, ▶epigenesis

Dual-Topology Proteins: They can insert into membranes in two different orientations. Frequently, the positively charged amino acids are oriented toward the cytoplasmic side of the inner membrane. Duplication permits specialization, i.e., the pairs may display opposite orientation (Rapp M et al 2006 Nature Struct Biol 13:112). ▶duplication

Duane Retraction Syndrome: A defect of moving the eyeball (globus), encoded in the region 2q31. The Duane Radial Ray (Okhiro syndrome) is due to mutation in SALL4 at 20q13. SALL4 is 1053 amino acid organ-specific transcription factor with eight Zn-finger domains. About 5% of the strabismus cases show similar defect. ▶strabismus, ▶eye diseases; Al-Baradie R et al 2002 Am J Hum Genet 71:1195.

Dubin-Johnson Syndrome (hyperbilirubinemia II, DJS, 10q24): A recessive disease with a relatively high frequency (8×10^{-4}) among Iranian Jews. It involves jaundice, hyper-bilirubinemia, melanin-like deposits in the liver. It is a defect of the detoxification mechanism of the liver. Detoxification is mediated by conjugation with glutathione, glucuronides or sulfates, resulting in negatively charged amphiphilic compounds that can be effectively secreted into the urine. The excretion is carried out with the assistance of canalicular (tubular) multispecific organic anion transporter (cMOAT). Hyperbilirubinemia is also caused by the Gilbert syndrome (synonymous with Arias type hyperbilirubinemia and the Crigler-Najjar syndrome type II defects in the UDP-glucuronosyl-transferase) in human chromosome 2 and deficiency

of Factor VII in human chromosome 13q34. The Rotor syndrome is apparently the same as DJS. ▶hyperbilirubinemia, ▶glutathione-S-transferases, ▶antihemophilic factors, ▶Crigler-Najjar syndrome

Dubinini Effect: The change of dominance in alleles (variegation) because of transposition (of heterochromatin) in *Drosophila*. ▶position effect, ▶heterochromatin, ▶dominance reversal; Dubinin NP, Sidorov BN 1934 Amer Nat 68:377; Locke J, Tartof KD 1994 Mol Gen Genet 243:234.

Dubowitz Syndrome: A fetal-newborn physical and mental retardation complex under autosomal recessive control. The symptoms may resemble to those in fetal alcohol syndrome (non-genetic) and the autosomal recessive Fanconi anemia. ▶alcoholism, ▶Fanconi's anemia

Duch (DH blood group): It is extremely rare and has been identified in Aarhus, Denmark. ▶blood groups

Duchenne Muscular Dystrophy: ▶muscular dystrophy

Duck (*Anas platyrhynchos*): $2n = 78-80$.

DUE (DNA unwinding element): A part of the autonomously replicating sequence (ARS). ▶ARS

Duffy Blood Group, (Fy) Alleles: In human chromosome 1q12-q21 control a red blood cell antigen, frequently used as genetic markers in population studies; 99% of the Chinese and 65% of the Caucasians are positive, whereas 95–99% of the black Africans are of the negative type (Fy^{-}/Fy^{-}). Individuals lacking these antigens [$Fy(a^{-}b^{-})$] are protected against the African malaria-causing *Plasmodium vivax* protozoan. ▶blood groups, ▶ethnicity; Hamblin MT et al 2002 Am J Hum Genet 70:369.

Dulbecco's Medium (PBS): A minimal animal tissue culture solution containing buffered sodium pyruvate, streptomycin, glucose and calcium chloride and penicillin and various nutrients may be added. (Lawson MA, Purslow PP 2000 Cells Tissues Organs 167[2–3]:130; Baust JM et al 2000 In Vitro Cell Dev Biol Anim 36[4]:262)

Dumbbell Oligonucleotides: These are short double-stranded DNA or DNA–RNA with closed loops at both ends. Ring-shape “dumbbells” are created by the fusion of two hairpins. They are very resistant to nucleases and can bind to very specific sequences and block transcription factor access. They may carry antisense RNA or antisense DNA, or may include sequences within the stem (in between the loops) where specific transcription factors can bind and exert interference with transcription this way. Dumbbell technology may have therapeutic value against viral infection. ▶decoy receptor, ▶antisense technologies;

Clausel C et al 1993 Nucleic Acids Res 21:3405; Park WS et al 2000 Biochem Biophys Res Commun 270:953.

Dumping: The transfer of the contents of nurse cells to the oocyte via cytoplasmic bridges. ▶oocyte, ▶nurse cell

‘Dumposome’: Protein Pdd1 of *Tetrahymena* that may be targeted to DNA degradation within cells of organisms. ▶apoptosis

Duncan Syndrome (X-linked lymphoproliferative disease): An Xq25 immunodeficiency with immediate hypersensitivity to various allergens, caused by higher than normal levels of IgE. The affected individuals are particularly sensitive to Epstein-Barr virus infections, and usually die of lymphoma or aplastic anemia. ▶immunodeficiency, ▶immunoglobulins, ▶Epstein-Barr virus, ▶lymphoma, ▶aplastic anemia, ▶anaplastic lymphoma, ▶lymphoproliferative diseases X-linked

Dunnigan Syndrome (1q21.2, 3p25): A dominant lipodystrophy with onset after puberty when the fat tissue is much reduced in the extremities and relocated to face, neck or other body parts. It manifests itself more conspicuously in females. Among many other symptoms, it involves insulin-resistant hyperinsulinism and diabetes. ▶lipodystrophy familial, ▶diabetes; Cao H, Hegele RA 2000 Hum Mol Genet 9:109.

Duodenum: A 12-fingerbreadth long section of the digestive tract between the pylorus (distal opening of the stomach into the duodenum) and the jejunum (small intestine extending from the duodenum to the ileum, next to the appendix, cecum).

Duplex: In a polyploid (e.g., *AAaa*) or triploid or trisomic (e.g., *Aaa*), duplex carries two dominant alleles at a locus and the other allele(s) at the same locus are recessive. ▶autopolyploid

Duplex DNA: It is double-stranded. ▶Watson–Crick model

Duplicate Genes: They convey the same (or very similar phenotype) but segregate independently, therefore, in F_2 the phenotypic proportions are 15 dominant: 1 recessive. The assumptions are that duplicate genes provide functional backup or regulatory role or gene dosage function. However, experimental studies in yeast suggest that the most important role of duplicate genes is that they provide means for gene evolution. The evolving gene—although has overlapping function with the original—it allows for the development of new metabolic tasks for the paralogue (Kuepfer L et al 2005 Genome Res 15:1421). In yeast and *Caenorhabditis* silencing duplicate genes does not have as serious have serious consequences as

silencing singletons. In mouse, based on study of ~3,900 knockouts, single copy and duplicated genes are almost equally essential indicating the duplicates rapidly acquire needed function (Liao B-Y, Zhang J 2007 Trends Genet 23:378). ►modified Mendelian ratios

D

Duplicate Ratio: ►duplicate genes

Duplication: A eukaryotic chromosomal segment is repeated side-by-side (tandem duplication) or may be repeated at another location within the chromosome or in another chromosome (see Fig. D110). The duplication is cytologically detectable in duplication heterozygotes if it is of sufficient length. In prophase, when paired with the non-duplicated strand, it bulges out because the normal counterpart cannot pair with the extra chromosomal tract:

Figure D110. Duplication

The duplication may be direct →→ or inverted →←. After insertion of transposable elements, duplications may occur at the target sites. Transposable elements generally carry in addition terminal direct or inverted repeats. Duplications and deficiencies are generated by crossing over within the inverted segments of para- and peri-centric inversions, breakage-fusion-bridge cycles, crossing over between sister chromatids of ring chromosomes, unequal crossing over, adjacent I and adjacent II distribution of chromosomes in the meiosis of translocation heterozygotes, etc. Duplications may have evolutionary significance because the extra piece of DNA may be modified to carry out a new function(s) or may be used as a backup for the original gene (Kuepfer L et al 2005 Genome Res 15:1421). Molecular evolutionary studies provide many examples of duplications followed by differentiation and divergence. Complex genes are more likely to be preserved by evolution than simple ones because they offer greater chances for the development of new functions (He X, Zhang J 2005 Current Biol 15:1016). It was suggested that reduction in alternative splicing increases the chances of duplications during evolution in providing starting material for evolution (Su Z et al 2006 Genome Res 16:182).

More than 97% of human proteins have a history of duplication of some part of their length, and 80% of the proteins show relationships to more than one other protein in different regions, reflecting an

ancient composite structure. The latter information was obtained from the KGMV library, which consists only of proteins of known function, showing that these conclusions apply to working proteins. KGMV (for known genes maximum variant) library included 13,298 members (Britten RJ 2006 Proc Natl Acad Sci USA 103:19027). It has been estimated that the α and β chains of the human hemoglobin, after duplications, separated about 500 million years ago. Subsequently, from the β chain the γ and δ chains evolved. (The rhesus monkey, however, does not have the δ chain). Similarly, the protein superfamily of trypsin, chymotrypsin, elastase, thrombin, kallikrein, plasmin and bacterial trypsin all have structural similarities indicating common ancestry. Complete nucleotide sequence data of prokaryotic genomes revealed unexpected extensive duplications. In *Bacillus subtilis* more than 1/4 of the genome indicates duplications of recent origin. In *E. coli* there are about 80 transport proteins of common origin. In *Haemophilus influenzae* 284/1709 (~17%), in *Saccharomyces cerevisiae* 1858/6241 (~30%), in *Caenorhabditis elegans* 8971/18424 (~49%) and in *Drosophila melanogaster* 5536/13601 (~41%) of the protein-coding genes appear to have arisen by duplication. The progress of sequencing of the human genome also revealed several duplications (8595 duplicated regions of more than 5000 bp), mainly in the pericentromeric and telomeric heterochromatin of the same or different chromosomes (Bailey JA et al 2002 Science 297:1003). In humans and mouse, more genes moved to the X chromosome from autosomes than to autosomes from the X chromosome. In addition, more duplication occurred within the X chromosome than in the autosomes (Emerson JJ et al 2004 Science 303:537). In *Drosophila*, the duplicated genes appear dispersed although a cluster of 17 paralogous genes of not yet known function has been identified. In *Caenorhabditis* there is some clustering of seven-transmembrane domain paralogous genes. Almost 30% of the *Drosophila* proteins are orthologous with those of *Caenorhabditis* and ~20% of the fly and worm genes also share common origins with yeast. About half of the fly and about 36% of the worm's genes/proteins may have some similarity to that of humans, depending on the stringency of the comparisons. Seven hundred and forty four families or domains of proteins were judged common to all three of these lower eukaryotic organisms. The flies, worms and humans seem to have 300, 500 and more than 600 protein kinases and 85, 185 and > 300 protein phosphatases, respectively. There are 450 and 260 peptidases in the fly and worm, respectively. The numbers of multidomain proteins in fly, worm and yeast are 2130, 2261 and 672, respectively. The number of G protein-coupled receptors (GPCR) are

very high in the worm (~1100) while in flies (160) and humans (~700) fewer were identified. The number of olfactory receptors in the mouse is ~1000 while in the fishes there are only ~100. Of the 289 human genes where the molecular/cytological basis of a disease is known, 177 had orthologs in *Drosophila*, and 68% of the oncogenes also had apparently orthologous fly counterparts by year 2000. The flies do not have breast cancer gene or leptin orthologues. During evolution polyploidization may be followed by loss of genomic sequences (Bowers JE et al 2003 Nature [Lond] 422:433). Similar situation was found in *Saccharomyces cerevisiae*, which apparently arose by complete duplication of the genome of *Kluyveromyces waltii* and the subsequent loss of the one of the representative sequence in 95% of the cases (Kellis M et al 2004 Nature [Lond] 428:617). In yeast, the divergence is increased more after the initial duplication event than during its later evolution. The original and the duplicated forms evolve at different rates (Gu X et al 2005 Proc Natl Acad Sci USA 102:707). Sister regions are scattered along the genome. Many cell cycle, cytoskeleton, cell adhesion, cell signaling, apoptosis, neuronal signaling, cell defense (immunity) genes of *Drosophila* have counterparts in the lower animals. In human chromosome 12 duplications (>greater than 90% identity) constitute 2.66% of this chromosome whereas in the entire human genome 6.37% (Scherer SE et al 2006 Nature [Lond] 440:346). About 27% of the duplications in the human genome terminate within Alu repeats indicating a role of this element in their origin (Bailey JA et al 2003 Am J Hum Genet 73:823). Some of the duplications evolved not by tandem repeats but they were recruited to a certain function from other locations, first probably by gene sharing then to carry out a structural role because of their desirable stability, e.g., the crystallin eye protein genes, α , β and δ , which probably acquired the structural function before duplication (Piatigorsky J, Wistow G 1991 Science 252:1078). Genes determining hereditary disorders are frequently flanked by duplicated regions and indicate that copy number polymorphism favors instability by facilitating non-homologous recombination (Sharp AJ et al 2006 Nature Genet 38:1038).

The SVA family of retrotransposons has increased to 3,000 copies in the human genome. Similar to LINE elements, SVA elements are supposed to rely for transcription on RNA polymerase II and have the ability to transduce downstream sequence. This means that RNA transcription machinery sometimes (in ~10% in humans) skips the element's own weak polyadenylation signal and terminates transcription by using a downstream polyadenylation site located in the 3' flanking genomic sequence. The transcript

containing the retrotransposon along with the extra genomic sequence is subsequently integrated back into the genome through retrotransposition, a process called *3' transduction*. The experimental results indicate retrotransposon-mediated sequence transduction is one mechanism for gene duplication and the creation of new gene families as well as of exon shuffling (Xing J et al 2006 Proc Natl Acad Sci USA 103:17608) ▶ [evolution and duplications](#), ▶ [concerted evolution](#), ▶ [Alu](#), ▶ [paralogous loci](#), ▶ [orthologous loci](#), ▶ [deficiency](#), ▶ [chromosomal aberrations](#), ▶ [duplication-deficiency](#), ▶ [redundancy](#), ▶ [deletion](#), ▶ [heterochromatin](#), ▶ [polyploidy](#), ▶ [gene number](#), ▶ [core proteome](#), ▶ [gene numbers](#), ▶ [olfactogenetics](#), ▶ [oncogenes](#), ▶ [cancer](#), ▶ [breast cancer](#), ▶ [leptin](#), ▶ [immune system](#), ▶ [protein domains](#), ▶ [dual-specificity proteins](#), ▶ [pseudogenes](#), ▶ [subfunctionalization](#), ▶ [copy number estimates](#), ▶ [polyploidy](#), ▶ [Paramecium](#), ▶ [exon shuffling](#); Rubin GM et al 2000 Science 287:2204; Gu X et al 2002 Nature Genet 31:205; Conant GC, Wagner A 2002 Nucleic Acids Res 30:3378; Wolfe KH, Li W-H 2003 Nature Genet 33 (Suppl.):255; duplication and divergence; Taylor JS, Raes J 2004 Annu Rev Genet 38:615; theories of gene evolution by duplication: Hughes AL 2005 Proc Natl Acad Sci USA 102:8791; Bailey JA, Eichler EE 2006 Nature Rev Genet 7:552 [corrigendum to this paper in Nature Rev Genet 7(11)].

Duplication-Deficiency: Cells are produced by adjacent-1 and adjacent-2 distribution of chromosomes in translocation heterozygotes, in para- and pericentric inversion heterozygotes when crossing over takes place within the inverted segment. They may occur in case there is a sister chromatid exchange in ring-chromosomes and all other cases when dicentric chromosomes are produced (breakage fusion-bridge cycles), unequal crossing over, etc. ▶ [inversion](#), ▶ [translocation](#), ▶ [dicentric ring chromosome](#), ▶ [genomic variation](#)

Duplicons: These are chromosome-specific low-copy repeats at multiple areas of the human genome. Homologous recombination between duplicons may lead to chromosomal aberrations such as duplications, deletions and inversions. Such alterations may occur at a frequency of about 10^{-3} and cause genetic diseases. ▶ [chromosomal rearrangements](#); Ji Y et al 2000 Genome Res 10:597.

Durum Wheat: A member of the allotetraploid series with AB genomes. ▶ [Triticum](#)

DUST: A computer program designed to identify low-complexity regions in DNA sequences.

Duty Ratio (duty cycle): Duty ratio indicates the frequency of the time when a motor protein is attached to its filament, it is supposed to move. ▶ [motor protein](#)

Dwarfism: It is caused by several *dominant* genes in apparently different human autosomes. The distinguishing features include (i) narrow vertebrae, (ii) thickening of the tubular bone associated with farsightedness, lower than normal level of blood calcium, (iii) low birth-weight, stiff joints and eye defects, (iv) Myhre syndrome involving pre- and postnatal growth retardation, anomalies of face morphology, poor mobility of joints, defects in sex organs, heart and hearing. Some *autosomal recessive* dwarfism, (v) like the Dubowitz syndrome involves intrauterine growth retardation, mental and hearing defects, sex organ anomalies, unusually high or low voice, no response to growth hormone, etc. (vi) Various other types are accompanied by mental retardation, heart anomalies, hip dislocation, very short arms and digits and the absence of fibula (the smaller bone of the leg). ▶**pituitary dwarfism**, ▶**achondroplasia**, ▶**hypochondroplasia**, ▶**Ellis-von Creveld syndrome**, ▶**thanatophoric dysplasia**, ▶**macromelic dwarfism**, ▶**dyschondrosteosis**, ▶**spondyloepiphyseal dysplasia**, ▶**chondrodysplasia**, ▶**cleidocranial dysplasia**, ▶**pseudohypoparathyroidism**, ▶**osteogenesis imperfecta**, ▶**Kniest dysplasia**, ▶**Williams syndrome**, ▶**animal hormones**, ▶**somatotropin**, ▶**corticotropin**, ▶**growth retardation**, ▶**Pygmy**, ▶**SHORT syndrome**, ▶**stature in humans**, ▶**Mulibrey nanism**, ▶**Seckel' dwarfism**, ▶**Donohue syndrome**, ▶**limb defects**, ▶**diastrophic dysplasia**, ▶**Langer-Nielsen mesomelic dwarfism**, ▶**Laron type dwarfism**, ▶**Moore-Federman syndrome**, ▶**dyssegmental dysplasia**, ▶**GHRH**, ▶**GHRHR**

Dwarfism also occurs in plants. This condition in plants may be remedied in some cases by the supply of gibberellic acid or ethylene. Some of the gibberellin-insensitive dwarf mutants of plants are defective in G proteins that have key role in signal transduction. Agromically advantageous semi-dwarf rice plants with normal grain yield have been generated by the expression of a gibberellin oxidase gene under the control of a leaf and stem specific promoter (Sakamoto T et al 2003 Nature Biotechnol 21:909). Auxins, ethylene and brassinosteroids are also regulators of plant cell elongation. Defect in auxin transport class of P-glycoproteins results in dwarf habitus in *Arabidopsis*, maize and sorghum. In the latter species the *dw3* mutations are tandem duplications and because of unequal crossing over an unusually frequency of reversions occur (Multani DS et al 2003 Science 302:81). ▶**plant hormones**, ▶**brassinosteroids**, ▶**de-etiolation**, ▶**ABC transporter**, ▶**unequal crossingover**

Dyad: Chromosome with two chromatids, also the two cells (dyads) formed by the first meiotic division. ▶**chromatid**

Dyads, Spaced: ▶**spaced dyads**

Dye Primer and Dye Terminator Chemistry: During DNA sequencing it may correct errors due to gel compression or base-calling. ▶**compression in gels**, ▶**base-calling**, ▶**doublestranding**

Dyggve-Melchior-Clausen Dysplasia: A bone formation defect with morphological similarity to Smith-McCort dysplasia. The diagnostic difference that DMC involves retarded physical and mental development. Both diseases are under the control of apparently the same gene (18q12-q21), only the mutations appear different. ▶**osteochondrodysplasia**; Cohn DH et al 2003 Am J Hum Genet 72:419.

Dynactin: A dynein regulating protein with the role of moving organelles, and it may interact with the kinetochore and anchors there dynein. ▶**dynein**, ▶**spindle**; Muresan V et al 2001 Mol Cell 7:173.

Dynamic Allele-Specific Hybridization (DASH): DASH has been designed to detect SNIPS. Two DNA sequences are hybridized initially at low stringency. A fluorescent marker that binds only double-stranded DNA and only then emits the signal monitors the hybrid DNA. When the temperature in the reaction well is raised, the SNIP areas lose the signal because they no longer form hybrid and the mismatch is identified. ▶**SNIP**, ▶**allele-specific probe**; Prince JA et al 2001 Genome Res 11:152.

Dynamic Instability: This may occur when microtubules oscillate between growth and shortening during mitosis along with treadmilling. ▶**treadmilling**

Dynamic Molecular Combing: The physical method for mapping distances between fluorochrome-labeled DNA molecules stretched out on the surface of microscopic cover slides. ▶**physical mapping**; Michalet X et al 1997 Science 277:1518.

Dynamic State: The biochemical concept stemming from the realization that the constituents of the living body, irrespective whether they are metabolic or structural, are in a steady state of flux.

Dynamic Time Warping (DTW): A quadratic time algorithm to determine the smallest distance and optimal alignment between two numerical sequences, possibly of different length: <http://bioinformatics.bc.edu/clotelab/BTW/>. (Kruskal JB and Liberman M 1999 The symmetric time-warping problem: from continuous to discrete In: Kruskal JB, Sankoff D (eds) Time Warps, String Edits, and Macromolecules: The Theory and Practice of Sequence Comparison. Stanford CSLI Publications, pp. 125–161)

Dynamin: ~100 kDa proteins with guanosine triphosphatase activity, are associated with other proteins, play an essential role in coated vesicle formation and are localized at the plasma membrane around the neck

of emerging coated pits (see Fig. D111). Several forms of dynamins are known and they display tissue-specificity. They are involved in vesicle recycling, nerve terminal depolarization, etc. ▶coated pits, ▶endocytosis, ▶synaptojanin, ▶synaptogamin, ▶clathrin, ▶synaptic vesicles, ▶GTPase, ▶DRP, ▶apoptosis, ▶myopathy; Hinshaw JE 2000 Annu Rev Cell Dev Biol 16:483.

Figure D111. Dynamin ring

Dyne Unit of Force: It is needed so that a body of 1 g can be accelerated one centimeter per second per second.

Dynein: A multisubunit protein (1.2 MDa), associated with bundles of microtubules (axoneme) in cilia and flagella and assists their movement in an ATP-dependent process (see Fig. D112). Dynein is supposed to move the microtubules toward the centrosome. Dynein is also involved in the development of left-right asymmetry along the axis of the body and it mediates the breakdown of the nuclear membrane. Several motor neuron diseases are dynein defects. ▶microtubules, ▶tubulin, ▶flagellum, ▶cilia, ▶axoneme, ▶kinesin, ▶dynactin, ▶ankyrin, ▶spectrin centrosome, ▶situs inversus viscerum, ▶left-right asymmetry, ▶amyotrophic lateral sclerosis, ▶spinal-bulbar muscular atrophy, ▶spinal muscular atrophy, ▶Kartagener syndrome, ▶asthenozoospermia; Lee IH et al 2001 Mol Biol Cell 12:2195; Burgess SA et al 2003 Nature [Lond] 421:715; Hafezparast M et al 2003 Science 300:808; Mallik R et al 2004 Nature [Lond] 427:649; review; Oikawa K, Sakakibara H 2005 Current Opin Cell Biol 17:98; Diagram substantially modified after Hirokawa N 1998 Science 279:519.

Figure D112. Dynein and associated proteins on the cargo membrane

Dynia Factor: A blood factor controlling the antihemophilic factor. ▶blood clotting pathways, ▶antihemophilic factors, ▶hemostasis

Dynodes: A set of auxiliary electrodes that amplify electrons as they are hit by an electron beam. Dynodes are used in various types of photomultipliers and mass spectrometers, employed in proteome research. ▶proteomics

Dynorphin: An opiate receptor ligand. ▶opiate

Dysarthria: A speech disorder caused by nerve or neuromuscular defect.

Dysautonomia (FD, 9q31): The malfunction of the central nervous system resulting in hypertension, emotional instability, cold hands and feet, excessive sweating and red skin spots. Generally, the prospect of survival to age 40 is poor. It is caused by a defect in splicing of the RNA transcript of IKBAP (inhibitor of κ light chain polypeptide). This protein is part of the IKK complex that includes the NF- κ B-inducing kinase, IKK- β (inhibitor of κ -B kinase β), IKK- α (inhibitor of κ -B kinase α), NF- κ B/RelA and protein IKAP (IKK complex associated protein). Its prevalence is high ($\sim 2-3 \times 10^{-4}$ in Ashkenazy Jewish populations. ▶neuropathy, ▶Riley-Day syndrome; Anderson SL 2001 Am J Hum Genet 68:753; Slaugenhaupt SA, Gusella JF 2002 Current Op Genet Dev 12:307; Cuajungco MP et al 2003 Am J Hum Genet 72:749.

Dysbetalipoproteinemia: A defect in apolipoprotein E. ▶apolipoproteins, ▶hyperlipoproteinemia

Dyscalculia: A brain defect manifested in difficulties handling numerical problems.

Dyschondrosteosis (Leri-Weill syndrome): A dominant dwarfism of the forearms with about four times as high occurrence in females than in males. It may be caused by p22-q12 X-Y translocations or a large deletion at the Xp22.3 region involving the SHOX gene. The same gene is involved in the Langer mesomelic dwarfism. ▶dwarfism, ▶achondroplasia, ▶hypochondroplasia, ▶stature in humans, ▶pseudautosomal, ▶short syndrome

Dyscrasia: A pathological condition of different manifestations in the blood or plasma, plasma proteins.

Dyschromatosis Symmetrica Hereditaria (1q21.3, 6q24.2-q25.2): It occurs mainly in Japan and Korea at a frequency of about 1.5×10^{-5} as a dominant, harmless pea-size hyper and hypopigmented spots on the upper side of the hands and feet or other parts of the body (see Fig. D113). It is caused by mutation in adenosine deaminase. ▶adenosine deaminase

deficiency, ►LEOPARD syndrome, ►xeroderma pigmentosum; Miyamura Y et al 2003 Am J Hum Genet 73:693; photo courtesy of the March of Dimes Foundation.

Figure D113. Dyschromatosis

Dysequilibrium Syndrome: Autosomal recessive cerebral palsy, mental retardation, muscular insufficiency, poor motor control, etc. based on a malfunction of dopamine- β -hydroxylase activity.

Dyserythropoietic Anemia (HEMPAS for hereditary erythroblastic multinuclearity with positive acidified serum test): An endopolyploidy apparently limited to the bone marrow cells. As a consequence anemia appears. The basic defect seems to be a deficiency in the enzyme *N*-acetyl-glucosaminyl transferase II affecting the biosynthesis of glycoproteins. GATA1 mutations result in this disease and thrombocytopenia. ►GATA, ►thrombocytopenia

Dysferlin: A protein defective in both limb-girdle muscular dystrophy 2B and Myoshi myopathy. Dysferlin defect causes disruption of the repair of muscle fibers. ►muscular dystrophy, ►Miyoshi myopathy; Liu J et al 1998 Nature Genet 20:31; Bansal D et al 2003 Nature [Lond] 423:168.

Dysfibrinogenemia: In contrast to fibrinogenemia, where the synthesis of fibrinogen is reduced, these individuals fail to assemble the fibrinogen monomers into normally functional molecules. This human chromosome-4 dominant condition most commonly is not associated with heavy bleeding but may suffer from periodic clot formation in the blood vessels (thrombosis). ►antihemophilic factors, ►afibrinogenemia, ►fibrin-stabilizing factor

Dysgenesis: A mechanism or process producing dysgenic individuals. ►dysgenic, ►hybrid dysgenesis

Dysgenic: Deleterious, undesirable genetic trait ►hybrid dysgenesis

Dyskeratosis (DKC, Xq28; DKBI 4q35): The autosomal dominant forms involve hyperpigmentation of the skin, pre-cancerous skin lesions, poor bone and nail development, no dermal ridges (fingerprints). The benign form does not affect much the individual's well-being. The autosomal recessive form is

also similar. The Xq28 linked form afflicts primarily males who may be also affected by testicle atrophy, anemia, cancer, and lacrimation because of defects in the lacrimal ducts. The DKC1 gene product, dyskerin (514 amino acids), is a nucleolar protein and suspected to have a role in ribosomal function (Mochizuki Y et al 2004 Proc Natl Acad Sci US 101:10756). DKC1 encodes a pseudouridine synthase that modifies ribosomal RNA. In Dkc1tm mutant mouse the defect involves the internal ribosome entry site (IRES) and impairs translation of mRNAs with IRES element such as p27^{Kip}, Bcl-xL, XIAP inhibitors of apoptosis (Yoon A et al 2006 Science 312:902). Dyskerin is also associated with telomerase RNA function and by shortening the telomeres, it may hinder the proliferation of the human somatic cells in the epithelium and blood. Short telomeres, even in the presence of normal telomerase function, result in mice similar tissue development phenotypes as in human dominant dyskeratosis (Hao L-Y et al 2005 Cell 123:1121). The dominant intraepithelial benign dyskeratosis (HBID) is caused by duplication at 4q35 and it is responsible for red eye and other superficial lesions. A large, 821-bp deletion of the 3'-end of a dyskerin gene, encoded at 3q, involves the RNA component of the telomerase enzyme. ►keratosis, ►keratoma, ►skin diseases, ►fingerprints, ►telomeres, ►IRES, ►p27^{Kip}, ►BCL, ►IAAP; Marciniak RA et al 2000 Trends Genet 16:193; Vulliamy T et al 2001 Nature [Lond] 413:432.

Dyskerin: ►dyskeratosis

Dyskinesia: Involuntary movements beyond self-control.

Dyslexia: A highly variable difference in the central nervous system causing difficulties in reading and understanding or tiredness of reading. In some forms, it appeared to be associated with left-handedness and speech defects. Dyslexia may not necessarily be associated with deficiencies of the general intelligence (IQ) and can be compensated for by tutoring type of education. It has been suggested that a dominant gene (DD) in human chromosome 6p22.2 determines some specific forms of it with preferential penetrance in males. Its heritability according to twin studies is very high. Chromosome 15 also harbors a gene for dyslexia. Several QTLs in different chromosomes determine dyslexia. A major QTL has been assigned to 18p11.2 (Fisher SE et al 2001 Nature Genet 30:86). Complicated orthography aggravates the condition whereas it is less serious in near-phonetic languages. ►mental retardation, ►hyperlexia, ►IQ, ►QTL; Wysman EM et al 2000 Am J Hum Genet 67:631; Paulesu E et al 2001 Science

291:2165; Temple E et al 2003 Proc Natl Acad Sci USA 100:2860; genetic factors: Paracchini S et al 2007 Annu Rev Genomics Hum Genet 8:57.

Dyslipidemia: Abnormally high (cholesterol, low-density lipoprotein and triglycerides [LDL]) or low high-density lipid (HDL) content of the blood. High LDL and low HDL content involves risks of heart disease, diabetes, hypothyroidism, kidney and liver anomaly, etc., may be indications of other diseases or metabolic alterations or disorders.

Dysmelodia: An apparently autosomal dominant gene with low penetrance causes reduced musical ability. There is also another autosomal dominant gene (perfect pitch) enabling the individual to remember and play a tune. ▶ [Bach](#), ▶ [musical talent](#)

Dysmorphology: Abnormal morphological change. (Baraitser M, Winter RM 2001 London Dysmorphology Database London Neurogenetics Database & Dysmorphology Photo Library on CD-ROM (Windows). Oxford Univ. Press, New York). (http://www.lmdatabases.com/about_lmd.html)

Dysostosis: A defect in ossification ▶ [bone formation](#)

Dysplasia: Abnormal organization of the cells within the tissue. ▶ [malformation](#)

Dysploidy: The basic chromosome number varies within a population either because of the presence of B-chromosomes or because of Robertsonian translocations or misdivision at the centromere. The change in number does not involve an increase or decrease of an integer of the basic chromosome set. ▶ [polyploidy](#), ▶ [aneuploidy](#), ▶ [B chromosomes](#), ▶ [misdivision](#), ▶ [Robertsonian translocation](#); Baldwin BG, Wessa BL 2000 Am J Bot 87:1890.

Dyspnea: Difficulty in breathing due to various genetic or other causes.

Dyspraxia, Developmental Verbal (SPCH1, 7q31): A dominant expressive and receptive speech, grammar and language defect without substantial sensory or neurological impairment. It is caused by defect in a putative transcription factor including the gene FOXP2, which encodes a polyglutamine tract and a DNA-binding forkhead domain. ▶ [FKH](#), ▶ [speech and grammar disorder](#); Lai CSL et al 2001 Nature [Lond] 413:519.

Dysreproductive Genes: These impair fertility of the individual because of lowering or adversely affecting the reproductive system either by structural and developmental defects or as subvitals, semi-lethals and lethals.

Dyssegmental Dwarfism (dyssegmental dysplasia): Autosomal recessive phenotype involving abnormal

development of the vertebrae. It is accompanied with various other symptoms such as dwarfism, cleft palate, hydrocephalus, etc. A defect in the normal formation of collagen is suspected. The DDSH gene (Silverman-Handmakers disease, 1p36.1) involves defect in the synthesis of perlecan (heparan sulfate proteoglycan), a component of the basement membranes. ▶ [dwarfism](#), ▶ [cleft palate](#), ▶ [hydrocephalus](#), ▶ [collagen](#), ▶ [basement membrane](#), ▶ [Schwartz-Jampel syndrome](#); Arikawa-Hirasawa E et al 2001 Nature Genet 27:431.

Dystasia (areflexic dystasia): ▶ [claw-foot](#)

Dystonia: The lack of muscle coordination caused by a dominant factor at human chromosome 9q32-q34 in the region of the dopamine-β-hydroxylase locus. The prevalence of the disease (torsion dystonia) in Ashkenazy Jewish populations is high, $2-5 \times 10^{-4}$, and the penetrance is about 30%. The torsin gene encodes an endoplasmic reticulum and nuclear envelope protein, torsin A. Increased localization of torsin to the nuclear envelope is one cause of dystonia (Goodchild RE, Dauer WT 2004 Proc Natl Acad Sci USA 101:847). Some dystonias respond favorably to DOPA. Autosomal recessive expression (or possibly mitochondrial origin) may be accompanied by visual defects. In some X-linked forms, the symptoms include deafness. The hereditary progressive DOPA-responsive dystonia in human chromosome 14 is caused by a deficiency GTP cyclohydrolase I. This enzyme controls bipterin biosynthesis required for dopamine. ▶ [neuromuscular diseases](#), ▶ [dopa](#), ▶ [bipterin](#), ▶ [idiopathic torsion dystonia](#), ▶ [myoclonous](#), ▶ [sarcoglycan](#), ▶ [Munchausen syndrome](#); Tarsy D and Simon DK 2006 New England J Med 355:818.

Dystroglycan: A part of the dystrophin-associated protein complex. It participates in the formation of the extracellular matrix in cells contacting basement membranes. It promotes the assembly of the acetylcholine receptors and the neuromuscular junctions. It is the receptor of *Mycobacterium leprae* and some arena viruses. ▶ [acetylcholine receptor](#), ▶ [basement membrane](#), ▶ [sarcoglycan](#), ▶ [Mycobacteria](#), ▶ [animal viruses](#), ▶ [muscular dystrophy](#); Michele DE et al 2002 Nature [Lond] 418:417; Kanagawa M et al 2004 Cell 117:953.

Dystrophin (DRP): The muscle protein that anchors muscle membranes to actin filaments in the myofibrils. The Xp21.2-chromosomal gene contains 79 exons spanning 2,300 kb and the transcription requires about 16 hours. Utrophin is also a dystrophin type protein (DRP1, 6q24) and DRP2 another dystrophin gene has been mapped to human chromosome Xq22. ▶ [muscular dystrophy](#), ▶ [gene size](#), ▶ [exon](#), ▶ [actin](#), ▶ [myofibril](#), ▶ [sarcolemma](#), ▶ [caveolin](#)

Dystrophy: Inadequate nutrition (of the muscles). **DZ:** Dizygotic twin. ▶twinning
▶muscular dystrophy, ▶atrophy

Dyszoospermia: An anomaly involving the formation of spermatozoa. ▶spermatogonia, ▶gametogenesis, ▶spermatid, ▶azoospermia

D

Historical vignettes

Henry Borsook noted in the *Journal of Comparative Cellular Physiology*. Suppl. 1:283 (1956) his recollections from the late 1920s.

Edwin Cohn, the physical chemist asked TH Morgan, the first Nobellaureate geneticist what his plans are. And Morgan's answer was "I am not doing any genetics. I am bored with genetics. But I am going out to Cal Tech where I hope it will be possible to bring physics and chemistry to bear on biology."

Shortly after Morgan arrived to Cal Tech Einstein visited the place and posed about the same question. The answer was about the same as before. Einstein shook his head and said, "No, this trick won't work. The same trick does not work twice. How on earth are you ever going to explain in terms of chemistry and physics so important a biological phenomenon as first love?"

Paul Doty told me that shortly after lapel buttons came in he was in New York and to his astonishment saw one with 'DNA' written on it. Thinking it must refer to something else he asked the vendor what it meant. 'Get with it, bud' the man replied in a strong New York accent, 'dat's the gene'. Crick also remembered "An even odder incident happened when Jim [Watson] came back to work at Cambridge in 1955. I was going into the Cavendish one day and found myself walking with Neville Mott, the new Cavendish professor [Bragg had gone on to the Royal Institution in London]. 'I'd like to introduce you to Watson' I said, 'since he's working in your lab.' He looked at me in surprise. 'Watson?' he said. 'Watson? I thought your name was Watson-Crick'.

(Crick F 1978 How to live with a golden helix. *The Sciences* 19[7]: 6–9.)

E

E1 (Ubc1): Ubiquitin-activating protein. ►ubiquitin, ►SCF

E2 (Ubc2): A ubiquitin carrier and ubiquitin-conjugating enzyme. Ubc2/Rad6 in yeast has dual functions of proteolysis and DNA repair. E2-C is involved in the degradation of cyclin B in cooperation with the APC/cyclosome. E2-C has been detected in many eukaryotes except *Saccharomyces cerevisiae*. ►ubiquitin, ►SCF, ►UBC, ►UbcD1, ►APC, ►cell cycle

E3 (Ubc3): A family of ubiquitin ligases includes 4 types of proteins: (i) acting on the N-end rule proteins (~200-kDa); (ii) E6-AP (papilloma virus E6 oncoprotein-associated protein, ~100-kDa), it includes also *hect* proteins (homologous to E6-AP); (iii) the cyclosome/APC associated enzyme acting on mitotic cyclins, anaphase inhibitors and spindle apparatus proteins; (iv) enzymes acting on the Bim mitotic motor proteins. ►ubiquitin, ►E2, ►SCF, ►N-end rule, ►Angelman syndrome, ►APC, ►cell cycle, ►Bim

E Box (Ebox): Genes controlling endogenous rhythm (circadian oscillators) or other regulators are equipped by promoters containing the conserved core 5'-CACGTG-3' or 5'-CACATG-3' to which the transcriptional activators of clock (and of other) genes bind. Myc, Max, Mad, Mxi, and related basic helix-loop-helix/leucine zipper proteins (TFE-3, TFE-B) preferentially bind to E boxes flanked by 5' C and 3' G but do not bind if the flanks are 5' T or 3' A. E box motifs may reside at the exon-intron 1 junction and regulate transcription and splicing. Some of the E boxes are highly conserved in intron sequences, others are not and thus shed some light on evolutionary paths of gene regulation. ►endogenous rhythm, ►clock genes, ►circadian rhythm, ►LCR, ►Myc, ►MAD/MAX, ►MXI/MAX, ►TFE, ►DNA-binding protein domains, ►brassinosteroids, ►transcription factors; Comijn J et al 2001 Mol Cell 7:1267; Kim C-H et al 2001 J Biol Chem 276:24797; Haggerty TJ et al 2003 Proc Natl Acad Sci USA 100:5313.

EC: Teratocarcinoma-derived pluripotent embryonal carcinoma cell. ►stem cells, ►cancer stem cell

EC: Enzyme classification number. ►enzymes

E. coli (*Escherichia coli*, Colon bacillus; Enterobacteriaceae): Most predominant bacterium in the intestinal flora of mammals (see Fig. E1). In year 2000, ~28%

of beef cattle in the USA was infected by *E. coli* (Elder RO et al 2000 Proc Natl Acad Sci USA 97:2999). Normally it is not pathogenic, but some strains (0157) may cause Winckel's disease (a possibly fatal jaundice of newborns), diarrhea, intestinal bleeding, and urinary infections. Also, the B2 group of the bacteria encodes a non-ribosomal peptide-polyketide synthase. *E. coli* expressing this genotoxin causes double-strand DNA breaks, activate DNA damage checkpoint pathway and can cause cell death (Nougayrède J-P et al 2006 Science 313:848).

The size of single cells of *E. coli* is about 1000 × 2400 nm, and its mass is about 2 pg. Its genome is 4,639,221 bp, containing 4,288 protein-coding genes but about 1/3 have no known function so far. 2,357 of the genes are on the replicational leading strand and 1,929 are on the lagging strand. The size of the *E. coli* chromosome may vary in the different isolates, from 4.5 to 5.5 Mb because of acquired DNA sequences in various locations of the genome (Bergthorsson U, Ochman H 1998 Mol Biol Evol 15:6). Detailed analysis of *E. coli* found that genes in a pair tend to be separated by integral multiples of 117 kb along the genome and positioned in a 117-kb grid of genomic locations. In addition, the most pair-dense locations coincide with regions of intense transcriptional activity and the positions of top transcribed and conserved genes (Wright MA et al 2007 Proc Natl Acad Sci USA 104:10559). By multiple deletions of nonessential genes the genome size of the K-12 strain can be reduced by ~15%. The smaller genome size may increase stability if transposable elements were eliminated, and facilitated electroporation (Pósfai G et al 2006 Science 312:1044). Transport and binding-protein genes (281) represent the largest group (6.55%). For DNA replication, recombination, modification, and repair 115 genes (2.68%) are allocated. Transcription, RNA synthesis, and modification require 55 genes, whereas translation and post-translational modification involve 182 genes (4.38%). Phage, transposons, and plasmids occupy 2.03% of the genome. There are various groups of repeated sequences of different length. It can harbor a variety of plasmids, and it can be a lysogen. At 37°C its generation time is about 20 min. *E. coli* is a genetically and biochemically most thoroughly studied organism. By 1997, the genome of the K-12 nonpathogenic laboratory strain has been completely sequenced almost independently in the USA and Japan. The enterohaemorrhagic strain 0157:H7 has also been sequenced by 2001. The sequence revealed the existence of 1,397 new genes of different functions organized in specific clusters (Fig. E2). ►conjugation, ►conjugation mapping, ►bacterial recombination frequency, ►recombination molecular mechanisms prokaryotes, ►electroporation, ►transposable elements,

Figure E1. *E. coli* cell

Figure E2. Physical map of *Escherichia coli* chromosome. Open reading frames color-coded by functional categories. (Courtesy of. Masaki Fumoto, see also <http://gib.genes.nig.ac.jp>)

►**genophore**; Blattner FR et al 1997 Science 277:1453; Riley M, Serres MH 2000 Annu Rev Microbiol 54:341; Perna NT 2001 Nature [Lond] 409:529; Schaechter M et al 2001 Microbiol Mol Biol Rev 65:119; Fumoto M et al 2002 Nucleic Acids Res 30:66; genetic techniques: Shuman HA, Silhavy TJ 2003 Nat Rev Genet 4:419; databases: <http://cgsc.biology.yale.edu> or <http://gib.genes.nig.ac.jp/>; <http://ecocyc.org/>; <http://ecoli.aist-nara.ac.jp>; predicted protein interaction database: <http://www.pdg.cnb.uam.es/i2h/>; regulatory systems: <http://regulondb.ccg.unam.mx:80/index.html>; post-genomics: <http://www.ecoli-york.org/>.

⌘ **Element**: At the 5'-end of the viral RNA minus strand it facilitates synthesis and encapsidation of the genome into the viral core. ►**retroid virus**

E Region of GTP-Binding Proteins: The E region interacts with effectors (amino acids 32–42 in RAS). Mutation

in this region may abolish oncogenic-transforming ability without affecting GTP-binding. ►**oncogenes**, ►**RAS**, ►**GTP**, ►**GTP binding protein superfamily**

E Site (exit site): The E site is on the ribosome to where the deacylated tRNA moves from the P site after the peptidyl-tRNA-mRNA complex moves from the A to the P site. The process may be reversible. The elongation factor EF-T mediates the regeneration of the active EF-Tu-GTP from EF-TU-GDP. Thus, besides the initially identified A and P sites, this third E site is now known. In contrast to the A and P sites, the E site may not be a permanent structure, rather it is just a transient intermediate stage of the peptide elongation process. ►**EF-TU-GTP**, ►**protein synthesis**, ►**ribosome**, ►**amino acid activation**

E Value: The e (expectancy) value in an alignment match (by BLAST) that is equivalent or better than expected by chance alone. The lower the E value, the better the score. ►**alignment**, ►**BLAST**

E Vector (self-inactivating vector, Ψ vector): A construct of large direct flanking repeats around the encapsidation signal (E/Ψ) that may bring about very high frequency of template switching of the reverse transcriptase. As a consequence, the viral (spleen necrosis virus, mouse leukemia virus) encapsidation protein may be deleted in 99% or even higher frequency and the virus thus inactivated. Also, suicide genes or other DNAs can be reconstituted by the same mechanism. Such a vector, when it includes selectable markers (e.g., neo), can be efficiently selected for in the presence of G418 antibiotic in gene therapy by retroviral vectors. ►**G418**, ►**neo**, ►**SIN vector**; Julias JG et al 1995 J Virol 69:6839; Delviks KA, Pathak VK 1999 J Virol 73:8837.

E1A: An adenovirus oncoprotein; it can reverse the growth-inhibitory effect of the transforming growth factor (TGF-β). E1A moves cells into the S phase by interacting with the retinoblastoma (Rb) and the p300

proteins. Rb recruits histone deacetylase and p300 attracts histone acetyltransferase. Both Rb and p300 are activated by phosphorylation at the G1/S checkpoint. ▶TGF, ▶T cells, ▶adenovirus, ▶cell cycle, ▶retinoblastoma, ▶p300, ▶chromatin remodeling, ▶histone deacetylase, ▶histone acetyltransferase, ▶CtBP; Fuchs M et al 2001 Cell 106:297.

E2A: An immunoglobulin enhancer-binding factor and basic helix-loop-helix protein encoded in human chromosome 19p13. (DNA binding domains; immunoglobulins).

EEA (excitatory amino acids): Glutamate and aspartate particularly can activate neurotransmitters. ▶neurotransmitter

Eadie-Hofstee Plot: In a coordinate system $v/(S)$ is plotted against v , where v is the enzymatic reaction velocity and (S) is the substrate concentration. ▶Michaelis-Menten equation, ▶Lineweaver-Burk plot

EAR (extra annual risk): The extra annual increase of incidence of cancer compared to (radiation) unexposed population. ▶risk, ▶ERR, ▶Armitage-Doll model

Earlobes Attached (at right, dominant is at left): Attached earlobes are generally, a recessive human trait (see Fig. E3).

Figure E3. Earlobes attached

Early Genes: Genes transcribed early during development; they are involved in the infection process of the virus, and before replication begins. ▶early-response gene, ▶late gene, ▶delayed-response gene

Early-Response Gene: The early-response gene is activated by growth factors within a few minutes without a pre-requisite for protein synthesis. ▶early gene, ▶delayed-response gene, ▶late gene

Earwax (cerumen): The product of ceruminous apocrine glands and in humans it is determined by a Mendelian factor at 16p11-q12.1. This is also the site of the ABC transporter, the ABCC11, ABCC12 multidrug resistance protein 8 (MRP8) variants. The earwax can be either sticky, brown, wet type, controlled by AA

homozygosis (at a single nucleotide polymorphism G/A538), or the dry type determined by GA heterozygotes or GG homozygotes. The dry type actually lacks cerumen. The dominant A allele involves lower excretion of cyclic guanosine monophosphate than the G. The dry type is predominant (80–95%) among East Asians whereas among Europeans and Africans it is rare (~3%). (See Yoshiura K-I et al 2006 Nat Genet 38:324; ▶apocrine gland, ▶multidrug resistance).

E3B1: A signal transducer between RAS and Rac. ▶EPS8, ▶Rac, ▶RAS, ▶signal transduction

EBF (early B cell factor): Transcription factor specific for B cells and expressed at antigen-independent stages. It regulates the immunoglobulin α chain. ▶B lymphocyte, ▶T cell

ebgA⁰: A gene of *E. coli* (map position 67) that through two mutations permits galactose utilization, although this newly evolved galactosidase is immunologically distinct from the *LacZ*-encoded β -galactosidase enzyme. ▶lactose operon; Hall BG 1999 J Bacteriol 180:2862; Hall BG 2001 Mol Biol Evol 18:1389.

EBNA: Epstein-Barr virus antigens and transactivating oncoproteins. This protein—along with latent membrane proteins (LMPs)—is required for the latent maintenance of the infection. ▶oncogenes, ▶Epstein-Barr virus, ▶transactivator, ▶transactivation response element; Hochberg D et al 2004 Proc Natl Acad Sci USA 100:239.

Ebola Virus (EBOV): A member of the filamentous filoviridae, a negative-stranded, enveloped, nonsegmented RNA virus of 18,958 nucleotides, encoding 7 structural and 1 nonstructural proteins. It is a very dangerous hemorrhagic pathogen of humans and other primates. In recent years the virus seems to have killed 5,000 gorillas and many chimpanzees in Gabon and the Congo (Bermejo M et al 2006 Science 314:1564). Ebola virus-like particles (ebola glycoprotein + matrix protein) appear immunologically active enough to afford effective protection against the virus when used as a vaccine in mice (Warfield KL et al 2003 Proc Natl Acad Sci USA 100:15889). Endosomal cysteine proteinases are required for processing viral glycoproteins and for infectivity. Cathepsin B and Cathepsin L enzymes are effective facilitators in viral entry and their inhibitors may be effective as means of protection. Transcription of the highly pathogenic Ebola virus depends on VP30, a nucleocapsid-associated Ebola virus-specific transcription factor. The transcription activator VP30 was shown to play an essential role in Ebola virus replication, most likely by stabilizing nascent mRNA. The crystal structure and the mutagenesis results

revealed a potential pocket for small-molecule inhibitors that might prevent VP30 activity and thus virus propagation as it has been shown by peptides, which interfere with VP30 homooligomerization (Hartlieb B et al 2007 Proc Natl Acad Sci USA 104:624). ►animal viruses, ►negative-strand viruses, ►cathepsin, ►Marburg virus; Burton DR, Parren PW 2000 Nature [Lond] 408:527.

E

E-Box: The minimal DNA element (CANNTG, where N is any nucleotide) required for binding HLH and b/HLH/Z transcription factors. ►HLH, ►bHLH, ►helix-loop-helix

EBP: Enhancer binding protein. ►enhancer, ►C/EBP

4E-BP1 (PHAS-1): A binding protein of eIF-4E. After it is phosphorylated it stimulates the activity of eIF-4F cap-binding protein, required for the beginning of translation. It appears that phosphorylation of 4E-BP1 releases eIF-4E from the inhibition by 4EGI-1. The formation of the eIF4E/eIF4G initiation of translation complex is inhibited by 4E-BP. ►eIF-4F, ►eIF-4E, ►translation initiation, ►4EGI-1; Heesom KJ 2001 et al Curr Biol 11:1374.

EBV: ►Epstein-Barr virus

EC: Embryonal carcinoma cells. ►carcinoma

EC₅₀ (endpoint concentration 50): Concentration of a chemical that causes half of the individuals to reach an endpoint, e.g., anesthesia.

ECAF: Endothelial attachment factor.

Ecdysone: A steroid-molting hormone of insects produced by the prothoracic gland. Ecdysone signaling is important also for mid-embryonic development. 20-hydroxyecdysone initiates major developmental transitions and insulin family molecules control growth and development. Actually, ecdysone impedes growth by insulin signaling to transcription factor FOXO and to the translation inhibitor 4E-BP (Colombani J et al 2005 Science 310:667). It apparently stimulates transcription and activates puffing at different locations in the salivary gland chromosomes of *Sciara*, *Drosophila*, and other dipteran flies. This hormone and its variants apparently also regulate development in crayfish, arthropods, schistosomes, and nematodes. Similar compounds (β-ecdysones) occur in plants as well. Ecdysone does not play a natural role in mammals, yet the ecdysone receptor transgene controls ecdysone response. In *Drosophila* hydroxyecdysone—the active hormone—is produced after 6 h before entering the prepupal stage and again 10 h after pupariation. The production of the waves of these steroids is accompanied by distinct

morphogenetic developments. The ecdysone, EcR (ecdysone receptor), and USP (*ultraspiracle* 1-[05]) complex (homologous to human retinoid receptor) then turns on various genes. Some of the gene products' (E75, DHR3) feedback inhibit the complex and at the same time regulate (through mid-prepupal protein, βFTZ1) the onset of the second, smaller wave of ecdysone synthesis by these and another set of proteins. EcR and ecdysone defects may extend insect life span (Simon AF et al 2003 Science 299:1407). The complete ecdysone response element (EcRE) is palindromic; some other response elements are homologous although they display variations of the basic sequence (see Fig. E4). Muristerone is an agonist of ecdysone and it occurs in animal and some plant tissues. ►puffs, ►salivary gland chromosomes, ►animal hormones, ►steroid hormones, ►brassinosteroids, ►retinoic acid, ►insulin, ►eIF4A, ►eIF4E, ►FOX; Segraves W 1998. In: Dickson RB, Solomon DS (eds) Hormones and growth factors in development and neoplasia. Wiley-Liss, New York; Koolman J (ed) 1989 Ecdysone, Georg Thieme, Stuttgart, Germany, Arbeitman MN; Hogness D 2000 Cell 101:67; Takeuchi H et al 2001 J Biol Chem 276:26819; Petryk A et al 2003 Proc Natl Acad Sci USA 100:13773.

Figure E4. Ecdysone and ecdysone response element

ECE: Extrachromosomal element, such as a plasmid. ►plasmid

Eceriferum Loci: in the eceriferum loci in various plant species determine the cuticular waxes or lack of them (see Fig. E5). In barley, a particularly large number of loci in different chromosomes have been analyzed genetically and biochemically. There is an amazing specific wax pattern associated with the mutations that are correlated with the biosynthetic relations among β-diketones, hydroxy-β-diketones, alkan-1-ol, and alkan-2-ol esters. In the Arabidopsis *cer5* mutation deficiency of an ABC transporter fails in cuticular lipid export (Pighin JA et al 2004 Science 300:702). ►fatty acids, ►ABC transporter; Wettstein-Knowles VP 1975 Molec Gen Genet 144:43.

Figure E5. Eceriferum loci. The scanned electron micrograph is courtesy of Dr. Penny von Wettstein-Knowles

ECGF: Endothelial growth factor.

Echinacea (cornflower): Species *E. angustifolia*, *E. pallida*, and *E. purpurea* (see Fig. E6); perennial composite wild flowers of North America and Mexico and attractive garden ornamental flowers with some supposed medicinal value of the dried aerial parts and roots. Its basic chromosome number is $n = 11$. It has a mild fragrance and initially sweet taste, which becomes bitter later. It contains pyrrolizidine alkaloids, yet it is not considered toxic. Herbal medicine supports the oral administration of its extracts against cold, respiratory and urinary infections by attributing to it immunostimulatory effects. It is recommended also for external use in wound healing. Some persons may be allergic to it. Contraindications are for treatment of AIDS, tuberculosis, and autoimmune diseases. A recent clinical study indicated ineffectiveness of *E. angustifolia* root extracts against rhinovirus infections (Turner RB et al 2005 New England J Med 353:341). Another report confirmed antioxidant effects and favorable immune response to *Echinacea* tablets (Agnew LL et al 2005 J Clin Pharm Ther 30(4):363). A survey of 322 articles of the effects of *Echinacea* treatment for cold are equivocal and controversial (Caruso TJ, Gwaltney JM Jr 2005 Clin Infect Dis 40:807).

Figure E6. *E. purpurea*

Echocardiography: An ultrasonic examination of the structure of the fetal heart as part of a repertory of prenatal diagnosis of congenital defects in anatomy.
▶ prenatal diagnosis

Eclampsia/Preeclampsia: Hypertension, edema, proteinuria, kidney failure in the latter part of pregnancy with a prevalence of 2–5%, caused by etiological and genetic factors presumably at chromosome 2p12/2p25; another is at 9p13 in Scandinavian populations and a fourth at 10q22 among Dutch females (van Dijk M et al 2005 Nat Genet 37:514; reexamination of these findings led to the conclusion that the STOX1 gene at 10q22 is not involved [Iglesias-Platas I et al 2007 Nat Genet 39:279; van Dijk M et al 2007, Nat Genet 39:280, claim that polymorphism may be involved but the original report is still correct]). Preeclampsia, early stage of eclampsia, causes complications—possibly fetal and maternal death—in pregnancy by inadequate blood supply to the trophoblasts on the uterus. It appears that if the mothers are lacking all or most of the natural killer cell (NKC) immunoglobulin receptors (KIR), and the fetus possessed HLA-C2 group antigens (contributed to the fetus by the father), there is nonimmune physiological reaction, which causes problems in placental development (Hiby SE et al 2004 J Exp Med 200:957). There are two types of KIR; the A type is inhibitory whereas the B group is stimulatory to NKCs. It seems that the soluble receptor for the vascular endothelial growth factor (VEGF), sFlt1, binds VEGF and the placental growth factor and interferes with blood supply to the placenta. The heterodimer of angiotensin-1 receptor for angiotensin II and the B₂ receptor for bradykinin increased the susceptibility to preeclampsia by four- to five-folds. These and other factors may threaten the survival of the baby or the mother or both. ▶ killer cell, ▶ trophoblast, ▶ HLA, ▶ angiotensin, ▶ kininogen, ▶ mother-fetus incompatibility, ▶ vascular endothelial growth factor, ▶ FLT oncogene; Moses EK et al 2000 Am J Hum Genet 67:1581; Abdalla S et al 2001 Nat Med 7:1003; Redman CW, Sargent IL 2005 Science 308:1592.

Eclipse: The (latent) period between viral infection of a bacterium and the burst of the new phage particles even if burst is induced. ▶ one-step growth, ▶ burst, ▶ induction of a lysogenic bacterium; Anderson TF, Doerman AH 1952 J Gen Physiol 35:657; Abedon ST et al 2001 Appl Environ Microbiol 67:4233.

Eclosion: The hatching of the adult form (imago) of insects from the puparium. ▶ pupa

ECM: ▶ extracellular matrix

EcoCyc: ▶ *E. coli*

Ecodeme: A population adapted to a particular ecological condition. See marine ecological genomes: <http://www.megx.net/>.

Ecogenetics (ecological genetics): Ecogenetics studies the genetically determined responses of organisms to environment(s). ▶adaptation, ▶adaptive radiation; Hoffmann AAS et al 1995 Annu Rev Genet 29:349.

Ecological Interference: The joint outbreak of two infectious diseases may be negatively correlated because of the death of susceptible individuals from the pool after an acute infection. High mortality rate caused by one type of infection thus lowers the recruitment rate of susceptibles to another disease. (See Rohani P et al 2003 Nature [Lond] 422:885.)

Ecological Race: A distinctly adapted group of an organism without sexual isolation from the ancestral form. ▶sexual isolation

Ecology: The study of the relationship of living systems and their environment. Examples: the increase of CO₂ concentration in the atmosphere and geosphere due to an increase of burning fossil fuels may increase the number of mitochondria in plants and alter the thylakoid structure in the chloroplasts. The temperature change that has been claimed may alter the habitats of all organisms and affect biodiversity. The ecology involves the networks of species that interact directly or indirectly in a complex manner (Montoya JM et al 2006 Nature [Lond] 442:259). ▶ecogenetics, ▶biodiversity, ▶inversion

Ecomorph: A species or group particularly adapted to a microhabitat (microenvironment).

Ecores: Orthologous coding sequences/evolutionarily conserved regions in genomes. ▶orthologous

EcoRI: Type II restriction endonuclease with a primary recognition site.

Å indicates potential base to be methylated, arrows indicate sites of cut.

The staggered cuts have a receding OH and a protruding p end -----OH

-----p

Although the above 6-nucleotide sequence is the primary recognition site, alternate recognition sites with different preferences are also known. These secondary activities (named EcoRI* [star]) depend on the composition of the incubation mixture. ▶restriction enzymes

EcoSeq: A database of a collection of DNA sequences of *E. coli* obtained from various sources.

Ecosystem: The relationship of living organisms to each other and to all environmental factors. Human

consumption has profound effects on the ecosystem (Imhoff ML et al 2004 Nature [Lond] 429:870). ▶species extant; Whitham TG et al 2006 Nat Rev Genet 7:510.

Ecotropic Retrovirus: An ecotropic retrovirus replicates only in the cells of the species from which it has been originally isolated. This specificity is determined by envelope glycoproteins that require specific receptors in the host. ▶amphotropic

Ecotype: A population adapted to a particular ecological condition. Besides the main genes determining the adaptive trait(s), the population may not be genetically homogeneous; usually it is not an isogenic line. ▶adaptation, ▶isogenic stocks

ECR: An evolutionarily conserved region revealed by comparative genome analysis.

Ectoderm: The surface layer of the embryo that develops into epidermis, skin, nerves, hair, nails, ears, eyes, enamel of teeth, internal mouth, and anal tissues. Transforming growth factor-β signals to the mesoderm and endoderm for homeostatic proliferation. For the formation of ectoderm attenuation of TGF-β is required. This task is performed by the protein ectodermin, a member of the Smad4 ubiquitin ligase family (Dupont S et al 2005 Cell 121:2). ▶gastrulation, ▶TGF, ▶smad, ▶ubiquitin

Ectodermal Dysplasia (EDA): Several *autosomal dominant forms* involve complex skin alterations and may eliminate the dermal ridges and alter palmar prints ▶fingerprints. In ectodermal anhidrotic dysplasia patients do not sweat and have a cleft lip and palate; in the hypohidrotic form sweating ability is only reduced whereas the hidrotic form shows normal sweating (see Fig. E7). The trichoodontochoial form is accompanied by deficiency of tooth, hair, breast and nipple formation. The *EEC* (ectrodactyly [missing fingers]) *ectodermal dysplasia* has most of the symptoms mentioned above plus abnormal tear ducts. The *autosomal recessive* ectodermal dysplasias include also complex features such as sweat gland tumors (eccrine tumors and ectodermal dysplasia), also anhidrotic type (due to mutation in connexin-30) dysplasia (HED or Coulson syndrome, 13q12) with neurosensory deafness, dysplasia with cleft lip and palate, mental retardation, syndactyly, hypohidrosis-hypothyroidism, hypohidrosis-hypothyroidism-lung disease. The human chromosome 2q11-q13 locus has both dominant and recessive mutations with hypohidrotic ectodermal dysplasia.

Figure E7. Ectodermal dysplasia. Missing teeth in hypohidrotic ectodermal dysplasia. Usually the teeth are also irregular

An *X-linked recessive* (Xq11-q21.1) ectodermal dysplasia is anhidrotic, shows reduction in hair and tooth development, hyperpigmentation around the eyes, short stature, etc. The Xq13.1 locus involves hypohidrotic ectodermal dysplasia (HED) and incontinentia pigmenti and the mutation is due to IKK-gamma (NEMO). The hypohidrotic ectodermal dysplasia with immunodeficiency is defective in switching from IgM to other classes of immunoglobulins. The latter gene is normally required for the activation of NF- κ B and its defect results in immunodeficiency. The X-linked ectodysplasin-A2 receptor (XEDAR) is different from the EDA-A1 receptor by the insertion of two amino acids. These receptors belong to the tumor necrosis receptor (TNFR) superfamily. In anhidrotic/hypohidrotic ectodermal dysplasia the Sonic hedgehog and its effectors, antagonists of the Wnt (wingless) and the bone morphogenetic (BMP) proteins as well as NF- κ B signaling pathway on lymphotoxin- β are involved (Cui C-Y et al 2006 Proc Natl Acad Sci USA 103:9142). ▶*dermatoglyphics*, ▶*fingerprints*, ▶*ectoderm*, ▶*anhidrosis*, ▶*connexin*, ▶*cleft palate*, ▶*cyst*, ▶*polydactyly*, ▶*EEC syndrome*, ▶*TNFR*, ▶*IKK*, ▶*BMP*, ▶*BMP*, ▶*Wingless*, ▶*NF- κ B*, ▶*incontinentia pigmenti*, ▶*NEMO*, ▶*skin diseases*, ▶*antibody gene switching*; Döffinger R et al 2001 Nat Genet 27:277; Jain A et al 2001 Nat Immun 2:223.

Ectokinases: A group of enzymes phosphorylating extracellular proteins and external domains of membrane proteins affecting cell interactions (Rodríguez F et al 2005 Proc Natl Acad Sci USA 102:4718).

Ectopic Antibody: An antibody molecule introduced exogenously into the cell. It may be genetically modified and specifically targeted. It may function as an effector or suppressor.

Ectopic Expression: The organ-specific expression of a gene is altered by fusing the structural gene to a promoter with different or no organ-specificity of expression. In more general meaning, ectopic expression is the displaced condition of an organ or function. ▶*promoter*, ▶*transformation*, ▶*allotopic expression*, ▶*orthotopic*

Ectopic Integration: The insertion of transforming DNA takes place at a target site different from that of the original position of the transforming DNA. ▶*transformation*, ▶*orthotopic*

Ectopic Pairing: The association between sites in nonhomologous chromosomes due to intercalary heterochromatin. ▶*chromosome pairing*, ▶*heterochromatin*; Aragon-Alcaide L, Strunnikov AV 2000 Nat Cell Biol 2:812.

Ectopic Pregnancy: An abnormality of ~1.2–1.4% incidence when the fertilized ovum develops outside the uterus. Risk factors are pelvic inflammation, *Chlamydia* infection, smoking, tubal surgery, endometriosis, etc., but a role for chromosomal aberrations could not be verified (Coste J et al 2000 Fertil Steril 74:1259).

Ectopic Recombination: The recombination between non-allelic but homologous chromosomal sequences or between a normal chromosomal site and an insert at a nonhomologous site. Recombination between dispersed repetitive DNA such as ribosomal RNA genes, multicopy transposable elements (e.g., Alu), multigene families, transgenes, centromeric and telomeric DNA elements. Ectopic recombination may result in chromosomal rearrangements, aneuploidy and the formation of nucleotide repeats causing various human diseases. There appears to be a selective restraint against such events. ▶*homologous recombination*, ▶*illegitimate recombination*, ▶*intrachromosomal recombination*, ▶*trinucleotide repeats*, ▶*Alu*, ▶*transgene*; Goldman AS, Lichten M 2000 Proc Natl Acad Sci USA 97:9537; Goebel P et al 2001 J Exp Med 194:645; Lam K-WG, Jeffries AJ 2006 Proc Natl Acad Sci USA 103: 8921.

Ectoplast: The cytoplasmic membrane surrounding the protoplast.

Ectrodactyly: Split foot and hand, absence of fingers/polydactyly. It is most likely under autosomal recessive control. Cleft lip and palate, skin, teeth, hair, nail defects and closure (atresia) of the lacrimal ducts may accompany it. The autosomal dominant gene (2q11-q13, ED3) and the (Xq12-q13, ED1) mutations also involve hypotrichosis, hypodontia, and hypohidrosis. Cleft lip and/or palate, EEC3 is at 3q47, Limb-Mammary syndrome is at 3q27,

E

ankyloblepharon-ectodermal defects-cleft lip/palate at 3q27, Adult's syndrome (acro-dermato-ungual-lacrima-digit) at 3q27, split-hand/foot malformation at 3q27. The symptoms are shared partly by a score of other syndromes involved in mutations of the p63 tumor-suppressor protein encoded at 3q27. The Rosselli-Gulienetti syndrome is at 11q23-q24, the EEC1 gene is at 7q11.2-q21.3. ▶[adactyly](#), ▶[polydactyly](#), ▶[split hand/split foot malformation](#), ▶[p63](#), ▶[Rapp-Hodgkin syndrome](#)

Ectromelia: Bone underdevelopment; also poxvirus causing disease of mice involving defect of the limbs and necrosis of visceral organs.

Eczema: Eczema refers to an itchy inflammation of the skin; it may be scaly or oozing and may be caused by various factors even as simple as drying of the skin in winter, food allergy or infections, or Kaposi sarcoma, etc. Loss of function of the filaggrin gene (in about 9% of European populations) is a predisposing factor to ichthyosis vulgaris as well as to asthma (Palmer CN et al 2006 Nat Genet 38:441). Filaggrin is the protein controlling the terminal differentiation of the epidermis. ▶[dermatitis](#), ▶[skin diseases](#), ▶[Wiskott-Aldrich syndrome](#), ▶[Kaposi sarcoma](#), ▶[acquired immunodeficiency syndrome](#), ▶[allergy](#), ▶[ichthyosis](#), ▶[asthma](#)

EDG (endothelial differentiation gene): The EDG, when overexpressed, enhances cell aggregation and an increase in the expression of cadherins, depending on the RHO protein and activation by sphingosine-1-phosphate (SSP). ▶[cadherins](#), ▶[sphingosine](#); Marletta MA 2001 Trends Biochem Sci 26:519; Robert P et al 2001 J Mol Cell Cardiol 33:1589.

Edges: Edges are interactions in genetics networks between nodes. ▶[networks](#)

Edible Vaccines: ▶[plant vaccines](#)

Editing: Some DNA polymerases, aminoacyl tRNA synthetases, aptamers also have nuclease functions and eliminate replicational mistakes or prevent translational errors. ▶[antimutator](#), ▶[DNA polymerases](#), ▶[error in aminoacylation](#), ▶[aptamer](#), ▶[RNA editing](#), ▶[mtDNA](#), ▶[string edit distance](#), ▶[editosome](#), ▶[ADAR](#)

Editosome: The complex which determines the selection of RNA bases for editing. The determination may involve a protein or RNA. In the mitochondria of *Arabidopsis*, 8% of codons are edited (5,285 codons) and 16 were edited twice. The specificity of selection of the correct cytosine residue may require only 2–8 nucleotides. ▶[RNA editing](#); Giegé P, Brennicke A 1999 Proc Natl Acad Sci USA 96:15324.

Edman Degradation: A procedure for protein sequencing. The reagent phenylisothiocyanate causes the formation of phenylthiohydantoin and cleavage of the terminal residue. This amino acid can then be identified. The same process can be repeated many times and the amino acid sequences of the entire macromolecule can be determined, step by step. The commercially available automatic protein sequencers use the same principle in an efficient way. (See Edman P, Begg G 1967 Eur J Biochem 1:80).

EDRF (endothelium-derived relaxing factor): EDRF is nitric oxide. ▶[nitric oxide](#)

EDTA (ethylenediaminetetraacetic acid): A chelating agent and as such an inhibitor of DNase. It is an anticoagulant and is also used for plant nutrient media for improving the solubility of iron, etc. ▶[DNA extraction](#), ▶[embryogenesis somatic](#), ▶[DNA fingerprinting](#), ▶[versenes](#)

Edward VII: King of England, one of the three sons of Queen Victoria who did not inherit the hemophilia gene. ▶[hemophilias](#)

Edward's Syndrome: Trisomy for human chromosome 18 with serious debilitating consequences or of prenatal or postnatal death within a few months; at most may survive up to a few years. Generally, the head is elongated, the ears are set low, eyelids are abnormal, fingers clenched, hypoplasia of nails, and almost all organs are affected. Its incidence is about 1 in 7,500–10,000 births with a predominance of females among the afflicted. The disomic chromosome is maternally contributed in 95% of the cases, and 95% of the incidences fail to survive till birth. Increased maternal age and meiosis II errors are factors in the incidence. ▶[trisomy](#), ▶[trisomic analysis](#), ▶[hypoplasia](#)

EEA-1 (early endosomal autoantigen 1): EEA-1 binds phosphoinositide-3-phosphate (PtdIns[3]-P) and Rab5 to the endosomes and mediates endosome fusion with the cooperation of phosphatidylinositol-3-OH kinase. ▶[endocytosis](#), ▶[phosphoinositides](#), ▶[Rab](#)

EEC Syndrome (ectrodactyly, ectodermal dysplasia, cleft lip/palate): An autosomal (3q27) dominant abnormality. The mutation involves the gene encoding p63, a homolog of p53, and it maps to a location identical with that of the Limb mammary syndrome. Components of the EEC syndrome are parts of the defects attributed to mutations at Split-hand/foot malformation syndromes 7q21.3-q22.1 (SHFM1), Xq26 (SHFM2) and 10q24-q25 (SHFM3). These human anomalies occur at an approximate frequency of 1.8×10^{-5} . ▶[ectrodactyly](#), ▶[ectodermal dysplasia](#), ▶[cleft lip](#), ▶[cleft palate](#), ▶[limb defects in humans](#),

►syndactyly, ►polysyndactyly, ►Pallister-Hall syndrome

eEF Eukaryotic elongation factors of peptide chain. Some of them recruit the aminoacyl-tRNA to the ribosome while others control the translocation of the ribosome on the mRNA. ►Spt; Negrutskii BS, El'skaya AV 1998 Prog Nucleic Acid Res Mol Biol 60:47.

eEF-1A (eEF-1 α): Eukaryotic translation factor, binds amino acid-tRNA; also a GTPase and regulates cytoskeletal (microtubule) rearrangements. It occurs in two isoforms encoded by two genes with tissue-specific expression. It is similar to prokaryotic EF1A. ►protein synthesis, ►EF1A; Hotokezaka Y et al 2002 J Biol Chem 277:18545.

eEF-1 β (eEF1B or eEF-1 $\beta\gamma\delta$): Mediates GTP-GDP exchange on eEF-1 α in eukaryotic translation. It is similar to prokaryotic EF1B. ►protein synthesis, ►EF1B

eEF-1 γ : Mediates GTP exchange with the aid of eEF-1 β in translation. ►protein synthesis

eEF-2: Eukaryotic translation factor; stimulates peptide chain translocation on ribosome. When phosphorylated it may slow elongation rate. It is also a GTPase. It is similar to prokaryotic EF-2 ►GTPase, ►translocation, ►protein synthesis, ►EF-2

eEF3: A unique fungal translation factor without exact homologs in other taxonomic categories. ►structure; Andersen CBF et al 2006 Nature [Lond] 443:663.

EEG (electroencephalogram): A record of the electric current developed in the brain, measured after electrodes are applied to the scalp, to the surface of the brain, or into the brain material. It reveals the functional state of the central nervous system. The EEG pattern depends on a number of factors, but also has a hereditary component indicating psychological responses of the family.

EF-2 (EF-G): A ~77-kDa translation elongation factor in prokaryotes; it catalyzes translocation on ribosomes. Although the reaction derives energy by the hydrolysis of guanosine triphosphate, the tRNA-mRNA-ribosome complex of prokaryotes may alone provide energy for the peptidyl transferase (Fredrick K, Noller HF 2003 Science 300:1159). ►protein synthesis

EF1A (EF-Tu): A (44 kDa) prokaryotic GTP-binding peptide chain elongation factor. It mediates the aminoacylated tRNA binding to the ribosomes. E-Tu and flagellin activate defense signaling in *Arabidopsis* against *Agrobacterium* infection (Zipfel C et al 2006 Cell 125:749). ►flagellin; LaRiviere FJ et al 2001 Science 294:165.

EF-1 α : A translation initiation factor in eukaryotes. ►protein synthesis

EF1B: (Ef-Ts): A prokaryotic translation factor.

E2F1: A family of transcription factors, activated by RB and MDM2 oncogenes. High E2K level may be reached by mutation in RB, and then MAD2 is overexpressed leading to aneuploidy, a common feature of oncogenic transformation (Hernando E et al 2004 Nature [Lond] 430:797). They are involved in the regulation of the cell cycle, apoptosis, neoplasia, etc. E2F interacts with cyclinA/Cdk2 and it is phosphorylated by the latter thereby down-regulating its DNA binding and transcription activation (Rubin SM et al 2005 Cell 123:1093). E2F also regulates p53. E2F1 also regulates p73 protein and apoptosis by T cell receptor activation induced cell death even in the absence of p53. ►MDM2, ►ARF, ►retinoblastoma, ►p53, ►p73, ►DP1, ►pocket, ►cancer, ►EMA, ►histone deacetylase, ►histone methyltransferases, ►retinoblastoma, ►CDF, ►CDC14, ►cell cycle; Takahashi Y et al 2000 Genes Dev 14:804; Wu L et al 2001 Nature [Lond] 414:457; Ogawa H et al 2002 Science 296:1132.

e1F-2B: A translation factor involved in GTP-GDP exchange. ►protein synthesis, ►GTP

$$E = \sum_T w_T H_T$$

Effective Dose of Radiation (E): Where w_T = is the weighting factor varied according to the tissue absorbing, and H_T = equivalent dose to tissue. ►stochastic detriment, ►radiation hazard

Effective Mutagen: An effective mutagen causes all types of mutations (including chromosomal changes) at high frequency. ►efficient mutagen

Effective Number of Alleles The number of alleles that are maintained in the population. ►effective population size

Effective Number of Loci: The number of loci involved in a quantitative trait; also called segregation index. ►gene number in quantitative traits

Effective Population Size (N_e): The number of individuals that leave offspring in a population. Although, from several viewpoints (economic, agricultural, ecological, demographic, insurance, welfare), the total number of individuals may be the most important, geneticists are concerned primarily with that fraction of the population that passes on genes to future generations. The *genetically effective size of the population* is represented as (N_e). If the effective population size is small (even if the mating is random), the allelic and genotypic frequencies may be biased. In cases when unequal numbers represents

the two sexes the effective population size will be lower than the sum of the males and females. Each individual has a 0.5 chance to contribute a particular allele to the offspring (through the egg and sperm) and the chance of contributing two of the same allele is $0.5 \times 0.5 = 0.25$. The probability that the same female contributes two alleles is:

$(1/N_f)(1/4)$ and for a male it is: $(1/N_m)(1/4)$, where N_f and N_m are the number of females and males, respectively. Therefore, the probability that any two alleles of the population comes from the same individual is: $\frac{1}{4N_f} + \frac{1}{4N_m} = \frac{1}{N_e}$ hence $N_e = \frac{4N_mN_f}{N_m+N_f}$. Fluctuations in population size from generation to generation as well as the nonrandom distribution of family size may affect the allelic sampling.

The sampling variance of the alleles is equal to: $\sigma^2 = \frac{q(1-q)}{2N}$.. and hence $\sigma = \sqrt{\frac{q(1-q)}{2N}}$... where q is the frequency of one of the alleles and N is the population size. If the frequency of the a allele is 0.5 and $N = 25$, the standard deviation of the frequency of the a allele becomes: $\sigma = \sqrt{\frac{0.5 \times 0.5}{2 \times 25}}$.. $= \sqrt{0.005}$... ≈ 0.071 . This indicates that chance alone can modify the frequency of the a allele in a small population. And 31.74% of the loci (because according to the normal distribution 68.26% of the population is supposed to be within $M \pm 1\sigma$) may carry the allele with frequencies more extreme than 0.429 to 0.571 rather than 0.5 ($0.50 \pm$ standard error). In other words, this also means that if the population is broken up into smaller breeding units, 31.74% may have gene frequencies in the range of 0.429 and 0.571. In cases of polygeny, the N_e is reduced as determined by the formula: $4MF/(M + F)$ where M and F are the number of males and females, respectively. The N_e for autosomal and Y populations is dependent on the ratio of mating men and mating women (R), and $N_e \approx (2 + 2R)/R$.

The effective number of breeding individuals can be estimated also from the number of heterozygotes, in excess of expectation, on the basis of the Hardy-Weinberg equilibrium, because when the number of breeders is small, by chance, the allele frequencies will differ in the males and females. This procedure is applicable only to polygamous or polygynous populations with few breeders and many loci with multiple alleles (Luikart G, Cornuet J-M 1999 Genetics 151:1211).

Any shift in the gene frequencies brought about by the random fluctuation in gametic sampling is called *random genetic drift*. The drift is completely accidental. Such events may take place in the population in any breeding season if the number of breeding individuals is reduced. Once such a sampling bias of gametes (in mating) has taken place, the

process may continue in either direction but there is a definite chance that the allelic composition of the small population permanently changes. A special case of the random drift is the *founder effect*. A small number of individuals (immigrants) introduced into new habitats may not represent accurately the genetic constitution of the population of their origin. Their descendants then may form the basis of a divergent trend from the norm of their ancestors. Such a phenomenon is not uncommon if animal or plant species migrate to new parts of the world or to regions that are spatially isolated from their old homeland.

Organelle DNAs (mitochondrial and chloroplast) have smaller genetically effective population sizes than the nuclear DNAs because they are inherited uniparentally and are effectively haploid (Birky CW Jr et al 1989 Genetics 121:613). Also, their genetic diversity is more limited and evolves faster because of these facts. [►speciation](#), [►isolation genetic](#), [►standard error](#), [►normal distribution](#), [►F_{ST}](#), [►gamma selection parameter](#), [►polygamy](#), [►polygeny](#), [►Amish](#); Anderson EC et al 2000 Genetics 156:2109; Wall JD 2003 Genetics 163:395.

Effector: A small molecule which assists either in activating or deactivating a molecular event. Interaction of the RAS protein with effectors uses 32–40 amino acids, the effector region, varying in conformation in GTP- and GDP-bound RAS. Effector lymphocytes are activated to destroy the foreign antigens. [►GTP](#), [►RAS](#), [►signal transduction](#), [►lymphocyte](#); Alto NM et al 2006 Cell 124:133.

Effector Cell: An activated B cell or T_H cell that mediates the adaptive immune system. The activation results in an increase in antigen-specific killer cells. After an episodic infection the effector CD8 T cells may migrate to nonlymphoid tissues and become long-lived memory cells. Effector memory T cells are more potent in immunotherapy of cancer because of higher lytic ability and because of the release of more TNF- γ . This property has relevance for the development antitumor vaccines (Klebanoff CA et al 2005 Proc Natl Acad Sci USA 102:9571). [►immune system](#), [►B cell](#), [►CCR](#), [►CD34](#), [►killer cell](#), [►memory immunological](#), [►tumor vaccination](#); Gazitt Y 2000 Stem Cells 18:390.

Effector Domain: The effector domain of an antibody contains the region that recognizes specifically the cognate antigen. [►antibody](#), [►antigen](#)

Effector Gene: An effector gene encodes an enzyme that, in combination with other molecule(s), functions as an effector. [►effector](#)

Efficient Mutagen: An effective mutagen produces primarily point mutations and relatively low amount

of chromosomal alterations. ►effective mutagen, ►point mutation

Efflux Systems: Efflux systems carry out energy requiring active pumping of harmful agents from the cells.

EF-G: A translation factor and a motor protein that is also a GTPase. It mediates the GTP-dependent transfer of peptidyl-tRNA-mRNA complex from ribosomal A site to P site. Its domain IV has some structural similarity to the elongation factor. ►protein synthesis, ►ribosome, ►aminoacylation, ►EF-Tu

EF-Ts: A prokaryotic translation factor protein involved in GTP-GDP exchange. ►protein synthesis

EF-Tu.GTP: An active prokaryotic elongation factor of protein synthesis in which EF-Tu interacts with aminoacyl-tRNA and promotes the translocation of the peptidyl-tRNA from the ribosomal A to B site and the release from the ribosome of the deacylated tRNA. ►aminoacylation, ►protein synthesis, ►ambiguity in translation, ►tRNA; Frederick J et al 2001 Science 294:165.

E.GDP: A bound (inactive) form of guanosine diphosphate in signal transduction. ►E region of GTP-binding proteins

EGF: An epidermal growth factor, binds to receptors such as the protein coded for by the protooncogene ERBB, triggering growth-promoting signals. The *v-erbB* viral oncogene encodes a truncated EGF that continuously binds to a ligand and provides a constitutive supply of growth signals. EGF controls a wide range of cellular processes. ►growth factors, ►oncogenes, ►TGF; Iressa Daub H et al 1997 EMBO J 16:7032; Pierce K L et al 2001 J Biol Chem 276:23155; signals: VivekanP, Rebay I 2006 Annu Rev Genet 40:139).

eGFP (enhanced green fluorescent protein): Different variations exist, all depending on engineered amino acid replacements in the *Aequorea* GFP. The point mutations alter the emission peaks (color) and the added nucleotide sequences assure high expression and maximize signal intensity and are suitable for dual color (blue and yellow) detection. Some expression vectors are commercially available. ►ae-*quorin*; Yang T-T et al 1998 J Biol Chem 273:8212.

EGFR (epidermal growth factor receptor): The EGFR has been localized in the nucleus of different cells. Its localization and stability are mediated by ubiquitination of the Lysine 6-linked polyubiquitin chain in its kinase domain (Huang F et al 2006 Mol Cell 21:737). It has been found in association with the promoter of cyclin D1 indicating that it is a transcription factor. The EGFR family includes ErB2, ErB3, and ErB4 proteins. Its inhibitor, Iressa, is a potential anticancer

agent. ►ERBB1, ►RTK, ►LDL receptor; Bogdan S, Klämbt C 2001 Curr Biol 11:R292; Lin S-Y et al 2001 Nat Cell Biol 3:802; down-regulation mechanism: Landau Met al 2004 Structure 12:2265; Herbst RS et al 2004 Nat Rev Cancer 4:956.

Egg (ovum): The final haploid product of female meiosis. The eggs are huge cells (ca. 100 µm in diameter in humans) (see Fig. E8) compared to the other ones in the body (about 20µm). The egg cytoplasm contains yolk, a very condensed store of nutrients, especially in organisms that lay outside the eggs. In mammals, the yolk is comparatively minimal. (A generalized composite drawing is given in the diagram.) In mammals, the zona pellucida membrane surrounds the egg. In lower vertebrates there is a *vitelline layer* and also other ones. In birds there is the *egg white* and before laying the egg the *shell* is added in the oviduct. The vitelline layer of the insects is covered by the so-called *chorion*, secreted by the *follicle cells* of the *ovary*. In the layer under the plasma membrane (*cortex*) are the *cortical granules*. Their content protects the egg from fertilization by more than one sperm. During fertilization the sperm is attracted to the egg by chemotactic peptides causing changes in the voltage of the membrane and in altering the concentration of cAMP, cGMP, Ca²⁺, and K⁺ ion channels. In mammals, parthenogenesis is normally absent, yet in immature and mature mouse oocytes, by appropriate expression of the *Igf2* and *H19* genes with major roles in imprinting, fulltime development of offspring from two maternal nuclei was successful (Kono T et al 2004 Nature [Lond] 428:860). ►oocyte, ►ovary, ►gametogenesis, ►menopause, ►fertilization, ►imprinting, ►parthenogenesis, ►polyspermic fertilization, ►RPTK, ►sperm

Figure E8. Human egg

Egg Cylinder: A very early mammalian embryonal structure, including the cells that will form the fetus and the embryonal sacs (amnion, allantois), some extra embryonic tissue that form the outer embryo sac (chorion), and the trophoblastic tissues of the placenta.

E

Egg Donation: The providing of eggs for in vitro fertilization for research or assisted reproductive technology. The donor female takes a gonadotropin-releasing hormone agonist to delay ovulation. Then administration of follicle-stimulating hormone facilitates the production of several egg-containing follicles. Another hormone is used for maturation of eggs, which are retrieved surgically from the ovary through the vagina. The procedure is not without risks for the donor. ▶GnRHA, ▶gonad, ▶stem cells, ▶ART

Egg Number in Humans: Each of the two human ovaries contains more than 200,000 primary oocytes yet only about 400 eggs develop to maturity during the period from puberty to menopause. In mammals, the production of egg stem cells was thought to be completed before birth. It appears, however, that proliferative female germ cells may exist in the postnatal ovary just as it is the case in the male gonads (Johnson J et al 2004 Nature [Lond] 428:145). The size of a human egg is comparable to a period in this print. ▶puberty, ▶menopause, ▶oogenesis, ▶oocyte, ▶egg, ▶dictyotene

Egg Plant (*Solanum melongena*): A tropical-subtropical vegetable with $2n = 2x = 24$ chromosomes. (See Doganlar S et al 2002 Genetics 161:1697 and 1713).

Egl-1 (Eglin): A proteinase inhibitor, it controls the proapoptotic caspase-9 and other proteins. ▶caspases; Komiyama T, Fuller RS 2000 Biochemistry 39:15156.

4EGI-1 (eIF4E/eIF4G interaction inhibitor): 4EGI-1 (see Fig. E9) inhibits complex formation between translation initiation factors eIF4E and eIF4G (Moerke NJ et al 2007 Cell 128:257).

Figure E9. 4EGI-1

Egr-1: A mitogen-induced transcription factor, a serum-inducible nuclear phosphoprotein with zinc finger. Egr2 is a Zn-finger protein regulating cell proliferation. Egr-3 (NGFI-C) is essential for muscle spindle development. ▶NGFI-A, ▶TIS8, ▶platelet derived growth factor, ▶zinc finger, ▶Krox; Calogero A et al 2001 Clin Cancer Res 7:2788.

E.GTP: The bound (active) form of guanosine triphosphate in signal transduction. ▶E region of GTP-binding proteins

Ehlers-Danlos syndrome (EDS): An extremely complex and usually a dominant disorder involving loose joints that stretch excessively, excessive stretchability of the skin that is bruised easily, and characterized by frequent appearance of pseudo-tumors after some trauma (see Fig. E10). The anomalies are caused either by a deficiency of procollagen peptidase (recessive EDS type VII) or the lack of a collagen type. EDS I is deficient in COL5A2 and 5A1 encoded at 2q31 and 9q34.2, respectively.

Figure E10. Ehlers-Danlos symptoms: Genu recurvatum (hyperextension of the knee or back knee), deformed toes, tumors under the ankle and on the front part of the foot. (From Bergsma D (ed) 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

EDS II is the most common form of the disease and is also deficient in COL5A1 and COL5A2 encoded at 9q34.2-q34.3. COL1A1 is encoded at 17q21.3-q22. Low hydroxylysine content of the connective tissue prevents effective cross-linking. EDS type VII (dermatosparaxis) is recessive/dominant at 5q23 and has a deficiency of procollagen protease and lysyl oxidase (LOX). Type VIA (encoded at 1p36.3-36.2) is deficient in lysyl hydroxylase whereas in type VIB the hydroxylysine level is normal. Lysyl oxidase level is reduced in the individuals afflicted by EDS types

VI, VII, and IX. Type IV (2q31, dominant) suffers from mutation in type III procollagen and increases the risk of aneurysm. Type V disease has a defect in the α chain of collagen mapped to human chromosome 9q34, but a type EDS V is X-linked and is caused by lysyl oxidase deficiency. EDS VIII (12p13) is involved in periodontal disease (Rahman N et al 2003 Am J Hum Genet 73:205).

The EDS has many different variations, from mild to severe, and its incidence may be estimated to be in the $1-2 \times 10^{-4}$ range. Type X (2q34) involves platelet abnormality and it is due to the deficiency of fibronectin. ▶collagen, ▶skin diseases, ▶fibronectin, ▶connective tissue disorders, ▶cardiovascular disease, ▶Menkes syndrome, ▶aneurysm, ▶periodontal disease; Schwarze U et al 2000 Am J Hum Genet 66:1757; Wenstrup RJ et al 2000 Am J Hum Genet 66:1766.

Ehrlich ascites: ▶ascites

EI: EI is ethyleneimine (C_2H_5N), a powerful alkylating mutagen and carcinogen. ▶alkylating agent

Eicosahedron: A 20-faceted body (see Fig. E11). ▶DNA tumor viruses

Figure E11. Eicosahedron

Eicosanoids: Eicosanoids are mammalian autocrine signaling molecules affecting muscle contraction, platelet aggregation, pain, and inflammation. They are produced at the expense of phospholipase-degraded phospholipids. Eicosanoid is the systematic name of arachidonic acid. ▶fatty acids, ▶signal transduction, ▶autocrine, ▶platelet, ▶phospholipase, ▶leukotrienes, ▶prostaglandins; McMahon B et al 2001 Trends Pharmacol Sci 22[8]:391.

eIF: An eukaryotic initiation factor of protein synthesis. ▶IF; Karim MM et al 2001 J Biol Chem 276:20750; functions of the eIF initiation complex: Gilbert RJC et al 2007 Proc Natl Acad Sci USA 104:5788.

eIF-1: A 12.7-kDa (human) and 12.3-kDa (yeast) translation factor stimulating the 40S ribosomal subunit preinitiation complex. It interacts primarily with eIF-3. ▶protein synthesis, ▶ribosome scanning

eIF-1A (eIF-4C): A ribosome dissociation factor (17–22 kDa) and 40S preinitiation complex-stimulating protein in translation. It shows ~20% homology with the prokaryotic IF1 (Petroulakis E, Wang E 2002 J Biol Chem 277:18718).

eIF-2: A heterotrimeric (α , β , γ) translation elongation factor mediating the GTP-dependent Met-tRNA binding to the 40S ribosomal subunit. It may repress protein synthesis if its α subunit is phosphorylated. ▶protein synthesis, ▶ribosome, ▶GTP, ▶aminoacylation; Kimball SR 1999 Int J Biochem Cell Biol 31:25.

eIF-2A (eIF2 α): A heterotrimeric translation elongation factor controlling AUG-dependent Met-tRNA-GTP binding to the 40S ribosomal subunit. It is inactivated by phosphorylation through the hemin-regulated inhibitor kinase (HRI, PKR, PEK/PERK). eIF-2 phosphorylation of serine/threonine by RNA-dependent protein kinase (PKR, 68 kDa in humans) is induced by Interferon α/β in response to infection by a double-stranded RNA virus. In addition, PKR can phosphorylate tyrosine 101, 162, and 293. Tyrosine phosphorylation assures binding to dsRNA, dimerization, kinase activation, and eIF2 α phosphorylation and viral resistance by inhibition of translation (Su Q et al 2006 Proc Natl Acad Sci USA 103:63). Dephosphorylation can be inhibited by salubrinal (see Fig. E12) and prevents stress of the endoplasmic reticulum (Boyce M et al 2005 Science 307:935). GCN2 is activated by amino acid starvation. GCN4 activates the transcription of more than 30 amino acid synthesizing enzymes. ▶protein synthesis, ▶aminoacyl-tRNA synthetase, ▶essential amino acids, ▶GCN4, ▶HRI, ▶PEK, ▶PKR; Ito T et al 2004 Structure 12:1693.

Figure E12. Salubrinal

eIF-2B: A heteropentameric guanine nucleotide exchange factor (GEF) involved in translation by controlling phosphorylation of eIF2. Its defect may lead to leukoencephalopathy with vanishing white matter. (See Leegwater PAJ et al 2001 Nat Genet 29:383; van der Knaap MS et al 2003 Am J Hum Genet 73:1199).

eIF-2C (Co-eIF-2A): A translation initiation factor stabilizing ternary complexes (eIF2•GTP•tRNA) of translation. ▶protein synthesis, ▶ternary

eIF-3: A ~750-kDa, ~12 subunit, five-lobed mammalian elongation initiation factor; it is activated by phosphorylation in translation. It stimulates the formation of the 40S ribosomal preinitiation complex. ▶ribosome, ▶protein synthesis; Siridechadilok B et al 2005 Science 310:1513.

eIF-3A: A translation factor affecting ribosome dissociation by binding to the 60S ribosomal unit.

eIF-4A: An eukaryotic translation (mRNA cap-binding proteins, eIF4E) factor (46-kDa), RNA-dependent ATP-ase, helicase (eIF4A), which stimulates mRNA binding to ribosome. Several isoforms exist. Phosphorylation reduces its affinity for capped mRNA. ▶protein synthesis, ▶ATPase, ▶helicase, ▶mRNA surveillance, ▶FLAG, ▶DEAD-box proteins, ▶isoform, ▶oskar; Gingras A-Cet al 1999 Annu Rev Biochem 68:913; Scheper GC et al 2002 J Biol Chem 277:3303; Bordeleau ME et al 2005 Proc Natl Acad Sci USA 102:10460.

eIF-4B: An eukaryotic translation initiation factor (mRNA cap-binding protein, 69 kDa in humans); elongation initiation of translation upon phosphorylation. A helicase which stimulates mRNA binding to ribosomes. ▶protein synthesis, ▶ribosome, ▶helicase, ▶mRNA, ▶ribosome, ▶4E-BP

eIF-4C: The eIF-4C function is similar to that of eIF-1A and it appears to be synonymous with it.

eIF-4D: Probably the same as eIF-5A.

eIF-4E: A translation factor involved in binding of the circularized (by eIF-4G) capped mRNA to the 40S ribosomal subunit. It may exist in different forms. Loss of a specific eIF-4E isoform (IFE-2) that functions in somatic tissues reduces global protein synthesis, protects from oxidative stress, and extends lifespan in *Caenorhabditis elegans* (Syntichaky P et al 2007 Nature [Lond] 445:922). ▶cap, ▶ribosome, ▶protein synthesis, ▶4E-BP, ▶P body, ▶microRNA, ▶ecdysone, ▶longevity

eIF-4F: A heterotrimeric (including eIF-4E, eIF-4G and eIF-4A) key element of translation initiation; it recognizes the mRNA cap. It is a helicase, an elongation initiation factor and when phosphorylated may lead to overexpression and cancerous growth. Viral genes using IRES may not absolutely depend on the eIF-4F-cap complex. ▶protein synthesis, ▶translation initiation, ▶ribosome, ▶helicase, ▶cap, ▶cancer, ▶Pab1p, ▶IRES, ▶picornaviruses, ▶CDC 33

eIF-4G (eIF-4γ): Comprises two translation initiation factors (I, 171 kDa, and II, 176 kDa) for the 40S eukaryotic ribosomes. It functions as an adaptor between the cap-binding proteins eIF-4A, eIF-4E, eIF-3, and also it may bind to the PolyA tail-binding protein. The latter has been shown to involve translation stimulation. ▶protein synthesis, ▶cap, ▶IRES, ▶FLAG, ▶Pab1p; Gallie DR, Browning KS 2001 J Biol Chem 276:36951; Niedzwiecka A et al 2002 J Mol Biol 319:615; Gingras AC et al 1999 Annu Rev Biochem 68:913.

eIF-4H (25 kDa, monomeric): The stimulatory function of eIF-4H resembles that of eIF-4B.

eIF-5: Consists of 48.9-kDa (human) and 45.2-kDa (yeast) translation factors which promote the joining of the small and large ribosomal subunits into the 80S ribosome. It is crucial for the assembly of the preinitiation complex and its carboxy-terminal domain interacts with the eIF-1, eIF-2, eIF-3 and eIF-4G (Yamamoto Y et al 2005 Proc Natl Acad Sci USA 102:16164). It is a GTPase activator. ▶ribosome, ▶protein synthesis, ▶preinitiation complex

eIF-5A: Assists in the formation of the first peptide bond during translation. ▶protein synthesis, ▶peptide bond

eIF-5B: A homolog of prokaryotic IF-2. It interacts with eIF-2 and promotes the hydrolysis of GTP and generates the 80S initiation complex. Casein kinase-2 is essential for its function (Homma M et al 2005 Proc Natl Acad Sci USA 102:15688).

eIF-6 (p27^{BBP}, anti-association factor): eIF-6 is similar to eIF-3A. The 25-kDa protein dissociates the 80S ribosome and facilitates protein synthesis by maintenance of the 60S subunit. (See Ceci M et al 2003 Nature [Lond] 426:579.)

eIF-D: eIF-D is similar in function to eIF-5A.

Eigenvalue: Literally, this hybrid (German–English) word means proper value, and it is usually used (in physics) in the sense of a characteristic value.

Eincorn: (see Fig. E13). ▶Triticum A genome

EK2: The laboratory strain of *E. coli* defective in the synthesis of thymine and diaminopimelate. ▶thymine, ▶diaminopimelate, ▶*E. coli*

EKLF (erythroid Krüppel-like factor): A Zn-finger homolog of the *Drosophila* Krüppel gene, involved in blood β-globin and blood non-globin gene transcription regulation. ▶morphogenesis in *Drosophila*, ▶LCR, ▶Krüppel, ▶zinc fingers, ▶globins; Huber TL et al 2001 Curr Biol 11:1456.

Elastase: A proteinase released by the lysosomes of blood granulocytes upon inflammation. It breaks down collagen if not inhibited by protease inhibitors. ▶lysosome, ▶neutropenia

Elastic Fiber Diseases: Elastic fibers, components of the extracellular matrix, have many roles in normal health. Mice lacking a lysyl oxidase-like protein do not deposit elastic fibers into the uterine tract postpartum and develop pelvic prolapse, enlarged airspace in the lungs, loose skin and vascular abnormalities. The function of lysyl oxidase (LOX) is to maintain elastic fibers, cross-linking enzymes, and to provide a scaffold for elastin. The mammalian genome contains at least five LOX and LOX-like (LOXL) genes. ▶[elastin](#), ▶[emphysema](#), ▶[cutis laxa](#), ▶[Marfan syndrome](#), ▶[supravalvular aortic stenosis](#), ▶[Williams syndrome](#), ▶[Hurler syndrome](#), ▶[Costello syndrome](#), ▶[gangliosidosis](#), ▶[pseudo-xanthoma elasticum](#), ▶[ABC transporters](#), ▶[Menkes syndrome](#); Urbán Z, Boyd CD 2000 Am J Hum Genet 67:4; Liu X et al 2004 Nat Genet 36:178.

Elastin ($M_r \cong 70$ K): A rubber-like, cross-linked, glycine- and proline-rich, fibrous protein present primarily in the blood vessels near the heart, but also in the ligaments; modest amounts are present in the skin and tendons. It controls arterial development and proliferation of smooth muscles. Its defect may cause aortic stenosis. ▶[supravalvular aortic stenosis](#), ▶[coarctation of the aorta](#), ▶[Williams syndrome](#)

ELAV (embryonic lethal abnormal vision system): A member of the evolutionarily conserved RNA-binding protein family. Four ELAV-like proteins (HuB, HuC, HuD, HuR) are known in vertebrates. Three of them are specific for neural tissues and the fourth has rather general occurrence. ▶[AU-rich elements](#); Good PJ 1995 Proc Natl Acad Sci USA 92:4557; Pascale A et al 2005 Proc Natl Acad Sci USA 102:12065.

ELC: Expression-linked copy. ▶[Trypanosoma](#)

ELDI (electrospray-assisted laser desorption/ionization): Neutral molecules are desorbed from an ambient surface by nitrogen laser and use the charged droplets for post-desorption ionization of the ablated neutral molecules. Mass spectra of intact protein can be obtained without the use of a matrix. It is suitable for the analysis of the complex cytochrome c and illicit drugs or other complex proteins (Shiea J et al 2005 Rapid Commun Mass Spectrometry 19:3701). The TON (tungsten oxide nanowire) fiber variation permits the analysis of extremely small samples (Jeng J et al 2005 Anal Chem 77:8170). ▶[electrospray](#), ▶[mass spectrum](#)

Electrical Biochip: An electrical biochip detects biomolecular interactions by redox recycling of ELISA, metabolites, DNA microarray, viral infections, etc. ▶[ELISA](#), ▶[microarrays hybridization](#); Albers J et al 2003 Anal Bioanal Chem 377:521.

Electroblotting: The transfer of macromolecules in an electric field from a (polyacrylamide) gel onto a membrane.

Electrocardiography: Electrocardiography records the changes of the variations in the electric potentials of the heart muscles. The first deflections, denoted by P, are due to the excitation of the atria. The QRS indicates the depolarization phase of the excitation of the ventricles. The T wave indicates the complete repolarization of the ventricles. These intervals are measured in fractions of a second. The long Q-T (LQT) interval (see Fig. E14) may indicate abnormal function of either the potassium or sodium ion channel(s) or some other anomaly. The upper graph represents the normal QT. ▶[Jervell and Lange-Nielsen syndrome](#), ▶[HERG](#), ▶[Ward-Romano syndrome](#)

Figure E14. Electrocardiogram, partial

Electrochemical Gradient: An electrochemical gradient moves ions through biomembranes depending on their concentration and charge, at the two sides.

Electrode: The positive (+) anode or negative (−) cathode terminal of an electricity conducting system. ▶[microelectrode](#)

Electroelution of DNA: The procedure is as follows: separate DNA by electrophoresis in agarose gel containing 0.5 µg/mL ethidium bromide, locate band by long-wavelength UV light, cut out the band and place it into dialysis tube filled with 1 x TAE buffer. Let the slice sink to the bottom of the tube, seal, and turn on current in 1 TAE buffer (4–5 V/cm) for 2 to 3 h. Remove tube from apparatus and collect the buffer content of the tube containing the eluted DNA. ▶[electrophoresis](#), ▶[electrophoresis buffers](#)

Electroencephalogram: ▶[EEG](#)

Electrofusion: Cell fusion induced by electrical impulses.

Electrokinetic Enhancement of DNA Uptake: ▶[electroporation](#)

Electrolyte: A substance capable of dissociating into ions and then becoming a conductor of electricity. ▶[ion](#), ▶[polyelectrolyte](#)

Electromagnetic Radiation: The genetically effective range includes UV light, X-rays, and gamma rays. Under conditions of sensitization by various chromophores it may extend into the visible range. Some of the radiations may have contaminating components with potential genetic effects. Extremely low frequency electromagnetic fields (EMF) such as generated by power lines and household appliances have also been suspected to stimulate gene activity (MYC) and increase cancer risk. The experimental data are, however, insufficient to definitely rule in or out such an effect. ▶radiation protection, ▶radiation hazard assessment, ▶terahertz radiation, ▶illumination, ▶light intensities, ▶MYC; see Fig. E15.

Electromorph: A genetically determined variation that can be revealed by electrophoresis. ▶electrophoretic polymorphism

Electron: A small, negatively $[(4.80294 \pm 0.00008) \times 10^{-10}$ absolute electrostatic units] charged particle; its mass is 1/1837 of the H nucleus and its diameter is 10^{-12} cm. All atoms contain one nucleus and one or more electrons. Cathode rays and Beta rays are electrons. ▶cathode rays, ▶beta particles, ▶excitation

Electron Acceptor: An electron acceptor takes up electrons and therefore becomes reduced whereas the *electron donors* provide electrons to other molecules and become oxidized. ▶electrons

Electron Density Map of Proteins: The electron density map of proteins is determined by X-ray analysis and the results are interpreted by the Fourier method (see Fig. E16). The image represents the electron scattering by critical atoms in the molecule and reveals important structural properties. ▶protein structure, ▶X-ray diffraction analysis, ▶FT-IR; Vagin AA, Isupov MN 2001 Acta Crystallogr D Biol Crystallogr 57 [pt 10]:1451.

Figure E16. Electron density pattern, partial

Electron Microscopy: In the light microscope, the resolution of the objects is limited by the wavelength (within the 350–750 nm range) of the light used for illumination. The wavelength of electrons accelerated at high voltage (100 KV) may become only 0.004 nm. Because of aberrations of the lenses available, this minimum cannot be attained yet. Even with the best equipment, a resolution of about 0.1–2 nm, i.e., about 100–1,000 higher than with the light microscope,

Figure E15. Electromagnetic radiation. (After Lerner and Libby, 1976 Heredity, Evolution and Society, Freeman, San Francisco)

may be possible. In the *transmission electron microscope*, instead of visible light the extremely thin (50–200 nm) specimen, specially fixed and stained, is placed on a grid and is exposed to electron beams accelerated in a vacuum tube. The areas where the specimens reduce the focused electron flux, an image appears that can be viewed or photographed and enlarged by procedures similar to light microscopy. Electron microscopic specimens are usually prefixed in buffered 3% glutaraldehyde and postfixed in 1% buffered osmium tetroxide, then dehydrated and embedded in a propylene oxide-resin mixture that requires polymerization before sectioning by glass or diamond microtomes. The sections are placed on a circular copper grid of 3-mm diameter, covered by a carbon or plastic film. Either before or after sectioning, the biological specimen is treated usually by uranium or lead to assure contrast. Electron-microscopic specimens may be exposed also to substrates of enzymes in order to localize an electron dense precipitate if the enzyme is active. The specimens may also be coupled with specific fluorescent dyes or with colloidal gold, which may be recognized by an antibody, and thus its site is revealed. The material may also be *shadowed*—by spraying in an angle with other thin layers of metals (platinum, chromium)—for obtaining an apparent three-dimensional image. Macromolecules may also be studied by *negative contrast*. The solution in 1% phosphotungstate (or uranyl acetate) is thinly spread on a carbon film and when dried, an electron-dense layer is formed. At the position of the protein molecule there will be no tungstate. Thus a negative image is generated. A special technique in electron microscopy is *freeze-fracture*, which can provide images of the internal organization of delicate structures such as biological double membranes. This freezing technique does not require fixation that usually denatures the material. The specimen is frozen in liquid nitrogen in the presence of a cryoprotectant (glycerol, dimethylsulfoxide) to prevent the formation of ice crystals. The frozen material is then fractured with a knife to crack the double membrane between the two layers. The surface so generated is shadowed with a metal, and after the organic material is dissolved and removed, the remaining metal replica is examined. This replica is a negative image of the biological structure. A similar procedure is *freeze-etching*. Again, the frozen sample is cracked, the moisture is removed by lyophilization, and the inner and outer structures exposed are shadowed. A four-dimensional ultrafast electron microscope has also been designed (Lobastov VA et al 2005 Proc Natl Acad Sci USA 102:7069).

Biomedical Electronmicroscopy: Illustrated Methods and Interpretations. Acad Press, San Diego, CA.

Electron Paramagnetic Resonance (EPR): EPR can be used to measure the radiation exposure in human or mammalian populations. When paramagnetic substances are placed in a stationary magnetic field and exposed to electromagnetic radiation they register the field of strength and the frequency of the radiation. Paramagnetic substances contain molecules or atoms whose electrons move and produce weak magnetic fields. This method can then be used for the determination of the concentration of radiation-induced radicals in, e.g., hydroxyapatite, present in teeth and bones. The tooth enamel is 97% hydroxyapatite and does not metabolize ^{90}Sr , a common product of atomic fallout. Dentine, which is made up of only 70% from hydroxyapatite, metabolizes this isotope. Therefore, ^{90}Sr will be found mainly in the dentine. The isotope emits short-range β -rays (0.6–1 mm path). One study showed that humans with chronic radiation disease received 1 Gy (gray unit) whereas the dentine showed 5.5 Gy γ -radiation. Thus, it is possible to determine whether the radiation came internally or externally. ▶ [radiation measurement](#), ▶ [radiation hazard assessment](#), ▶ [fallout](#); Swenberg CE et al 1994 Adv Space Res 14(10):181.

Electronic PCR: Searches for EST in DNA sequences. ▶ [PCR](#); Rostmistrovsky K et al 2004 Nucleic Acids Res 32(WEB Server Issue):W108.

Electron Transport: The movement of electrons toward the lower level of energy by electron carriers. The mitochondria and other organelles have important roles in the process.

Electron Volt (eV): $1 \text{ eV} = 1.60207 \pm 0.00007 \times 10^{-12} \text{ erg}$. ▶ [erg](#)

Electronic PCR: STSs can be amplified and defined by a pair of PCR primers and used with the aid of an appropriate computer program to locate the STS to existing genetic or physical markers in a map without performing any experiment. ▶ [EST](#), ▶ [STS](#), ▶ [PCR](#); Schuler GD 1997 Genome Res 7:541.

Electrophile: An electrophile is eager to accept electrons and can covalently bind nucleophiles. ▶ [electron](#), ▶ [nucleophile](#), ▶ [nucleophilic attack](#)

Electrophoresis: Separating charged molecules (such as polypeptides or polynucleotides) between the two poles of an electric field (see Fig. [E17](#)). The material is generally contained in a support medium (cellulose, starch, agarose polyacrylamide) and bathed in an appropriate buffer, and may also contain specific stains. The basis of the separation of the components of a mixture is the relative charge, shape or molecular

size of the components. Larger nucleic acid molecules are generally separated in agarose gels of various concentrations, depending on the size of the molecules. Smaller nucleic acid fragments are separated in polyacrylamide gels. SDS-PAGE electrophoresis treats the proteins with the detergent sodium dodecyl sulfate (SDS) and separates them by polyacrylamide gel electrophoresis (PAGE). The detergent breaks the noncovalent bonds of the proteins and when β -mercaptoethanol is added the disulfide bonds are also eliminated. The proteins so treated migrate in the gel according to their molecular weight rather than by their charge. Nucleic acids have uniform charge, thus their separation is based on their molecular size. Ultrathin gel electrophoresis permits the use of higher voltage without deleterious heat effect because of the increased heat transfer. Also, it increases the speed of separation by an order of magnitude although it may decrease resolution and read length, and it is under experimental study. Another innovative approach is the matrix-assisted laser desorption and ionization method (MALDI) which permits single charged ions from proteins as large as 300-kDa to be produced and analyzed. Mass spectrophotometry MALDI (MALDI-MS) is capable of discriminating length difference in short oligonucleotides due to a single base. ▶pulsed field electrophoresis, ▶isoelectric focusing, ▶gel electrophoresis, ▶two-dimensional gel electrophoresis, ▶dodecyl sulfate sodium salt, ▶capillary electrophoresis; Rickwood D, Hames BD 1990 Gel electrophoresis of nucleic acids: A practical approach. Figure E17. Electrophoretic gels

Electrophoresis Buffers: TAE (Tris-acetate EDTA), TPE (Tris-phosphate EDTA), TBE (Tris-borate EDTA), alkaline 50 mM NaOH-1 mM EDTA are commonly used.

Electrophoretic Karyotyping: Separation of small chromosomes by pulsed field gel electrophoresis according to size. ▶pulsed field; Geiser DM et al 1996 Curr Genet 29:293; Shin JH et al 2001 J Clin Microbiol 39:1258.

Electrophoretic Polymorphism: Protein or DNA variations in a population affecting charge or size. In proteins it may be detectable on the bases of amino

acid (glutamic, and aspartic acid, lysine, histidine, arginine) substitutions by altered electrophoretic mobility or by size of polypeptides. Restriction enzyme digests of DNA provide such information after gel-electrophoresis or by PCR analysis. ▶electrophoresis, ▶isozyme, ▶SDS-polyacrylamide gels, ▶RFLP, ▶PCR; van der Bank H et al 2001 Biochem Syst Ecol 29(5):469; Zhu X et al 2001 Electrophoresis 22:1930.

Electroporation: The transport of DNA across cellular membranes with the aid of electric current pulses; the genes may display transient expression in the target cells. It is also a means of genetic transformation, the conditional regulation of gene expression from electroporated plasmids in the postnatal rat retina and the embryonic mouse brain. For temporal regulation of electroporated genes, Cre/loxP-mediated inducible expression vectors can be used in combination with a vector expressing a conditionally active form of Cre recombinase, which is activated by 4-hydroxytamoxifen. The timing of 4-hydroxytamoxifen administration regulated the onset of gene expression. By using promoters specific for rod photoreceptors, bipolar cells, amacrine cells, Müller glia or progenitor cells, the transgenes were spatially regulated (Matsuda T, Cepko CL 2007 Proc Natl Acad Sci USA 104:1027). ▶transformation, ▶microfusion, ▶Cre-LoxP, ▶Tamoxifen, ▶amacrine cell, ▶glia; Neumann E et al 1982 EMBO J 1:841; Fromm ME et al 1986 Nature [Lond] 319:791; Tsong TY 1991 Biophys J 60:297; Golzio M et al 2002 Proc Natl Acad Sci USA 99:1292.

Electrospray MS (tandem mass spectrometry, ESI): A procedure for determining the molecular weight of unknown proteins and for the study of non-covalent interactions between proteins and other large molecules, thus facilitating their location and identification with the aid of databases. The nanoelectrospray is a low-flow device equipped with a needle of $\sim 1\text{-}\mu\text{m}$ internal diameter and delivers a mixture of molecules, e.g., peptides, into a mass spectrometer. The peptides are separated in the first step and are subsequently fragmented (in this tandem process). The fragmentation in the mass spectrometer is achieved by collision with gas molecules. The fragments obtained from the NH_2 end of the protein are called “b” and those from the COOH terminus are “y” ions. Another procedure involves the initial separation of the peptides by liquid chromatography and then sequencing as they are passed into the electrospray ion source. The fragments are sorted by the molecular mass of one amino acid. This way the location of the amino acid is then revealed in the peptide. Two amino acids with known location (called *peptide sequence tag*) suffice to fish out the

peptide in large sequence databases. The extreme sensitivity of the procedures for 50–100 ng or even smaller amounts of proteins (femtomole range) may be analyzed. The method determines the mass-to-charge (m/z) of the polar molecules and the signal intensity is displayed by the algorithm used in discrete peaks. Some of the procedures are automated. ▶laser-capture microdissection, ▶mass spectrum, ▶laser, ▶MALDI, ▶genome projects, ▶STM, ▶proteome, ▶chromatography; Null AP et al 2001 Anal Chem 73:4518; Takáts Z et al 2004 Science 306:471.

Element, Chromosomal: Conserved sequences (genes) within chromosomes.

Elephants: *Elephas maximus* $2n = 56$; *Loxodonta africana* $2n = 56$. The small pygmy elephants that lived in the Mediterranean islands and have been extinct for 10,000 years appear to have evolved from mammoths—according to new DNA evidence—rather than from the present-day elephants. Earlier, based on mitochondrial cytochrome evidence, the dwarf elephant, *Palaeoloxodon antiquus falconer*, appeared to be closer to *Elephas* than *Loxodonta* or *Mammuthus* (Poulakakis N et al 2002 J Mol Evol 55:364). (See Roca AL et al 2001 Science 293:1473; mammoth).

Elephant Man: A person with abnormally enlarged body parts. The cause of Joseph Merrick's anomaly has been attributed to neurofibromatosis and to Proteus syndrome, but the real cause remains unclear. It is different from elephantiasis, a tropical infection of the lymphatic nodes, limbs, genitalia, etc., causing inflammation and hypertrophy as the result of the obstruction of the lymphatics by several species of nematodes. ▶neurofibromatosis, ▶Proteus syndrome

Elicitor: ▶host-pathogen relation, ▶immune system

ELISA (enzyme-linked immunosorbent assay): ELISA is capable of detecting vg quantities of protein per gram tissue by the use of an antibody attached to a particular enzyme such as alkaline phosphatase (or peroxidase, urease). The + antibody complex binds to the protein antigen present in the reaction vessel and the cleavage of a chromogenic substrate (e.g., *p*-nitrophenyl phosphate) by the enzyme results in the development of color (absorbance detected by spectrophotometer) that is proportional to the amount of the antigen protein. ▶immunoglobulins, ▶antibody, ▶immune reaction, ▶immunoprecipitation, ▶immuno-labeling, ▶IRMA; Davis LG et al 1986 Basic Methods in Molecular Biology. Elsevier, New York.

Elite Plants: Elite plants were specially selected and reproduced under the control of the plant breeder.

ELK (oncogene): ELK1 (human chromosome Xp11.2) and ELK2 (14q32.3) are expressed in human lungs and testes. These oncogenes show homology with the ETS oncogenes. (see Fig. E18).

Figure E18. Elk-1 protein structure (top) complexed with DNA (below). (Courtesy of Marmorstein, R. From Mo Y et al 2000 Nature Struct Biol 7:292)

The ELK proteins bind to the SRE element of the chromosomes and, after phosphorylation, may activate transcription. ▶oncogenes, ▶ETS, ▶signal transduction, ▶SRE, ▶SAP-1; Cesari F et al 2004 Genesis 38:87.

ELKS (12p13): A 105-kDa subunit of IκB and required by NF-κB. It is named ELKS because ~44% of the protein is built of E (glutamic acid), L (leucine), K (lysine), and S (serine). Some tumors show ELKS/RET fusion. ▶NF-κB, ▶RET oncogene; Ducut Sigala JL et al 2004 Science 304:1963.

ELL: Human RNA polymerase II elongation factors in chromosome 19-13.1. ELL1 is ~620 and ELL2 is ~640 amino acid size. They increase the rate of transcription after initiation as they suppress pausing of the polymerase along the DNA. Functionally they are similar to ELONGIN, another transcription elongation factor controlled by the von Hippel-Lindau tumor suppressor gene and the MLL gene products of leukemias (encoded at 11q23) by binding to the A subunit of ELL. The ELL proteins may also hinder initiation by hindering interaction of polymerase II with TBP. The ELLs have a conserved region homologous to the zonula occludens protein sequences that bind MAGUK. ▶von Hippel-Lindau

syndrome, ▶elongin, ▶elongation factors, ▶MLL, ▶transcript elongation, ▶PITSLRE, ▶TEFb, ▶TBP, ▶zonula occludens, ▶MAGUK, ▶leukemias; Luo RT et al 2001 Mol Cell Biol 21:5678; Eissenberg JC et al 2002 Proc Natl Acad Sci USA 99:9894; regulators of ELL: Kong SE et al 2005 Proc Natl Acad Sci USA 102:10094.

E

Elliptocytosis (ovalocytosis): The shape of the erythrocytes (red blood cell) is not round as in normal, but elliptic, indicating an often fatal autosomal dominant hemolytic anemia (see Fig. E19). In the *Camelidae*, elliptocytosis is a normal condition. Mutations in spectrin (SPTA1, 1q21) frequently lead to defects in the formation the $\alpha\beta\sim\alpha\beta$ tetrameric spectrin molecules. This may be the basic cause and a variety of this condition has been described. Some forms may be correlated with protection against malaria. The α -spectrin gene was assigned to human chromosome 1q21 (Rhesus-unlinked type elliptocytosis). The Rhesus-linked type was assigned to 1p34-p33. An atypical elliptosis is apparently recessive. ▶anemia, ▶spectrin, ▶ankyrin, ▶spherocytosis, ▶poikilocytosis, ▶erythrocyte; Wandersee NJ et al 2001 Blood 97:543.

Figure E19. Elliptic red blood cells

Ellis-van Creveld Syndrome: A human chromosome 4p16 recessive. At this locus, the evolutionarily and highly conserved two genes *EvC* and *EVC2* are in head-to-head configuration, and their mutation is responsible for the varied phenotypes (Ruiz-Perez VL et al 2003 Am J Hum Genet 72:728). It involves dwarfism, polydactyly, short extremities, heart malformation, dystrophy of finger nails, “partial hare lip”, teething by birth, heart defects, etc. It is quite common in some Amish populations. ▶Amish, ▶face/heart defects, ▶polydactyly, ▶hare lip, ▶dystrophy, ▶Weyers acrocardial dysostosis, ▶McKusick-Kaufman syndrome, ▶achondroplasia

ELMS (expected maximum lod score): ELMS is computed by weighting the sum of lod scores by their probability. ▶lod score

ELOD: ▶interval mapping, ▶lod score

Elongation Factors (EF): Elongation factors are proteins assisting translation on the ribosomes; see individual factors (eIF) separately listed. Factors eIF-2, eIF-3, eIF-4A, eIF-4B, eIF-4F, and ATP are required for the formation of the *elongation initiation complex I*, which is unstable. The addition of eIF-1 and eIF-1A

to complex I results in the formation of the stable *elongation initiation complex II*. The biosynthesis of many proteins in response to intracellular, attenuation environmental factors (e.g., heat shock) are regulated at the level of transcription. The prokaryotic proteins carry out similar functions as the eukaryotic ones but they are structurally different. ▶protein synthesis, ▶transcription shortening, ▶transcription factors, ▶transcription termination, ▶attenuation, ▶rm, ▶TIIFS, ▶promoter clearance, ▶translation termination, ▶ELL, ▶eIFs, ▶transcript elongation; Sonenberg N et al (eds) 2000 Translational Control of Gene Expression. Cold Spring Harbor Lab. Press, Cold Spring Harbor, NY.

Elongators (ELP): Elongators are proteins associated with the hyperphosphorylated carboxyl domain of RNA polymerase II and their activity is correlated with histone acetyltransferases. The complex replaces the Mediator complex, which is associated with the unphosphorylated Pol II during the initiation phase of transcription. ▶histone acetyltransferases, ▶mediator complex, ▶transcript elongation, ▶Spt, ▶RNA polymerase; Li Y et al 2001 J Biol Chem 276:29628; Hawkes NA et al 2002 J Biol Chem 277:3047.

Elongin: A three subunit (A, B, C, ~770, 118 and 112 amino acids, respectively) protein stimulatory to in vitro RNA transcript elongation. The A subunit has the major role and B and C reinforce A. The elongin-von Hippel Lindau-cullin complex may play a ubiquitin ligase role and target genes for degradation by the proteasome. ▶ELL, ▶elongation factors, ▶transcript elongation, ▶von Hippe-Lindau syndrome, ▶cullin, ▶proteasome; Luo RT et al 2001 Mol Cell Biol 21:5678.

ELSI (ethical, legal, social implications of genetics): ▶ethics, ▶bioethics, ▶copyright, ▶patent, ▶risk, ▶genetic screening, ▶genetic discrimination

ELSI: ▶ROSI

Elston-Stewart Algorithm: A computer-based linkage analyses in general pedigrees. The data are first “clipped” to small nuclear families in a large population and then the information is collapsed to one of the parents or other close relatives whose sibship is analyzed. The procedure is continued iteratively until all the information is collapsed to the proband. Usually a small number of markers are considered. ▶collapsing data, ▶iteration, ▶proband, ▶Lander-Green algorithm; Elston RC, Stewart J 1971 Hum Hered 21:523.

Eluate: That flows off a chromatographic column.

Elutriation: The sedimentation or separation of particles from suspensions. The heaviest particles settle first and the light ones may float. *Centrifugal elutriation*

employs a special centrifuge in which a flow is generated in the direction opposite to the rotation. The latter can handle large volumes fast. ►[centrifuge](#)

EMA (E2F-binding site modulating activity): EMA is 2.4-kb DNA translated into a 272-amino acid protein. EMA binds to transcription factors DP-1 and DP-2. It recognizes better the TCCCGCC rather than the TCGCGCC core sequences of the E2F binding sites. EMA is a transcriptional suppressor. ►[E2F1](#); Koziczak M et al 2000 Mol Cell Biol 20:2014.

EM-Algorithm: A principle that can be applied for the calculation of recombination frequencies in special cases.

Emanuel Syndrome (Opitz-Frias syndrome, deletion at 22q11.2): It involves dominant or recessive hypertelorism (abnormal distance between organs), neuromuscular defects, defects of the esophagus (alimentary tube) throat, hypospadias (defect of the urinary tube in the penis), cryptorchidism (failure of the testes to descend into testicular pouch), and problems with the anus (end of the intestinal tract).

E-MAP (epistasis miniarray profile): The determining of genetic networks on the basis of epistatic interaction of genes (Schuldiner M et al 2005 Cell 123:507). The yeast chromosome biology E-MAP involves 743 proteins (Collins SR et al 2007 Nature [Lond] 446:806). ►[genetic networks](#), ►[transcriptome](#)

EMAPII (endothelial monocyte-activating polypeptide): Stimulates leukocytes, monocytes, chemotaxis and myeloperoxidase, tissue factor and TNF α synthesis. EMPAII domains are evolutionarily conserved and their homologs occur at the C-terminal domain of aminoacyl-tRNA synthetases for one or more amino acids (Eubacteria and Caenorhabditis: Met; Yeast: Met, Gln; Mammals: Tyr, Glu, Asp, Met, Pro, Glu, Arg, Lys); in yeast and mammals other homologies may also be found. Tyr-tRNA synthetase along with cytochrome c, released from the mitochondria, prepare the cell for the apoptotic process. Secreted Tyr-tRNA synthetase in mammals undergoes proteolysis and is converted into an N-terminal catalytic fragment with IL-8 properties and into C-terminal cytokine-like fragment. EMPAII migrates also to the sites of inflammation. ►[aminoacyl-tRNA synthetase](#), ►[IL-8](#), ►[cytokine](#); Shalak V et al 2001 J Biol Chem 276:23796.

Emasculation: ►[castration](#)

EMB Agar: ► [\$\beta\$ -galactosidase](#)

Embden-Meyerhof Pathway: An anaerobic process of glycolysis. The six-carbon sugars are converted into glucose-6-phosphate and through a number of steps to glyceraldehyde-3-phosphate, and eventually to pyruvate. An oxidation step generates NADH and pyruvate is further oxidized to form the acetyl units of acetyl coenzyme A that may be oxidized in the citric acid cycle, and become the core reactions of both carbohydrate and fat metabolism.

Embedding: Microscopic specimens requiring thin sections for examination may be surrounded (infiltrated) by paraffin wax, resins or other suitable material before sectioning by microtomes. ►[microtomes](#), ►[sectioning](#)

Embedded Gene: A gene within the boundary of another. ► [\$\phi\$ X174](#)

EMBL (<http://www.ebi.ac.uk/embl/index.html>): EMBL stores databases for macromolecular sequences (without sequence limit since 2004). EMBL3: A lambda DNA vector carrying polylinkers at both sides of the *red* and *gam* sites and, if equipped with adjacent promoters, the RNA polymerase can directly transcribe genes cloned into the “stuffer” region without subcloning. ► [\$\lambda\$ DASH](#), ► [\$\lambda\$ FIX](#), ►[GeneScribe](#), ►[Lambda phage](#), ►[stuffer region](#)

Embryo: The differentiated zygote; in mammals up to about a 1/5 of the normal time of gestation. In plants, the embryo stage is considered to last up to the maturing and germination of the seed. ►[embryogenesis](#), ►[fetus](#), ►[embryo culture](#)

Embryo Culture: When developing plant embryos are lifted from the ovaries about 10–14 days after fertilization, they can survive and mature in aseptically cultures.

This procedure may be applied for the rescue of hybrid embryos that may not survive in their natural

environment because of the collapse of the endosperm, the nurturing tissue, or the overgrowth of the nucellus. Although this technique itself does not overcome hybrid sterility, viable seedlings can be produced that may become fertile after doubling the chromosome number (with colchicine).

Plant ovaries for embryo culture (in ear or fruit) require disinfection by calcium hypochlorite ($\text{Ca}[\text{OCl}]_2$ 5%, for 8–10 min and several rinses in sterile H_2O).

E2 culture medium mg/L H_2O , final conc.: $\text{NH}_4\text{-NO}_3$ 400, KNO_3 200, and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 100, $\text{CaH}_4(\text{PO}_4)_2$ 100, KH_2PO_4 100, K_2HPO_4 50. Before use add 2.5 mL/L chelated iron ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ 556 mg or diethylenetriamine pentaacetic acid 786.4 mg, H_2O 100 mL). Supplement it with 3% sucrose and add agar to solidify without making it too hard (about 0.6%) and autoclave.

Embryonic stem cells of mammals may also be cultured successfully although it is more difficult to maintain totipotency of these cells and to obtain viable embryos. ▶[in vitro](#), ▶[embryo](#), ▶[ovary](#), ▶[nuclear transplantation](#), ▶[tetraploid embryo complementation](#); Rappaport J 1954 Bot Rev 20:201; Nagy A et al 1993 Proc Natl Acad Sci USA 90:8424.

Embryo Node: A temporary structure located at the anterior tip of the primitive streak ▶[organizer](#) in birds, reptiles, and mammals. It is the starting point of the organization of the gastrula. ▶[gastrula](#), ▶[primitive streak](#)

Embryo Rescue: ▶[embryo culture](#)

Embryo Research (human): NIH recommendations: embryos (14) 18 days or older are not acceptable. Unacceptable procedures: transfer human embryos to animals for gestation; transfer research embryos or parthenotes (unfertilized eggs) to humans; separation of blastomeres for generating twins; cloning by nuclear transplantation; creation of any type of chimera (human–human, human–animal); creation of embryos in the lab from stem cells; cross-fertilization by human gametes with the exception of clinical laboratory sperm penetration tests with animal eggs; embryo transfer to cavities other than the uterus; sex selection with the exception of preventing sex-chromosome-linked disease; use of sperm or egg without consent; use of sperm or egg from donor who was paid more than reasonably expected. The embryo research policies vary in different countries, and may/may not permit the use of embryos/tissues for studying infertility, contraception, genetic screening, gene therapy, cloning, construction of chimeras, interspecific implantation, sex-selection, etc. Embryo culture and embryo

transfer had minimal effects on postnatal growth when compared with in vivo development with an equivalent litter size in mice. However, embryo culture, and to a lesser extent embryo transfer, led to an enhanced systolic blood pressure at 21 weeks compared with in vivo development independent of litter size, maternal origin, or body weight. Moreover, activity of enzymatic regulators of cardiovascular and metabolic physiology, namely, serum angiotensin-converting enzyme and the gluconeogenesis controller, liver phosphoenolpyruvate carboxykinase, were significantly elevated in response to embryo culture and/or embryo transfer in female offspring at 27 weeks, independent of maternal factors and postnatal growth (Watkins AJ et al 2007 Proc Natl Acad Sci USA 104:5449). ▶[stem cells](#), ▶[ART](#), ▶[phosphoenolpyruvate](#), ▶[gluconeogenesis](#), ▶[angiotensin](#)

Embryogenesis in Animals: Fertilization generally takes place in the oviduct and the zygote is implanted into the uterus. In the preimplantation embryo several maternal genes are expressed. After fertilization the oocyte-stored mRNAs are degraded in about 90% by the two-cell stage of mice. After that the zygotic genome is activated in stages. A major wave of gene activation takes place at the eight-cell stage of mice and that establishes blastomere polarity (see Fig. E20).

After the two-cell stage polarity develops; one cell forms the inner cell mass, which is pluripotent (able to develop into multiple cell types). At this stage several transcription factors are expressed. OCT4, the leukemia inhibitory factor (Lif, it is interleukine-6 cytokine) and a HOX transcription factor (NANOG) are essential for the determination of the embryonic stem cells. CDX2 is essential for regulation of the expression of OCT4 and NANOG and trophoblast development. The ascidian *Ciona intestinalis* body consists of only ~26,000 cells and its genome includes only 16,000 genes, yet its body plan is similar to that of vertebrates. Localized expression of 76 regulatory genes in 3,000 combinations facilitated to reveal the control of embryonic cell lineages (Imai KS et al 2006 Science 312:1183).

Eomes mediate differentiation at the blastocyst stage and blastocyst activity is required for implantation into the uterus. Endocannabinoids (anandamide) and the MAPK pathway are important signals for implantation. Implantation is controlled by several protein factors. A large number of proteins are required for further function of the uterine even at later stages in adulthood. Progesterone and oestrogen and their receptors are essential for implantation in the majority of mammals. HOX10 is involved in the formation of the decidua. The HEDGEHOG-PATCHED-GLI and

Figure E20. Embryogenesis in mouse.

other proteins are essential for embryo development. Formation of the deciduas and the endometrium assures the appropriate nurture of the embedded embryo (see Fig. E21). Vascular endothelial growth factor and ancillary proteins secure the appropriate blood supply to the fetus. Preeclampsia may result in abortion. (See terms among the alphabetically listed entries, ▶ART, ▶stem cells; Wang H, Dey SK 2006 Nature Rev Genet 7:185; history of ideas on evolution and embryogenesis: Horder TJ 2006 Nature Rev Genet 7:892.

Figure E21. Embryogenesis in vertebrates. (This widely accepted model of Ernst Haeckel has been seriously challenged recently)

Embryogenesis in Plants: Takes place after the sperm within the embryo sac has fertilized (see Fig. E22) the egg. The embryo sac is located within the ovule. The pattern of embryogenesis of higher plants is shown below. The steps are genetically controlled and numerous mutations have been identified that are responsible for the different morphogenic steps.

The information regarding the molecular mechanisms involved in plants is studied less than that in animals. The seed coat is an entirely maternal tissue and, therefore, the inheritance of seed-coat traits is “delayed”. The endosperm develops from the fertilized fused “polar cells” and is generally triploid. In the majority of dicots, by the time the seed matures, the endosperm tissue is generally insignificant in amount or entirely absorbed. In the majority of monocots, the endosperm constitutes the bulk of the seed. In common language the monocot fruit is also called a seed but its proper designation is kernel. The outermost layer of the kernel is the maternal pericarp. Just under the pericarp there is the membrane-like seed coat. The outer layer of the endosperm is called aleurone. The scutellum of the monocots corresponds to the cotyledons of dicots. Seed size and growth form evolved in a coordinated manner and large differences exist in seed size (Moles AT et al 2005 Science 307:576).

While the cotyledons emerge from the seed during germination, the scutellum does not. The “germline” of plants is not set aside during development as in animals, yet the cells of the plant meristems form cell lineages that can be traced if visible genetic differences occur during ontogenesis. The size of the sectors formed permits an estimate on the time when the genetic alteration has taken place during development. Large sectors indicate early event and small sectors show late mutations. ▶megagametophyte, ▶microgametophyte, ▶phyllotaxy, ▶morphogenesis, ▶Drosophila, ▶development, ▶gametogenesis, ▶embryo culture, ▶gametophyte, ▶gametogenesis, ▶endosperm; Chaudhury AM et al 2001 Annu Rev Cell Dev Biol 17:677.

Embryogenesis, Somatic: Plant somatic embryos can be obtained by the techniques of tissue culture. The diagram shows embryogenesis in suspension culture

Figure E22. Embryogenesis in plants. The pattern of embryogenesis in plants is different in dicots from that in monocots. Additional variations exist within these two groups. The dicot pattern is exemplified by the crucifer *Arabidopsis* and the monocot pattern is generalized on the basis of maize and wheat

and compares it with *in planta* embryogenesis (see Fig. E23). In most species it is not necessary to go to protoplasts and embryos may develop from other tissue cells on regeneration media. Several nutrient media have been developed in various laboratories (see Murashige and Skoog; Gamborg 5). For tobacco and *Arabidopsis* the following protocol is quite effective. **R4 Medium:** **I.** Major mineral salts, mg/500 mL H₂O: NH₄NO₃ 1,800, KNO₃ 800, MgSO₄·7H₂O 100, CaH₄(PO₄)₂ 100, KH₂PO₄ 100, K₂HPO₄ 50. **II.** CaCl₂ 15g/100 mL. **III.** KI 75 mg/100 mL. **IV.** Microelements mg/500 mL: H₃BO₃ 6,200, MnSO₄·H₂O 16,900, ZnSO₄·7H₂O 8,600, NaMoO₄·2 H₂O 250, CuSO₄·5 H₂O 25, CoSO₄·7H₂O 29.54. **V.** Chelated iron: in 100 mL H₂O FeSO₄·7H₂O 556 mg, diethylenetriamine pentaacetic acid 786.4 mg. **VI.** Vitamins, mg/50 mL: myo-inositol 5,000, thiamin 500, nicotinic acid amide 50, pyridoxine.HCl 50. Final solution: **I.** 50 mL. **II.** 290 µL. **III.** 100 µL. **IV.** 50 µL. **V.** 500 µL. **VI.** 100 µL, pH 5.6, sucrose 3 g. Fill up to 100 mL, agar about 600 mg (varies according to batch) or Gellan gum 180 mg (must be separately dissolved in distilled water on hot plate (with magnetic stirrer). The culture generally requires

5 stages with hormones added in µg/mL: R4-1 (callus initiation) 9RiP 1.5, 2,4-D 0.025–0.050, R4-2 (callus growth and regeneration) 9RiP 2.0, NAA 0.1, R4-3 (leafy callus) 9RiP 1.5, NAA 0.1, R4-4 (shoots appear) BAP 1, NAA 0.1, R4-5 (rooting), BAP 0.0005, NAA 0.05. After R4-4, *Arabidopsis* can be transferred to E2 medium *in vitro* (see ►embryo culture) where they produce seeds even in the absence of roots. Alternatively, after R4-5, the seedlings can be transferred to soil or commercial soil substitute. (RiP = isopentenyl adenosine, 2,4-D = dichlorophenoxy acetic acid, NAA: α-naphthalene acetic acid, BAP: benzylamino purine). Heat stable components are autoclaved, and vitamins and hormones are filtered. ►embryo culture, ►cell genetics, ►tissue culture, ►ART

Embryoid: An embryoid develops through somatic embryogenesis. ►embryogenesis somatic

Embryoid Body: Such as endoderm, ectoderm, neurons, yolk, cartilage, muscle cells and ovary-like structures formed from embryonic stem cells. ►stem cell, ►endoderm, ►ectoderm

Figure E23. Zygotic and somatic embryogenesis at comparable stages in *Daucus carota*. (Redrwan after Stree, H.E. & Withers, L.A. 1974 in Tissue Culture and Plant Science. Acad. Press, London, UK)

Embryology: The study of embryogenesis from fertilization until the birth (hatching) of an animal, or to the maturation of seeds of plants by genetic, morphological, and molecular techniques ►embryogenesis, ►cell lineages, ►fate map

Embryonal Disk: ►imaginal disk, ►*Drosophila*

Embryonic Induction: The interaction between and among tissues leading to tissue differentiation in the embryo. Vg-1, activin, bone morphogenetic factor, fibroblast growth factor, etc., have been isolated from various sources and found to be effective in regulating embryonic differentiation in animals by binding to receptors, by being restricted in diffusion through the extracellular matrix, affecting signal transduction pathways, etc. ►embryogenesis, ►morphogenesis

Embryonic Lethal: Death occurs before birth.

Embryonic Polarity: The directional determination of the cells in the embryo along longitudinal, vertical, or other directions. The anterior/posterior axis of development is influenced by the sperm-derived centrosomes and the subsequent development of the microtubules. (See Schier AF, Talbot WS 2005 Annu Rev Genet 39:561).

Embryonic Stem Cell (ES): Cells of the early embryo capable of continuous growth and differentiation of animals. They are comparable to the meristems of plants. They represent cells that have not undergone differentiation into somatic cell lineages. These cells can be maintained in vitro in this stage for prolonged periods. They can be reintroduced into preimplantation embryos and thus chimeric animals may be generated. They are suitable for transfection by transgenes and can be used to generate in vitro mutations and are amenable to a variety of modifications such as gene trapping. Several gene products have been identified that are required for the maintenance of self-renewal (Ivanova N et al 2006 Nature [Lond] 442: 533). ►meristem, ►gene trap vectors, ►trapping promoters, ►stem cells

Embryo Sac: The embryo sac of plants develops after meiosis from one of the (generally the basal) megaspores (see Fig. E24). The role of the three antipodals is unclear. The diploid polar cell is fertilized with one of the sperms and gives rise to the triploid zygote and embryo. The synergids (flanking the egg) probably have an early role in nurturing the egg and zygote. The photo shows clearly only 4 nuclei (which were in the same plane) in the embryo sac ►gametophyte, ►embryogenesis, ►gametogenesis

EMC: ►enzyme mismatch cleavage, ►mutation detection

EMC: Encephalomyocarditis virus with RNA genetic material.

Emerin: A 254 amino acid serine-rich integral membrane protein encoded by the STA gene, responsible for the Emery-Dreifuss muscular dystrophy. (Emery-Dreifuss muscular dystrophy, Wolff N et al 2001 FEBS Lett 501:171)

Emery-Dreifuss Muscular Dystrophy: ►muscular dystrophy, ►emerin, ►laminopathies

EMF (extremely low frequency electromagnetic fields): ►electromagnetic radiation

EMG Syndrome: ►Beckwith-Wiedemann syndrome

Figure E24. Plant ovule with embryosac diagram at right, photomicrograph of the embryosac with 4 nuclei at left

EMI1 (early mitotic inhibitor of mitosis): A zinc-binding F-box protein that controls the anaphase-promoting complex (APC) by binding to CDC20. ▶F-box, ▶APC, ▶CDC20, ▶Evi oncogene; Reimann JDR et al 2001 Cell 105:645.

EMLS (expected maximum lod score): The sum of lod scores weighted by their probability. EMLS for sharing values of Y (= probability of allele sharing) varies according the size of the population studied. ▶allele sharing; Risch NJ 2000 Nature [Lond]: 405:847.

EMMA: The European Mouse Mutant Archive in Monterotondo, Italy, maintains mutant mouse/frozen embryos for research. ▶mouse

Emmer Wheat ▶Triticum

EM-MS: (electron monochromator-mass spectrometer): An analytical technique especially useful for the analysis of complex biological samples, including complex mutagens and carcinogens of the environment. It applies the electron resonance energy spectrum in the analysis (Havey CD et al 2006 J Phys Chem A Mol Spectrosc Kinet Environ Gen Theory 110:4413).

Emotion: ▶stress

Emphysema, Pulmonary: Pulmonary emphysema is characterized by pathological inflation of the lungs and possible atrophy of the tissues. It appears to be due to autosomal dominant genes or to environmental causes (smoking). Emphysema may show up in infancy as a complication of other ailments. Emphysema develops in case of deficiency of α -antitrypsin. It can be medicated by regular supply of antitrypsin. The heme oxygenase (HMO1, 22q12, inducible; HMO2, 16p13.3, constitutive) genes may regulate susceptibility to chronic pulmonary emphysema (CPE) with lung antioxidant influence. ▶antitrypsin, ▶serpin, ▶elastic fiber diseases

Empirical Risk The occurrence or recurrence of certain genetic defects cannot be predicted on the basis of theoretical principles or mathematical formulas because the genetic mechanisms and their control are not known. Some observations in larger populations indicate, however, a certain tendency of recurrence in families that have had an afflicted individual in the pedigree. The calculation may take into consideration the empirical experience of onset of a disease with both genetic and age components. For example, 100 families have 40 afflicted children older than 50 years, and 170 unaffected who are still in the age group of 20–50. Experience indicates that usually the age of onset begins at 50 and about half of the offspring of afflicted parents eventually expresses the condition. The empirical risk for the still healthy individuals then is $(170 \times 0.5)/210 = 0.41$. ▶genetic risk, ▶risk, ▶recurrence risk, ▶clinical genetics, ▶inbreeding coefficient

EmrE: A family of small multidrug resistance transporters composed of 105–120 amino acids of four transmembrane helices. EmrE confers resistance to antibiotics (tetracycline), ethidium and tetraphenylphosphonium. Crystal structure of this multidrug transporter has been determined (Pomillos O et al 2005 Science 310:1950). ▶multidrug resistance

EMS: A very potent alkylating mutagen and carcinogen. ▶ethylmethanesulfonate

EMSA (electrophoretic mobility shift assay): EMSA detects in vitro the formation of protein complexes by changing the mobility of the complex in the electric field (Fried M, Crothers DM 1981 Nucleic Acids Res 9:6505).

En Blood Group: The En blood group is apparently limited only or mainly to individuals of Finnish descent; it is very rare. ▶blood groups

ENA-78 (epithelial cell-derived neutrophil attractant): A 78-residue chemokine of epithelial cells, monocytes,

neutrophils, fibroblasts, platelets, and some cancer cells. ► [chemokines](#) and other separate entries

ENaC (epithelial sodium channel): ► [ion channels](#), ► [hypoaldosteronism](#)

Enantiomorphs: Enantiomorphs are stereoisomers, molecules with structures that are mirror images of each other. In some instances, only one of the enantiomorphs supports normal metabolism. Interestingly, in nature, L amino acids and D sugars predominate. It has been suggested that the amino acid proline is historically the source of the asymmetry, which was advantageous in the early prebiotic environment and evolution preserved the left-handedness in amino acids. Chirality (enantiomorphs) in the mixture of common insecticides makes a great difference in degradation (an environmental concern) and the toxicity to target and nontarget organisms (Liu W et al 2005 *Proc Natl Acad Sci USA* 102:701). ► [D-amino acids](#), ► [chirality](#), ► [racemate](#); Norden B 1978 *J Mol Evol* 11:13; asymmetric amplification based on solid-liquid phase of amino acid solutions: Klusmann M et al 2006 *Nature [Lond]* 441:621.

Encephalitis: Brain inflammation. ► [Rasmussen encephalitis](#), ► [encephalopathies](#), ► [viral encephalitis](#)

Encephalomyelitis: Brain and spinal cord inflammation. ► [encephalopathies](#)

Enkephalon: Brain; prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon/telencephalon (hindbrain) are distinguished. ► [brain](#)

Encephalopathies: Usually recessive degenerative brain diseases. The childhood recurrent (autosomal dominant) form involves impaired muscular coordination and speech troubles. The Gerstmann-Sträussler disease (GSD) is also an autosomal dominant encephalopathy with late onset (around age 50) and involves feeble-mindedness. The central nervous system shows myeloid plaques, similar to those in the Creutzfeldt-Jakob disease (CJD). The bovine spongiform encephalopathy (BSE) is responsible for the fatal "mad cow disease" which bears similarities to scrapie in sheep and it was believed that a virus induces it. Current views do not support the viral origin; rather it is attributed to an infectious protein (PrP^{Sc}). Recent observations, however, demonstrate 25-nm virus-like arrays in two cell lines productively infected with either sheep-derived scrapie or human-derived CJD agents passaged in mice. Comparable particles were not found in uninfected controls. This data, along with other drug and PrP immunogold binding studies here, lend further credence to the actuality of a transmissible spongiform encephalitis (TSE) virion that is structurally independent of

pathological PrP in the intact cell (Manuelidis L et al 2007 *Proc Natl Acad Sci USA* 104:1965).

In mice that have a null allele for the PrP^C gene, i.e., they are Prn^{P0/0}, even large doses of prions do not cause brain damage. There may be an undetermined chance that these encephalopathies are transmitted to humans from animals by consumption of meat. Most encephalopathies usually have late onset. The incubation period for BSE may be several years. There apparently is evidence now to show that humans are infected by BSE in the form of a new variant of the Creutzfeldt-Jakob disease (Scott MR et al 1999 *Proc Natl Acad Sci USA* 96:15137). It is also known that mice can be infected with scrapie. The major outbreak of BSE is attributed to the feeding of infected sheep offal to cattle. Infectivity can be abolished only by heating the animal products at high temperature and by some solvents. There is no sufficient data on whether milk or eggs or poultry meat would transmit any source of infective material. After decisive control measures, the BSE cases are on a decline since the 1992 peak. An estimated 1 million cattle was infected by BSE and about 160,000 died of the disease in England. The BSE risk to humans is reduced when cattle of over 30 months of age are excluded from consumption. BSE infection through processed meat (brain tissues) can be diminished by orders of magnitude when the infected animal tissue is exposed to several short, high-pressure pulses at temperatures of 121–137° (Brown P et al 2003 *Proc Natl Acad Sci USA* 100:6093). For the complete eradication of the encephalopathies threatening the human populations too, prion-resistant animals may have to be produced. It is known that sheep homozygous for Arg at position 171 in the protein escape scrapie. The kuru, BSE and some forms of the Creutzfeldt-Jakob disease, scrapie transmissible mink encephalopathy, and the feline spongiform encephalopathy are transmitted horizontally whereas the Gerstmann-Sträussler disease and the Creutzfeldt-Jakob disease are transmitted vertically. The hepatic encephalopathy is an apparently nongenetic neuropsychiatric disorder caused by exposure to ammonia. Certain cyclic tetrapyrroles (deuteroporphyrin IX 2,4-bis[ethylene glycol] iron III, phthalocyanine tetrasulfonate) may inhibit the formation of the protease-resistant prions. Prions are not inactivated by nucleases, UV irradiation, psoralen dyes that cross-link DNA, divalent cations, metal chelators, by pH between 3 and 7, hydroxylamine, formalin, boiling and by proteases. The human prions are not contagious like microbial or viral infections but they are transmitted by prion-containing animal residues or by prion transgenes.

Brain tissues (particularly the outermost membranes, the dura mater) are richest in prions but

infection by human blood is controversial although rodent blood seems to transmit it. Peripheral nerves, lung and liver seem to have low infectivity; skeletal muscles, milk, blood, bone, hair, and urine may not transmit prions. There is also some risk that humans may develop a variant of the Creutzfeldt–Jakob disease (vCJD) by ingesting industrial (e.g., gelatin, polysorbate) or medical (e.g., heparin, insulin) products made of or with infected animal material. There is a risk of transmission by inadequately sterilized surgical instruments and particularly by brain tissue specimens, even by aerosols generated by autopsy or through wounds penetrating the gloves during dissection. Fixation of tissue samples in formalin does not abolish infectivity. Autoclaving for 4.5 h at 132°C, denaturing in 50% phenol, guanidine isothiocyanate or hydrochloride at > 4 M, or exposure to 1 N NaOH for 24 h or 2 N NaOH for 2 h inactivates prions. Animal assays for animal prions are generally very slow. Transgenic mice expressing the bovine prion (PrP) may respond faster. The incubation period after infection by a BSE agent is much affected by genetic factors of the recipient mouse. Immunoassays (ELISA) or Western blots for PrP^{Sc} (the scrapie protein) are effective in detection of the condition but their sensitivity is low. Conformation-dependent immunoassay based on the difference between the α -helical PrP^C and the β -sheet component of PrP^{Sc} may be quite efficient. Ovine encephalopathy protein can now be propagated in vitro (Villette D et al 2001 Proc Natl Acad Sci USA 98:4055). In neural cell cultures, specific CJD attenuated the effects of scrapie-derived protease-resistant prions in the absence of an effective immune system (Nishida N et al 20056 Science 310:493).
 ▶prion, ▶scrapie, ▶Gerstmann-Sträussler disease, ▶Creutzfeldt-Jakob disease, ▶kuru, ▶fatal familial insomnia, ▶neurogastrointestinal encephalomyopathy, ▶porphyria, ▶Seitelberger disease, ▶chronic wasting disease

Enchondromatosis: Cartilage tumor(s) regulated by a parathyroid hormone-related protein and Indian hedgehog signals. ▶parathormone, ▶hedgehog; Hopyan S et al 2002 Nature Genet 30:306.

Enciphering: The information regarding the nature of a protein, such as a prion, is contained in its tertiary structure rather than in a nucleic acid. ▶prion

ENCODE (Encyclopedia of DNA Genetic Elements): Pursues the identification and localization of all functional elements such as promoters, transcriptional regulators, replicational origins, etc. The promoter associated region is frequently called ENCODE region. Detailed analysis of a targeted 1% of the human genome indicates that the DNA is generally transcribed

and the majority of the bases are present in transcripts even of noncoding sequences; there is new light on transcriptional start sites and regulation (ENCODE Consortium 2007 Nature [Lond] 447:799). The 2007 data shed new light on the functional organization of the genes. ▶human genome, ▶gene, ▶pseudogene; Science 306:636 [2004], Genome Research ENCODE 17(6), issue 2007; <http://www.genome.gov/10005107>; <http://genome.ucsc.edu/ENCODE>; unified portal of ENCODE: <http://research.nhgri.nih.gov/ENCODedb/>.

Encyclopedia of the Mouse Genome: It contains genetic and cytogenetic information on mouse, electronically obtainable through File Transfer Protocol (FTP), Gopher or World Wide Web Software (WWW) in Sun (UNIX) or in Macintosh versions. ▶mouse, ▶databases

End: Bacterial genes coding for DNA-specific endonucleases.

End Labeling: The Klenow fragment of bacterial DNA polymerase I can add α -P³² dNTP to the 3'-OH end of a nucleotide (polynucleotide). Or transferring the γ -phosphate of ATP to the 5'-OH end of DNA or RNA (forward reaction) or by exchanging the 5'-P of a DNA (in the presence of excess ADP) by the γ -P of radiolabeled ATP, using T4 bacteriophage polynucleotide kinase. This 5'-labeling is used for the Maxam & Gilbert method of DNA sequencing or in any other procedure when 5' labeling is required.
 ▶Klenow fragment, ▶DNA sequencing

3'-End of Nucleic Acids: The OH at the 3' C atom on the ribose or deoxyribose. ▶nucleic acid chain growth

5'-End of Nucleic Acids: The first nucleotide in the chain retains the three phosphates whereas the subsequent ones form phosphodiester bonds with one phosphate between the 5' end and the 3' -OH position of another.
 ▶phosphodiester bond, ▶nucleic acid chain growth

Endangered Species: ▶species extant, Convention on International Trade of Endangered Species (CITES) 1973 Public Law 93–205.

Endemic: Indigenous to a population rather than introduced; confined to a population or area.

Endergonic Reaction: An endergonic reaction consumes energy.

End-Joining: The restoration of broken chromosome ends, or fusion of broken chromosomes, e.g., in translocation or other type of breakage. ▶translocation chromosomal, ▶double-strand break, ▶nonhomologous end-joining; Smith J et al 2001 Nucleic Acids Res 29:4783.

Endocannabinoids: ▶cannabinoids

Endocardial Fibroelastosis (Barth syndrome, cardiomyopathy with neutropenia and abnormal mitochondria, BTHS): A human Xq28-linked recessive thickening of the heart wall muscles due to collagen proliferation (Type I). In Type II methylglutaconic aciduria, besides the defects in the heart muscles, neutropenia (decrease in the number of neutrophilic leukocytes) morphological anomalies of the mitochondria was detectable by electron microscopy. Barth syndrome may be caused by tafazzin acetyl transferase associated with altered metabolism of mitochondrial phospholipid cardiolipin. Tafazzin mutation in *Drosophila* can serve as an animal model for BTHS (Xu Y et al 2006 Proc Natl Acad Sci USA 103:11584). ▶heart disease, ▶neutropenia, ▶neutrophil, ▶collagen, ▶methylglutaconic aciduria, ▶cardiolipin; Bione S et al 1996 Nat Genet 12:385.

Endocarp: The inner layer of the fruit wall of plants such as the stony pit of peaches, cherries.

Endokaryosis: The acquisition of a nucleus by ingesting another organism during evolution.

Endocrine: Hormone-producing glands which, in response to peptide activators within an organism, secrete their product into the blood stream without the reliance on a special duct. ▶endocrine network; <http://endonet.bioinf.med.uni-goettingen.de/>.

Endocrine Neoplasia, Multiple (MEN): The autosomal dominant MEN 1 (11q13) involves endocrine adenomas in several tissues (stomach, lung, parathyroid, pituitary, colon, pancreas, etc.). The MEN1 gene has 10 exons and it is translated into a 610 amino acid protein, menin. The dominant MEN2 and MEN2A, involving also phaeochromocytoma and amyloid-producing medullary thyroid carcinoma, are apparently in chromosome 10q11.2. The latter is the location of the RET protooncogene. MEN2B is similar to MEN2A but frequently shows neural

hyperplasias of the mouth area and in the colon as well. All of these cases involve receptor-like tyrosine kinases. MEN3, also dominant, was located in the vicinity of MEN2A; it also shares the same symptoms and displays neural tumors. The prevalence is $1-10 \times 10^{-5}$. ▶adenoma, ▶phaeochromocytoma, ▶RET oncogene, ▶protein-tyrosine kinase, ▶menin

Endocrinology: The study of hormones, other biological secretions, and their physiological roles. ▶reverse endocrinology, ▶endocrine, ▶animal hormones

Endocycle: A specialized cell cycle involving genomic replication without cell division and resulting in polyploidy. ▶cell cycle, ▶polyploidy, ▶endomitosis, ▶endoreduplication

Endocytosis: An uptake mechanism of cells involving invagination of the cell membrane and then cutting off the (clathrin-coated) vesicle (endosome) so formed inside the cell (see Fig. E25). Some endocytotic pathways do not require clathrin. The cargo receptor transmembrane proteins recognize various molecules by some sort of specificity. To one terminus of the cargo proteins, an *adaptin* molecule (assembly protein; including arrestin, ARNO, AP2, NSF, MDM2) is attached, that in turn recognizes clathrins. Then clathrin-coated vesicles are formed. When the clathrin and adaptin molecules separate from the membrane, a membrane-bound vesicle is formed enclosing the cargo molecules. The adaptins are multisubunit adaptor molecules that can recognize the (Tyr, X, Arg, Phe) peptide signals near the carboxyl end of the receptor, reaching into the cytosol. The carboxyl end of phosphorylated M6P proteins are also recognized by the adaptin molecules in the Golgi apparatus. The M6P proteins are named as such by the mannose-6-phosphate groups that are linked to the amino ends of lysosomal enzymes.

Figure E25. Endocytosis

E

The M6P transmembrane proteins bind lysosomal hydrolases and assist in packaging them into transport vehicles that fuse with endosomes that transport molecules into lysosomes. The endosomal sorting-complex (ESCRT) involves several proteins and its crystal structure and regulatory roles have been determined (Teo H et al 2006 Cell 125:99; Kostelansky MS et al 2006 Cell 125:113). The endosomes are membrane-enclosed transport vesicles, carriers of material to the lysosomes. An endocytotic compartment of the B cells may accumulate class II type MHC molecules and antigens. The unique lipids in the internal membranes of the endosomes sort insulin-like growth factor 2, mannose-6-phosphate ligands, and lysosomal enzymes. These lipids are specific antigens for the antibodies of the antiphospholipid syndrome. The endocytotic pathway also has a signaling function. In addition, endosomes can be used for delivering DNA into cells. Usually a photosensitizer is added to the delivery system that destabilizes the endosomal membrane. A ternary complex composed of the core of DNA, packaged with cationic peptides and enveloped in the anionic dendrimer, phthalocyanine, is used to provide photosensitizing function. This construct assures the uptake of the DNA after laser irradiation and the internalization of the cargo (Nishiyama N et al 2005 Nat Mater 4:934). ▶caveolae, ▶raft, ▶clathrin, ▶triskelion, ▶lysosome, ▶antigen processing, ▶MHC, ▶insulin-like growth factors, ▶lysosome, ▶antiphospholipid syndrome, ▶coatamer, ▶Sec, ▶ARF, ▶SAR, ▶Golgi, ▶COP, ▶adaptin, ▶arrestin, ▶dendrimer, ▶gene delivery, ▶ARNO, ▶AP2, ▶NSF, ▶MDM2, ▶endoplasmic reticulum, ▶receptor-mediated gene transfer; Ungewickell E 1999 Proc Natl Acad Sci USA 96:8809; Itoh T et al 2001 Science 291:1047; D'Hondt K et al 2000 Annu Rev Genet 34:255; Katzmann DJ et al 2001 Cell 106:145; Di Fiore PP, De Camilli P 2001 Cell 106:1; Brodsky FM et al 2001 Annu Rev Cell Dev Biol 17:517; Pelham HR 2002 Curr Opin Cell Biol 14:454; Conner SD, Schmid SL 2003 Nature (Lond) 422:37; Bonifacino JS, Traub LM 2003 Annu Rev Biochem 72:395; Kaksonen M et al 2005 Cell 123:305; coordinating role of endocytosis: Polo S, Di Fiore PP 2006 Cell 124:897; molecular biology and networks: Schmid EM, McMahon HT 2007 Nature [Lond] 448:883.

Endoderm: The internal cell layer of the embryo from which the lung, digestive tract, bladder and urethra are formed. ▶ectoderm

Endodermis: The endodermis in plants is composed of heavy-walled cells and without intercellular space among them; they are found around the vascular system particularly in roots. ▶root

Endoduplication: Endoduplication is basically similar to what is called endomitosis but it was first used to denote the diploidization of androgenetic or gynogenetic embryos. ▶endoreduplication, ▶androgenesis, ▶gynogenesis, ▶c mitosis

Endogamy: Mating within a group, a sort of inbreeding. ▶inbreeding

Endogenote: The tract of the recipient bacterial genome that is homologous to the donor DNA paired with it. In this merozygous condition homo- and heterogenotes can be distinguished, depending on whether the donor sequences are identical or genetically different from that of the recipient. ▶exogenote, ▶merozygote, ▶conjugation bacterial

Endogenous Rhythm: The periodical (oscillatory) changes in cells that occur without external influences. ▶E box

Endogenous Virus: The endogenous virus is integrated into the host chromosome. Endogenous retroviruses may affect the transcription of genes where they are located. The development of superantigens responsible for autoimmune diseases has been attributed to HERV (human endogenous retrovirus) within the HLA gene cluster. The HERV elements retain the long terminal repeats but lack the functional viral envelope gene and are usually not expressed although they are capable of expression. HERVs may constitute ~1–2% of the human genome. HERVs have been used as phylogenetic markers by comparing the integration site polymorphism and for orthologous comparison of the changes in their nucleotide sequences. In vivo and in vitro experiments show that the envelope of a particular class of endogenous retrovirus of sheep, Jaagsiekte sheep retroviruses (enJSRVs), regulates trophectoderm growth and differentiation in the preimplantation conceptus (embryo/fetus and associated extraembryonic membranes). The enJSRV envelope gene is expressed in the trophectoderm of the elongating ovine conceptus after day 12 of pregnancy. If the endovirus is blocked the pregnancy may end (Dunlap KA et al 2006 Proc Natl Acad Sci USA 103:14390). ▶provirus, ▶temperate phage, ▶retroposon, ▶retrotransposon, ▶retrovirus, ▶HLA, ▶superantigen, ▶orthologous, ▶LINE, ▶SINE; HERVd: <http://herv.img.cas.cz>.

Endoglin: A homodimeric receptor glycoprotein on the vascular endothelial cells for the transforming growth factor β , encoded in human chromosome 9q34.1. ▶telangiectasia familial hemorrhagic, ▶vascular targeting, VEGF; Paquet ME et al 2001 Hum Mol Genet 10:1347.

Endolysin: Bacteriophage muralytic (wall-lysing) enzymes for degrading bacterial cell walls. ▶holin

Endomesoderm: A mesoderm layer originating from the endoderm of the early embryo. ▶[endoderm](#), ▶[mesoderm](#)

Endometrium: A three-layer mucous membrane lining the uterus. ▶[uterus](#), ▶[tamoxifen](#)

Endometriosis: A relatively common (10–15%) cause of female infertility due to poorly understood physiological anomaly of the ovaries. It involves excessive menstrual pain (dysmenorrhea) and pelvic pain with coitus (dyspareunia) or upon defecation (dyschezia) or chronic pelvic pain due to endometrial tissue outside the uterus. Gonadotropin-releasing hormone agonists can alleviate the pain because of receptor down-regulation, reduced pituitary gonadotropin secretion, and estrogen production (Berkley KJ et al 2005 Science 308:1586). Comparative genomic hybridization revealed losses in several human chromosomes, particularly in 1, 7 and 22 (Gogusev J et al 1999 Hum Genet 105:444). The presence of abundant plasma cells in endometriosis that produce IgM, and macrophages that produce BLYS/BAFF/TNFSF13B, a member of the TNF superfamily implicated in other autoimmune diseases, were detected. B lymphocyte stimulator (BLYS) protein was found elevated in the serum of endometriosis patients (Hever A et al 2007 Proc Natl Acad Sci USA 104:12451). ▶[comparative genomic hybridization](#), ▶[ovary](#), ▶[Müllerian duct](#), ▶[immunoglobulins](#), ▶[lymphocytes](#), ▶[TNF](#), ▶[autoimmune disease](#)

Endomitosis: Chromosome replication not followed by cell division resulting in polyploidy. In *Schizosaccharomyces* it was found that gene *rum1*⁺ overexpression permits repeated starts of the cell cycle without mitoses in between them, and deletion of the gene allows successive mitoses without an S phase in between them. It appears as if *rum1*⁺ would regulate CDC2, which apparently has two functional forms. Overexpression of *rum1*⁺ would lock CDC2 in the form when it promotes the synthetic (S) phase and deletion of *rum1*⁺ would switch CDC2 into the mitosis-promoting form. ▶[endoduplication](#), ▶[endoreduplication](#), ▶[c mitosis](#), ▶[polyploid](#), ▶[cell cycle](#), ▶[licensing factor](#), ▶[CDC27](#)

Endonuclease: An enzyme that cuts DNA or RNA at internal positions. ▶[exonuclease](#), ▶[restriction enzymes](#), ▶[homing endonuclease](#), ▶[abasic endonuclease](#)

Endonuclease III: Endonuclease III removes from the DNA oxidized pyrimidines such as 5,6-dihydrouracil, 5,6-dihydrothymine, and thymine glycol. ▶[glycosylases](#); Katcher HL, Wallace SS 1983 Biochemistry 22:4071.

Endonuclease IV: Endonuclease IV belongs to a class of trinuclear zinc metalloenzymes; they are apurinic/aprimidinic endonucleases involved in DNA repair in prokaryotes and eukaryotes (Ivanov I et al 2007 Proc Natl Acad Sci USA 104:1465).

Endonuclease V: T4 endonuclease V is called T4-pdg, T4-pyrimidine dimer glycosylase/AP lyase. Endonuclease V is a common base excision repair enzyme of prokaryotes. ▶[glycosylases](#), ▶[pyrimidine dimer](#), ▶[DNAS repair](#); Feng H et al 2005 Biochemistry 44:675; Fuhrmann M et al 2005 Nucleic Acids Res 33(6):e58.

Endonuclease VIII: A bacterial enzyme, which removes from the DNA oxidative-damaged bases by glycosylase/lyase function. ▶[DNA repair](#); Burgess S et al 2002 J Biol Chem 277:2938.

Endonuclease G: A mitochondrial enzyme (~28 kDa) that, upon apoptotic stimuli, moves to the cell nucleus and degrades their DNA independent from the caspase pathway. ▶[apoptosis](#), ▶[CAD](#), ▶[CED-3](#); Parish J et al 2001 Nature [Lond] 412:90; Li LY et al ibid. 95.

Endopeptidase: Proteolytic enzymes cleaving internal bonds at cysteine, serine, aspartic, metallic, or other residues.

Endophilin: A lysophosphatidic acid acyl transferase. It is an effector of dynamin and probably facilitates the invagination of membranes and the formation of synaptic-like microvesicles used in neurotransmission. ▶[lysophosphatidic acid](#), ▶[dynamin](#), ▶[neurotransmitter](#), ▶[synaps](#); Ramjun AR et al 2001 J Biol Chem 276:28913.

Endophenotype: A term used primarily in experimental neurology for describing the characteristics of human diseases (e.g., affective disorders such as schizophrenia) under multigenic control that cannot be defined by any single trait, but rather a collection of traits that vary among the individuals and that have variable expressivity according to age and environmental conditions. ▶[phenotype](#), ▶[neurodegenerative diseases](#)

Endoplasmic Reticulum (ER): The internal membrane system within the eukaryotic cell with secretory channels (see Fig. [E26](#), Fig. [E27](#)).

Figure E26. Endoplasmic reticulum in *Arabidopsis*

Figure E27. A portion of plant endoplasmic reticulum with ribosomes

Within these membrane-bound compartments proteins and lipids are synthesized, and glycosylation, sulfation of secretory and membrane-bound proteins, proteoglycans and lipids take place. The rough endoplasmic reticulum has attached ribosomes causing the non-smooth appearance (*rough endoplasmic reticulum*). Many nascent peptide chains are transferred to the ER where the synthesis of the proteins is completed and the proteins are folded. If the folding slows down the unfolded protein response (UPR) stimulates the transcription of ER-resident proteins. The Hac1 basic leucine zipper protein is a transcription factor that binds to the UPR element in the promoter of the UPR genes. Splicing that bypasses, the spliceosome is mediated by the presence of a tRNA ligase protein. After the completion of the synthesis the proteins are translocated with the aid of the Hsp70 chaperones. The energy is provided by associated ATP, UDP, GDP and CMP nucleotides. Within the endoplasmic reticulum quality control takes place by selecting the ones which have the proper conformation. The folding is mediated by BiP, lectins calnexin and calreticulin, and protein disulfide isomerase, GRP, and other ER chaperone proteins. The enzymes UDP-5'-diphosphate-glucose—glycoprotein, glucosyl-transferase and glucosidases—also play a role in substrate binding and release of ER proteins. Free cysteines participate in forming interchain disulfide bonds and aggregate and facilitate retention. These ER factors prevent the release of the proteins until their synthesis and folding is completed. The improperly folded polypeptides are degraded and only the correct ones are secreted to the cytosol through the Golgi. The structural surveillance in the ER prevents the release and then degrades some of the structurally mutant α_1 -antitrypsin molecules although they would be capable of function. In cystic

fibrosis the misfolded transmembrane conductance regulator protein may be degraded before it could be transported to the plasma membrane although, under conditions conducive to proper folding, some function may be recovered (see Fig. E28). In other instances the folding defect may cause precocious release of, e.g., β -lactoglobulin polypeptide. The released proteins may be transported with the aid of the cargo receptor to the Golgi apparatus where further processing may take place. A defect in the chaperones in terminally differentiated neurons leads to protein accumulation and stress in ER resulting in neurodegeneration as seen in Alzheimer's and Parkinson's diseases (Zhao L et al 2005 Nature Genet 37:974).
 ▶chloroplast endoplasmic reticulum, ▶signal peptide, ▶signal-sequence recognition particle, ▶cell structure, ▶protein synthesis [translation], ▶Sec61 complex [and other Sec proteins], ▶Hac1, ▶Hsp70, ▶TAP, ▶SsA, ▶SsB, ▶Ydj1, ▶architectural editing, ▶BiP, ▶calnexin, ▶calreticulin, ▶GRP, ▶lectins, ▶antitrypsin gene, ▶aggresome, ▶Golgi apparatus, ▶endocytosis, ▶COP transport vesicles, ▶inclusion body, ▶cystic fibrosis, ▶folding, ▶protein folding, ▶unfolded protein response, ▶endoplasmic reticulum-associated degradation; Parodi AJ 2000 Annu Rev Biochem 69:69; Yamamoto K et al 2001 EMBO J 20:3082; Lehrman MA 2001 J Biol Chem 276:8623; Glick BS 2001 Curr Biol 11:R361; Nicchita C 2002 Curr Opin Cell Biol 14:412; Hampton RY 2002 Curr Opin Cell Biol 14:476; Sitia R, Braakman I 2003 Nature [Lond] 426:891.

Figure E28. Quality control by ER

Endoplasmic Reticulum-Associated Degradation: Transmembrane and secretory proteins may enter the endoplasmic reticulum through the Sec61 channel. There they fold and may be oligomerized and then transferred to the Golgi apparatus. The status of glycosylation is critical for appropriate degradation. Misfolded proteins can be returned to the endoplasmic reticulum and finally to the cytoplasm where their degradation takes place. AAA-ATPases of the 19S proteasome may provide the energy for the transport. The protein may be ubiquitinated and degraded by the proteasome. Larger protein aggregates that occur in neurodegenerative diseases such as Huntington's

chorea and Parkinson's disease may not be ubiquitinated (Bennett EJ et al 2005 Mol Cell 17:351) and these are shuttled to the lysosomes for degradation by autophagy (Bjørkøy G et al 2005 J Cell Biol 171:603). ▶unfolded protein response, ▶AAA-ATPase, ▶CDC48, ▶Golgi, ▶ubiquitin, ▶proteasome, ▶autophagy; Römisch K 2005 Annu Rev Cell Dev Biol 21:435; Bukau B et al 2006 Cell 125:443.

Endopolyploid: A cell with increased chromosome number because of endomitosis, i.e., the chromosomes have replicated but cell division was skipped. Such phenomena commonly occur repeatedly in cultured plant and animal cells. ▶endomitosis, ▶endoduplication, ▶polyploidy

Endoproteases: A family of enzymes involved in the processing of proteins, e.g., the large peptide hormone precursors, large secreted proteins, pheromones, etc.

Endoreduplication: When the chromosome replication is not followed by centromere and cell divisions and therefore multistranded (polytenic) chromosomes are formed. The mechanism of this phenomenon requires the prolongation of the S phase and suppression of the M phase. Polytenic chromosomes are present in the salivary gland cells of some flies (*Drosophila*, *Sciara*, etc.), but they occur in some plant tissues too, e.g., the endosperm of cereals, in some cells (chalaza, antipodal) of *Allium ursinum*, *Aconitum ranunculifolium*, etc. In animals, the E2F-like proteins, and, in plants, the DP-E2F-like proteins regulate the process (Vlieghe K et al 2005 Curr Biol 15:59). Endoreduplication has been attributed, in plants, to the activities of topoisomerase II and topoisomerase VI during the mitotic cycles (Sugimoto-Shirasu K et al 2005 Proc Natl Acad Sci USA 102:18736). ▶polytenic chromosomes, ▶endoduplication, ▶chalaza, ▶antipodal cells, ▶replication during the cell cycle; Edgar BA, Orr-Weaver TL 2001 Cell 105:297.

Endorphins ("endogenous morphine"): Endorphins are neuropeptide ligands of opiate receptors in the brain pituitary gland and peripheral tissues of vertebrates. Their physiological effects mimic morphines. They have potential therapeutic use in nervous disorders, pain perception, etc. Introducing the β -endorphin gene into the cerebrospinal fluid may mitigate pain for longer periods than drugs. The prodynorphin opioid neuropeptide precursor might have played an important role in human evolution and in separation from the ape line (Rockman MV et al 2005 PLoS Biol 3(12):e387). ▶opiocortin, ▶pituitary, ▶morphine, ▶brain human, ▶POMC, ▶pain, ▶enkephalins; Coventry TL et al 2001 J Endocrinol 169:185.

Cope: A medical instrument for external examination of internal body cavities.

Endosome: ▶endocytosis

Endosomolysis: The disruption of the endocytotic vesicles and liberation their contents. ▶endocytosis

Endosperm: The nutritive tissue within the seed developed from the fertilized polar cells in the embryo sac. In some plants the endosperm develops to a substantial mass and persists as the bulk of the seed (the majority of the monocots). Alternatively, it may be gradually consumed and only traces are visible by the time the embryo fully develops because that function is relegated to the growing cotyledons (majority of dicots). In monocots the surface layer of the endosperm is called *aleurone*. Normally, the embryo is diploid and the endosperm is triploid. Some mutations may permit the development of the endosperm without fertilization of the fused polar nuclei. In species crosses, the 2:3 proportion may be altered with deleterious consequences for the embryo. By crossing a diploid female with a tetraploid male, the embryo will be triploid and the endosperm will be tetraploid (3:4), but by crossing a tetraploid female with a diploid male the number of genomes in the embryo remains the same (3n) but the endosperm will be pentaploid (3:5). Thus the gene dosage in the endosperm is usually different from that in the embryo. Some species of plants have different developmental patterns beginning with the embryo sac. ▶embryogenesis in plants, ▶embryo sac, ▶embryogenesis in plants; Olsen O-A 2001 Annu Rev Plant Physiol Mol Biol 52:233.

Endosperm Balance Number: The term was suggested for the unusual observations that within some species the tetraploids do not effectively fertilize other tetraploids (4x) but may do so with diploids (2x). When their chromosome number is doubled (8x) they may be crossed with tetraploids, except the progenitor tetraploid. Thus a curious chromosome balance is observed. ▶endosperm

Endosperm Mother Cell: The fused polar cells of the endosperm (2n) that when fertilized by a sperm give rise to the triploid endosperm tissue in the seeds of plants. ▶embryosac, ▶gametogenesis

Endospore: A dormant bacterial cell, resistant to most treatments that normally kill active cells. The process of sporulation has been extensively studied in *Bacillus subtilis*. *Clostridium tetani* and *Bacillus anthracis*, etc., also produce endospores. A fungal spore within a cell is also called an endospore. ▶forespore

Endostatin: A collagen XVIII C-terminal, ca. 20-kDa domain which, along with an angiostatin, can regulate angiogenesis and metastasis and may block

cancerous growth by denying the blood supply to tumors. Endostatin-integrin interaction is relevant to angiogenesis. More recent evidence questions the antitumor effectiveness of endostatin. ►angiogenesis, ►angiostatin, ►collagen, ►cancer, ►metastasis, ►integrin; Sim BK et al 2000 Cancer Metastasis Rev 19:181; Rehn M et al 2001 Proc Natl Acad Sci USA 98:1024; Kuo CJ et al 2001 Proc Natl Acad Sci USA 98:4605.

E

Endosteum: The lining of the bone medullary cavity, the endosteal lining.

Endosymbiont: An organism that lives within the cell of another. ►infectious heredity, ►mutualist, ►nucleomorph

Endosymbiont Theory: An evolutionary idea suggesting that plastids and mitochondria were originally free-living microorganisms, later captured by nucleated cells (archaebacterium) and which then became cellular organelles in eukaryotes see Margulis L 1993 in General references (Evolution). It appears that all photosynthetic plastids have a common origin as indicated by the analysis of the red alga *Cyanidoschizon merolae* (McFadden GI, van Dooren GG 2004 Current Biol 14:R514). This old hypothesis is supported by DNA sequence analyses primarily of organellar and eubacterial and archaebacterial rRNA genes. It appears that the plastid rRNA core sequences resemble that of Gram-positive cyanobacteria and the mitochondrial rRNAs indicate descents from eubacteria. The dispute among evolutionists regarding the monophyletic or polyphyletic endosymbiotic origins of these organellar genomes is still extant.

Secondary endosymbiosis is believed to occur when a eukaryote is ingested and retained by other eukaryotes with chloroplasts. In these cases four-layer membranes may enclose the organelles. The "old" endosymbiotic theory fails to interpret the fact that there are eukaryotes without mitochondria or hydrogenosomes. (In hydrogenosomes pyruvate is metabolized by pyruvate:ferredoxin oxidoreductase rather than by a pyruvate dehydrogenase complex.). Archaebacteria do not have evidence for structures homologous to those of eukaryotes. Also, mitochondrion-free eukaryotes seem to have genes, which resemble mitochondrial DNA sequences. Recently, the *hydrogen hypothesis* has been advanced (Martin W, Müller M 1998 Nature 392:37). According to the latter, an autotrophic archaebacterium host entered a symbiotic relationship with a eubacterium capable of respiration. This symbiont produced molecular hydrogen as a waste product of its heterotrophic metabolism that served well the host, thus forging

a stable relationship. In this system, from the symbiont hydrogenosomes, eventually mitochondria evolved. The symbiont transferred genes to the host for organic metabolism, enzymes, and ATP generation. Thus, from autotrophy heterotrophy evolved and the complex organism could utilize also the organic molecules. Eventually, more complex cellular structures evolved giving origin to eukaryotic cells. The obligate intracellular parasites of proteobacteria, *Rickettsia*, *Anaplasma* and *Ehrlichia* genomes appear to be closest to the mtDNA of animals. ►chloroplasts, ►mitochondria, ►nucleomorph, ►rRNA, ►Rickettsia, ►hydrogenosome, ►symbionts; Lang BF et al 1999 Annu Rev Genet 33:351; Wernegreen JJ 2004 PloS Biol 2:307.

Endosymbiosis: ►endosymbiont

Endosymbiotic Gene Transfer: ►organelle sequence transfer

Endothelin: The veins and inner tissues of the heart secrete this peptide hormone. It controls heart muscle functions, hypertension, including myocardial infarction, protein kinase A (PKA) and chloride, potassium and calcium ion channel functions. Mutation in the endothelin may lead to hereditary hypoventilation. Endothelin mutations may account for the Hirschsprung disease and the Shah-Waardenburg syndrome. The endothelin receptor (EDNRB) is required for melanoblast migration and development of the neural crest. Mast cells control endothelin level and limit its toxicity (Maurer M et al 2004 Nature [Lond] 432:512). Red wine reduces the synthesis of endothelin-1 and thus protects against coronary heart disease (Corder R et al 2001 Nature [Lond] 414:863). ►PKA, ►ion channels, ►Hirschsprung disease, ►Shah-Waardenburg syndrome, ►Alzheimer's disease, ►melanocyte, ►neural crest; Hunley TE, Kon V 2001 Pediatr Nephrol 16:752.

Endothelium: The layer of epithelial cells of mesodermal origin, and lining organ cavities.

Endothermic: A chemical reaction that takes up heat.

Endotoxins: Endotoxins are bacterial lipopolysaccharide toxins, attached to the outer membrane and secreted only inward in the cell and released only when the cell disintegrates. Endotoxins release large amounts of tumor necrosis factor (TNF) and interleukin-1 (IL-1). They may present a serious hazard to humans (diarrhea, bleeding, inflammation, increase of white blood cells, etc.) ►toxins, ►TNF, ►IL-1

Endpoint: In chemistry it indicates the highest dilution during titration that still gives a detectable reaction with another substance. In genetic toxicology it is the method of identification of the lowest effective dose of a mutagen or carcinogen that causes point mutations, chromosome breakage, unscheduled DNA synthesis, etc. ▶[bioassays of genetic toxicology](#), ▶[unscheduled DNA synthesis](#)

End-Product Inhibition: ▶[feedback control](#)

End-Sequence Profiling (ESP): ESP reveals genomic rearrangements by mapping sequence-tagged connectors. ▶[sequence-tagged connector](#); Volik S et al 2003 Proc Natl Acad Sci USA 100:7696.

Ends-In, Ends-Out Recombination: Site-specific, targeted recombinations (see Fig. E29). (See diagram, ▶[targeting genes](#); Gong WJ, Golic KG 2003 Proc Natl Acad Sci USA 100:2556)

Figure E29. Ends-in, Ends-out recombination. The shaded blocks represent homology. (From Gong WJ, Golic KG 2003). Ends-out, or replacement gene targeting in *Drosophila*. Proc Natl Acad Sci USA 100:2556–61. Copyright 2003 National Academy of Sciences, U.S.A.)

Ene: A Kaposi's sarcoma-associated herpesvirus polyadenylated nuclear RNA containing a 79-nt cis-acting element, which allows intronless polyadenylated transcripts to accumulate to high nuclear levels by protecting them from rapid degradation (Conrad NK et al 2007 Proc Natl Acad Sci USA 104:10412).

Enediynes: Enediynes are anticancer antibiotics. They cleave the DNA by generating benzenoid diradicals when activated. They cleave the DNA backbone by extracting from it hydrogen atoms. ▶[neocarzinostatin](#); Lode HN et al 1998 Cancer Res 58:2925; Liu W et al 2002 Science 297:1170.

Energy Charge: $[(ATP) + 1/2(ADP)] / [(ATP) + (ADP) + (AMP)]$; i.e., it measures the phosphorylating capacity of the adenylate system. The energy charge is 0

if only AMP is available and it is 1 if all AMP is converted to ATP. ▶[AMP](#), ▶[ATP](#)

Energy Coupling: The transfer of energy from one reaction path to another.

Enfuvirtide: Enfuvirtide is used for the successful infection of cells of the HIV virus; the surface glycoprotein complex is fused with the cell membrane. Peptides derived from the HR2 (heptad repeat) region of viral gp41 have been shown to have potent antiviral activity. Enfuvirtide (ENF/T-20/DP-178), the first approved fusion inhibitor for HIV, is a 36-aa peptide derived from this region. Novel fusion inhibitors that are active against ENF-resistant viruses and exhibit a higher genetic barrier to resistance are in development (Dwyer JJ et al 2007 Proc Natl Acad Sci USA 104:12772). ▶[acquired immunodeficiency](#)

Figure E30. *en*

Enhanceosome: A protein complex of special gene activators and HMG proteins involved in enhancing the activity (transcription) of interferon and other genes in response to various signals and cues (see Fig. E31). The enhanceosome includes histone acetyl transferases, CREB-binding proteins, and associated activators (GCN5).

HMGs are structural proteins facilitating their assembly after acetylation. Acetylation by CBP at lysine-65 destabilizes the complex but acetylation by GCN5 at lysine-71 stabilizes the complex, facilitates transcription, and fends off acetylation by CBP. ▶[enhancer](#), ▶[interferon](#), ▶[activator proteins](#), ▶[HMG](#), ▶[CREB](#), ▶[CBP](#), ▶[GCN5](#); Carey M 1998 Cell 92:5; Munshi N et al 2001 Science 293:1133.

Figure E31. Enhanceosome. DNA loop (continuous grey) is wrapped around the enhanceosome

Figure E32. MycCM3 enhancer directs LacZ expression in the neural tube • (Redrawn after Hallikas, O. et al. 2006 Cell 124:47)

Enhancer: Enhancers are cis-acting positive regulatory elements positioned (frequently near Z DNA) either upstream or downstream (by several kb) of the initiation of transcription. The enhancer may be located also within the transcription unit. Supercoiling of the DNA may facilitate enhancer activation of genes at a distance over 2,500 bp. It alters chromatin structure to facilitate transcription by binding special proteins (see Fig. E32). A single short or many short enhancer modules, which are bound by transcription factors, can control a single gene promoter. In case of multiple modules, the gene may be expressed in all tissues where one or more of the modules are active (Michelson AM 2002 Proc Natl Acad Sci USA 99:546). The enhancers may activate a gene for transcription or may increase the basal rate of transcription by two orders of magnitude. Enhancers (one or more) are present in all eukaryotic genes. The size of the enhancers varies from 50 bp to 1.5 kbp. Prokaryotes usually do not use enhancers, however, some σ^{54} subunits of RNA polymerase make this enzyme enhancer-responsive (Rappas M et al 2005 Science 3007:1972). Some of the clustered genes (e.g., HOX) may share enhancers. The prokaryotic enhancer element may also be situated upstream or downstream of the gene. For more about enhancers see Simian virus 40. On the basis of transcription factor-binding specificities a computational tool of enhancer element locator (EEL) has been developed. The method permits the genome-wide identification of multiple tissue-specific enhancers of genes/transgenes involved in control of growth and tumorigenesis (Hallikas O et al 2006 Cell 124:47).
 ▶G box, ▶silencer, ▶TAF, ▶activator, ▶regulation of gene activity, ▶octa, ▶core promoter, ▶POU, ▶homeotic genes, ▶transcription factor map; Bellen HJ 1999 Plant Cell 11:2271; Xu Z et al 2001 Gene 272:149; Liu Y et al 2001 Proc Natl Acad Sci USA 98:14883; enhancer browser: <http://enhancer.lbl.gov>.

Enhancer Competition: The imprinted genes *H19* and *Igf2* share the same enhancer, but *H19* is expressed in the maternal chromosome whereas *Igf2* is favored in the paternal chromosome and the two chromosomes were supposed to be in competition for the same enhancer. Newer evidence indicates that the differential control resides in ~2-kb region upstream from *H19*, the so-called ICR site (imprinting control region). ICR is apparently an allele-specific methylation-sensitive insulator, a boundary element. The conserved zinc-finger protein (CTCF) specifically binds to CG dinucleotide repeats, which occur in that region. ▶imprinting, ▶boundary element, ▶insulator; Cai HN et al 2001 Development 128:4339.

Enhancer Shuffling: The rearrangement of enhancer elements during development can account for differences in transcription. (See Kermekchiev M et al 1991 Gene Expr 1:71).

Enhancer Trapping: ▶gene fusion

Enhancesome: ▶enhanceosome

En-I (Enhancer-Inhibitor): A system of transposable elements of maize. ▶Spm

Enkephalins: Endogenous opioid peptides regulating pain, stress response, aggression, and dominance behavior. The pre-proenkephalin gene, encoding the precursor of Met-enkephalin, introduced by herpes simplex viral vector into the mouse afferent nerves may mitigate pain sensation for a longer term than analgesics. Enkephalin knockout mice displayed increased fear. Enkephalins regulate many neuronal and immunological functions. ▶opiates, ▶pain, ▶endorphin, ▶knockout

Enl: A serine- and proline-rich protein (encoded in human chromosome 19p13); in chromosomal translocations it may be responsible for acute lymphocytic leukemia. ▶leukemias

Enol Form: The form of a molecule that contains an OH group whereas the keto form has C = O (see Fig. E33). These may undergo enol-keto tautomerism; the enolic form may be subject to proton shift.
 ▶tautomeric shift, ▶hydrogen pairing

Figure E33. Enol and keto forms

Enolase (phosphopyruvate hydrolase, PPH, ENO): Enolase catalyzes the conversion of 2-phosphoglycerate into phosphoenolpyruvate; ENO1 is encoded in human chromosome 1pter-p36.13. The neuron-specific enzyme (ENO2) is encoded in human chromosome 12p13, and the muscle specific ENO3 is encoded in chromosome 17pter-p12.

Ensembl: An automated annotation program for some eukaryotic genomes and free software. (See series of articles in Genome Res [2004] 14:925 ff; <http://www.ensembl.org/>).

Ensoulment: A religious concept regarding the acquisition of soul by the human embryo. According to the current view of the Roman Catholic Church, ensoulment takes place at conception and that is the stage when life begins. Saint Thomas Aquinas, the thirteenth-century theologian and philosopher, entertained the view that ensoulment occurs during a later stage of embryonic development. The view on the stage of the beginning of life affects some doctrines on contraceptives, birth control, abortion, sanctity of life, and even criminal justice.

Entamoeba histolytica: A protist responsible for intestinal amoebiasis, a bloody diarrhea with high mortality in some underdeveloped areas of the world (see Fig. E34). Its infection generally stems from poor sanitation and feces-contaminated drinking water or raw vegetables, fruits and improper food handling, but it can spread by physical contact between infected persons or toilets. The organism does not contain mitochondria. Its genome contains 23,751,783 base pairs and 9,938 predicted genes. Its chromosomes do not condense and their number is uncertain. Apparently, lateral gene transfer from prokaryotes affected its evolution. ▶*Giardia*, ▶*Trichomonas*, ▶protozoa; Loftus B et al 2005 Nature [Lond] 433:865.

Figure E34. *Entamoeba* cell with ingested red blood cells

Entelechy: The vitalists postulated an inner force of organisms that is responsible for life and growth. In modern morphogenetic theory, it is the basis of the internal program of development.

Enterobacteria: A large group of gram negative bacteria with very wide distribution in insects, higher animals and plants, represented by *Escherichia coli*, *Salmonella*, *Shigella*, *Serratia*, *Klebsiella*, *Proteus*, *Shigella*, *Erwinia*, *Yersinia*, etc. Many of them are pathogenic, some are saprophytes, and others are facultative pathogens. (See genome annotation: <https://asap.ahabs.wisc.edu/asap/logon.php>).

Enterococcus faecalis V583: A gram-positive opportunistic pathogen bacterium. It has been sequenced and has 3,218,031 bp in the chromosome and the three plasmids are 66,320, 57,660 and 17,963 bp. It encodes 3,182 proteins, 12 rRNAs, 68 tRNAs, and 2 structural RNAs. More than one quarter of its genome is represented by mobile elements. ▶mobile genetic elements; Paulsen IT et al 2003 Science 299:2071.

Enterokinase Deficiency: An autosomal recessive defect in the activation of pancreatic proteolytic proenzymes (such as chymotrypsinogen, procarboxypeptidase, proelastase) by this intestinal enteropeptidase, and resulting, consequently, in hypoproteinemia and general weakness. ▶trypsinogen deficiency

Enteropeptidase: Same as enterokinase.

Enterotoxin: Enterotoxin is produced by enteric (intestinal) bacteria. ▶toxins

ENTH Domain: An epsin N-terminal homology domain that interacts with phospholipids of membranes. ▶epsin; Ritter B, McPherson PS 2006 Proc Natl Acad Sci USA 103:3953.

Enthalpy (H): The heat content or energy of a system.

Enthalpy Change (ΔH): The difference between the energy required for disrupting a chemical bond and the energy gained by forming a new one(s).

Entner-Doudoroff Pathway: In bacteria, from 6-phosphogluconate → 2-keto-3-deoxy-6-P-gluconate an aldolase generates pyruvate and triose phosphate.

Entoderm: Same as endoderm. ▶endoderm

Entomology: The study of insects. (See for plant health related data: <http://www.ent.iastate.edu/list/>).

Entomophagous: The feeding on insects.

Entomophagous Bacteria (entomopathogenic bacteria):
 ▶ *Bacillus thuringiensis*, ▶ *Photorhabdus luminescens*; de Maagd RA et al 2003 Annu Rev Genet 37:409.

E

Entrapment of mRNA: The molecule is kept inactive by a ternary complex. (See Schlax PJ et al 2001 J Biol Chem 276:38494).

Entrapment Vector: ▶ gene trapping vector

Entrainment: The exact match between the shift of an endogenous oscillator and the periods evoking the circadian rhythm. ▶ circadian rhythm, ▶ oscillator

Entrez (<http://www.ncbi.nlm.nih.gov/Entrez/>): The source of nucleotide and protein sequence information. Batch Entrez allows the retrieval of several sequences at once from a database and which after downloading can be analyzed on the local computer. Retrieval computer software and databases are distributed on CD-ROM. The software is public and available in Macintosh or IBM PC (Windows) formats. General questions through INTERNET: ▶ info@ncbi.nlm.nih.gov or ▶ net-info@ncbi.nlm.nih.gov. ▶ database, ▶ GenBank

Entrez Gene: Provides information on genes defined by sequence and/or NCBI's Map Viewer. It replaces LocusLink, and can be queried by names, symbols, accessions, publications, GEO terms, chromosome numbers, EC numbers and the products they encode, and by some other features. ▶ ENTREZ, ▶ Map Viewer; <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene>; gene statistics of >3,500 taxa: http://www.ncbi.nlm.nih.gov/projects/Gene/gentrez_stats.cgi.

Entrez Programming Utilities (E-Utilities): These tools support a uniform set of parameters used to search, link between, and download from the Entrez databases, and use in another environment (http://www.ncbi.nlm.nih.gov/entrez/query/static/eutils_help.html).

Entropic Trap Array: A nanofluidic device for the separation of 5,000 to 160,000 bp long DNA molecules. ▶ pulsed field electrophoresis

Entropy: The measure of energy unavailable for use within a system. The entropy increases by the natural processes of aging. The principle of entropy maximization can be applied to identification of the gene interaction network with the highest probability of giving rise to experimentally observed transcript profiles. Analysis of microarray data from genes in *Saccharomyces cerevisiae* chemostat cultures exhibiting energy metabolic oscillations identifies a gene

interaction network that reflects the intracellular communication pathways that adjust cellular metabolic activity and cell division to the limiting nutrient conditions that trigger metabolic oscillations. The success of the present approach in extracting meaningful genetic connections suggests that the maximum entropy principle is a useful concept for understanding living systems, as it is for other complex, nonequilibrium systems (Lezon TR et al 2006 Proc Natl Acad Sci USA 103:19033). ▶ genetic network

ENU (*N*-ethyl-*N*-nitrosourea): An ethylating agent; (see Fig. E35) one of the most potent point mutagens in mouse (mutation rate/locus 6.6 to 15 × 10⁻⁴). In *Arabidopsis*, within the concentration range of 0.25 to 1.25 mM (18 h exposure of seeds), it causes embryo lethals from 2.8 to 85.1% of the plants. (See Balling R 2001 Annu Rev Genomics Hum Genet 2:463; Herron BJ et al 2002 Nature Genet 30:185).

Figure E35. ENU

Enucleate: A cell without a nucleus. ▶ enucleation, ▶ nuclear transplantation, ▶ cytoplasm

Enucleation: The removal of the cell nucleus (see Fig. E36). (▶ nuclear transplantation, ▶ cytochalasin).

Figure E36. Enucleation

Env Z: A phosphorylating enzyme (kinase) on the bacterial membrane envelope.

Envelope: Envelopes are generally double-layer membranes (surrounding organelles) in the cell. The glycoprotein viral envelope surrounds the capsid of some viruses. ▶ virus

Environmental Deviation: Quantitative characters are manifested in a phenotypic value, called P that can be partitioned into a genotypic value G and an

environmental deviation, E, i.e., $P = G + E$ where P is measured as the mean value of a population. The value of G can be determined by heritability estimates. ► [heritability](#)

Environmental Effects: Environmental effects are of significant importance for the expression of genes. The genetic constitution provides the blueprint but the realization frequently has a variable environmental component. The genotype had been identified as providing a programmed *reaction norm*, but the temporal sequence and intensity of gene expression is determined by the internal regulatory DNA elements and the environment. Among the endless good examples are, the expression of inducible enzymes, the immune reactions, the switching from fetal hemoglobin ζζ in the early embryo to ααGγAγ by the 8th week then to ββδδ shortly before birth and by six months postnatal when it switches to ααββ with about 2% ααδδ. In plants, the onset of the flowering in many species requires vernalization and/or appropriate photoperiodism. Sometimes, environmental effects persist through meiotic events. ► [dauermodification](#), ► [delayed](#), ► [inheritance](#), ► [maternal](#), ► [effects](#), ► [epigenesis](#). The environment exercises greatest effect on the expression of quantitative genes. Many environmental factors are mutagenic, these may include food and feed additives, cosmetics, drugs, medicines, industrial and agricultural chemicals, natural food products, radioactive fallout. ► [quantitative traits](#), ► [heritability](#), ► [environmental mutagens](#), ► [salt tolerance](#), ► [cold-regulated genes](#), ► [case-case design](#); Xiong L et al 2002 Plant Cell 14:S165; human disease: Hunter DJ 2005 Nature Rev Genet 6:287.

Environmental Load: Some specific environmental conditions may favor and maintain alleles that convey inferior fitness to the individuals under usual, average conditions. The alleles so maintained represent the environmental load of the population. ► [genetic load](#)

Environmental Mutagens/Toxins: Carcinogens and teratogens occur in the laboratory, industry, and agricultural environment. According to the estimates of the U.S. National Research Council, approximately 70,000 chemicals are in use and their number is increasing steadily. Their biological effects are not completely known. A survey of about 80 products of engineered protein did not appear toxic (with the exception of interferon) and one humanized antibody + linker might have had some genotoxicity (Mutation Res. 436:137). Many potentially mutagenic agents are present in every household, in the industry and in the research laboratories. The response to these potentially hazardous agents is determined or influenced by the genetic constitution of the individuals

(susceptibility and resistance genes) and a number of factors in the environment besides the few agents named here. A very incomplete list follows:

- Acetaldehyde: An intermediate of organic solvents, preservative of certain food products; it may be present in small quantities in the sweet smell of ripening fruits.
- Acridine dyes: Laboratory chemicals and may be present in some antimalaria drugs.
- Acrylamides: Used for gel electrophoresis and are absorbed through the skin. They are present in some highly heated food but do not seem to pose a cancer risk because of the low amounts.
- Actinomycin D: An antibiotic used to block transcription in the laboratory is a carcinogen.
- Aflatoxins: About a dozen different natural products of *Aspergillus* fungi detectable on peanuts, grains and other feed and food and cause mutation as well as liver cancer.
- Allylthiocyanate: Present in cruciferous vegetables, mustard condiments, and horseradish.
- 3-Aminotriazole: A herbicide that is largely undetectable by mutagen assays, yet it is a powerful carcinogen.
- Aramite: An insecticide used some time ago for fumigation of greenhouses.
- Asbestos: A heat insulator and filtering agent, present in many buildings and can cause malignant mesothelioma (malignancy of the pleura [membrane of the thoracic cavity and lung], peritoneum [membrane of the abdominal wall] and pericardium [envelope of the heart]).
- Atabrine: An antimalaria drug.
- Atrazine: A herbicide that may be activated into a mutagen by the metabolism of plants.
- 5-Azacytidine: Interferes with DNA methylation.
- Benzimidazole: May be present in pharmaceuticals, preservatives and insecticides.
- Benzidine: A laboratory reagent.
- Benzo(a)pyrene: Regularly formed during combustion of many organic materials (in fire-places, automobile exhaust fumes, grilled-charcoal-broiled meat, tobacco smoke), refined mineral oils, and commercial wax products.
- Bisphenol A: Used for manufacturing resins and plastic coating of various containers. Bis-phenols are estrogenic endocrine-disrupting chemicals (EEDC) mimicking the action of estradiols. They affect (sexual) development and responses to diseases.
- β-Propiolactone: Used as plasticizer, in wood processing, tobacco processing, as an additive in leaded gasoline, and insecticides.
- Boric acid: Used for numerous industrial purposes and also as an insecticide and fungicide.

E

- Bracken fern extracts: Bracken ferns may be eaten by grazing animals and they are then exposed to mutagenic and carcinogenic compounds of this plant.
- Cadmium: In nickel-cadmium batteries, paints; an inhibitor of DNA mismatch repair.
- Caffeine: Caffeine itself is not mutagenic or carcinogenic, but it interferes with genetic repair mechanisms.
- Captan: A fungicide.
- Carbontetrachloride: A solvent and seed fumigant.
- Chloral hydrate: A microtechnical reagent and a sedative.
- 2-Chloroethanol: A polymerizing agent, insecticide, and herbicide. It is present in some sedatives.
- Chloroform: A laboratory solvent, found in some office supplies. It may be formed in chlorinated drinking water.
- Chloroprene: Chloroprene is present in elastomers and adhesives.
- Chlorpromazine: Present in some tranquilizers.
- Coal tar: Present in soot, roofing tar, and asphalt (bitumin).
- Colchicine: Used for polyploidization; it is very toxic.
- Cycasin: Present in cycade plants.
- Cyclosporin: An immunosuppressant and antibiotic drug.
- Diamines: Contained by some hair dyes.
- Diazomethane: A laboratory reagent.
- Dichlorvos: An insecticide.
- Diepoxybutane: An industrial polymerization agent; may be present in some pharmaceuticals.
- Diethylene glycol: An industrial chemical; has been used for pharmaceutical products as a counterfeit glycerol substitute and caused fatal poisoning.
- Diethylsulfate: A supermutagen.
- Dimethylsulfate: An industrial methylating agent of cellulose, a polymerizing compound, insecticide, and stabilizer.
- Dioxin: A contaminant in some herbicides and deodorant soaps (now banned).
- Dithranol: Present in some antidermatosis and ringworm drugs.
- EDTA (ethylenediamine tetraacetic acid): A chelator and antioxidant in laboratory and industry.
- Epichlorohydrine: Present in some epoxy resins, gum, paint, varnish, nail polishes, manufacturing crease-resistant fabrics, paper processing, and waterproofing.
- Epoxides: Precursors of ethylene glycol, dioxane, carbowax, monoethanolamine, acetonitrile, plastics, and gaseous sterilants. Epoxides may be trapped in the products or any material in contact with them and may be contaminated.
- Estrogen (β -estradiol): A fertility hormone used in ART and is indirectly carcinogenic. Estrogen-like substances in the environment may adversely affect the reproductive system.
- Ethidium bromide: Used as a nucleic acid stain and as a mutagen for mitochondrial DNA.
- Ethylmethane sulfonate: One of the most widely used and most potent laboratory mutagens.
- Some methanesulfonates are now banned ingredients of older prescription drugs.
- Ethyleneimine: Used for the manufacture of flame-retardant clothing, in crease-resistant and shrinkage controlling of fabrics, in insecticides, soil-conditioners, and synthetic fuels. It is a supermutagen.
- Ethylenedibromide: A fumigant for grain storage.
- Ethylmercuric chloride: A fungicide.
- Fats (after oxidation in rancid food): Such fats may become mutagenic and carcinogenic.
- Formaldehyde: A disinfectant, preservative of museum specimens of animals and organs, fixative, in adhesives, a crease-, crush-, and flame resistance aid in automobile exhausts.
- Fumes: Released by outdoor burning, defective wood-burning fireplaces, and coal furnaces.
- Glycidol: May be present in glycerol; it is used for manufacturing water-repellent fabrics and food preservative. It is a very powerful mutagen.
- Hair-dyes: Certain types are mutagenic/carcinogenic.
- Hydrazines: Found in photographic materials, rocket fuels, preservatives, solvents, and gasoline additives.
- Hydrogen peroxide: Used for bleaching flour, starch, paper, tobacco, cosmetics (hair lightener) stabilizers and plasticizers.
- Hydroxylamine: Used in nylon manufacturing, photographic materials, adhesives, and paints. It converts, specifically, cytosine into a thymine analog.
- Hydroxyurea: Breaks heterochromatin in the chromosomes and is present in some antileukemic, dermatological drugs.
- Isotopic tracers for emitting β and γ radiations.
- Lindane: A fungicide.
- Methylene chloride (dichloromethane): An industrial solvent; also used in food processing.
- Nicotine: An addictive component of tobacco; smoking is a major cause of human cancer.
- Nitrosoamines: Extremely powerful mutagens, but present in small quantities in nitrite treated meat products; formed from nitrites by the action of stomach acids and intestinal microbes.
- Nitrofurans (AF-2): A onetime widely used preservative in Japan for fish and soybean products.
- Nitrogen mustards: Used as anticancer drugs; they are powerful radiomimetic agents.

- Nitrosoguanidines: Extremely potent laboratory mutagens.
 - Nitrous acid: Widely used preservative for meat products, nitrous acid is a direct mutagen and can be converted by mammalian metabolism into nitrosoamines.
 - Organomercurials: Were widely used in fungicides.
 - PCB (polychlorobiphenyls): Present in electric transformers.
 - Perchlorate: A possible pollutant of rocket fuels, which may decrease the level of thyroid hormones and adversely affect brain development.
 - Perfluorooctanoic acid (PFOA/C8): A suspected carcinogen released from some food packaging material (popcorn bags) and overheated Teflon pot lining and other plastics.
 - Peroxides: Bleaching agents, disinfectants; they may be formed from tryptophan under UV.
 - Phenol: Used in DNA extraction. Phenol is extremely toxic and causes vesicles on skin; possibly mutagenic.
 - Phenylmethylsulfonyl fluoride (PMSF): Used in pulsed-field gel electrophoresis. It is very toxic and absorbed through the skin.
 - Phthalates: Plasticizers used in some cosmetics and nail polish.
 - Polybrominated diphenyl ethers: Flame retardants and developmental toxins (neurotoxins) and possible carcinogens.
 - Polychlorinated biphenyls: Once used for various industrial processes and in pesticides.
 - Polycyclic aromatic hydrocarbons: These include volatile, semivolatile and particulate material.
 - Propane sultone: May be present in detergents and dyes.
 - Pyrrolizidine alkaloids: Occur in several species of plants like *Senecio*, *Crotalaria*, etc.
 - Quinacrine: An antimalarial drug.
 - Safrrole: A food additive and coloring agent; it is also present naturally in root beer.
 - Sodium azide: A laboratory reagent and powerful mutagen in some organisms but not in others.
 - Sodium bisulfite: A preservative in fruit juices, wine, and dried fruits.
 - Sodium nitrite: A common preservative of cold cuts, fish and cheese, and can be converted in the body into nitrosoamines.
 - Soot: Contains hydrocarbons such benzo(a)pyrene and 7,12-dimethylbenz(a)anthracene.
 - Streptozotocin: A prescription drug used against athletes' foot fungus; an alkylating agent.
 - Styrene: In reinforced plastics, resins and insulators. It is a clastogen.
 - Tetramethylenedisulphotetramine: Banned rat poison, yet there are sporadic human exposures
 - Thiotepea: Used as a flame retardant, in crease-resistant and water-proof fabrics, and in manufacturing dyes, adhesives and drugs.
 - Trichloroethylene: A weak mutagen that may be present in dry-cleaning agents, degreasing fluids, paints, varnish and food-processing solvents.
 - Triethylenemelamine: A cross-linking agent, used for finishing rayon fabrics, waterproofing of cellophane, insect chemosterilant and in anticancer drugs.
 - Trimethylphosphate: A gasoline additive, insecticide, flame retardant, polymerizing agent, and insect chemosterilant.
 - Tri(2,-3-dibromopropyl) phosphate: A flame retardant.
 - Ultraviolet radiation: May cause skin cancer (melanoma) and mutation in tissues close to the surface; may also be hazardous through the peroxides generated. Wear protective goggles.
 - Urethanes: Used by the plastic industry for manufacturing resins, fibers, textile finishes, herbicides, insecticides, and drugs.
 - Vinyl chloride: The monomer of polyvinyl plastics. May be liberated from the polymers by heat (in a locked-up car) and may contaminate the surface of plastic sheets, bags, water hoses. The monomer is a powerful carcinogen and mutagen requiring metabolic activation. It forms the adduct N²-3-ethenoguanine.
- Many of the mutagens and carcinogens require metabolic activation for effectiveness. There is an inter-individual variability of susceptibility particularly at low degrees of exposure. It has been suggested that the majority of "environmental mutagens" are not the primary cause of mutagenesis/carcinogenesis, rather the endogenous pre-mutations are selected by these agents (Thilly WG 2003 Nature Genet 34:255). UV light, cigarette smoke may be, however, acting directly.
- Ames test, ► mutagen essays, ► bioassays for environmental mutagens, ► mutagenic potency, ► activation of mutagens, ► adduct, ► pseudo-cholinesterase deficiency, ► choline esterase, ► carcinogens, ► air pollution; Waters M et al 1999 Mutation Res 437:21; Albertini RJ et al 2000 Mutation Res 463:111; Johnson FM 2002 Env Mol Mutagen 39:69; <http://toxnet.nlm.nih.gov>, structure-searchable toxicity database: <http://www.epa.gov/nheerl/dsstox>; 1485 compounds of potential carcinogenic potency: <http://potency.berkeley.edu/cpdb.html>, geographic distribution of toxic substances released: ► toxmap; genes and environment initiative: <http://genesandenvironment.nih.gov/>, <http://nationalchildrensstudy.gov/>.

Enzootic: An infection that may be present among animals all the time but which shows up only sporadically or flares up only under certain conditions.

Enzyme: A protein (+ cofactor) that catalyzes (biological) reactions. ► [catalysis](#), ► [enzymes](#)

E

Enzyme Design: The replacement of amino acids in a protein may generate a new biological function (plasticity). Simultaneous incorporation and adjustment of functional elements by insertion, deletion, mutation, and substitution of several active sites into an existing protein scaffold causes new catalytic activity. The introduction of β -lactamase activity into a metallohydrolase scaffold of glyoxalase II resulted in the creation of a new metallolactamase that lost its original activity but catalyzed the hydrolysis of cefotaxime and increased the resistance of *E. coli* to this antibiotic by ~ 100 fold. (Park H-S et al 2006 Science 311:535). Genuinely new enzymatic activities can be created de novo, without the need for prior mechanistic information, by selection from a naive protein library ($>10^{12}$) of very high diversity, with product formation as the sole selection criterion. Ligases have been selected this way with rate enhancements of more than two-million-fold (Seelig B, Szostak JW 2007 Nature [Lond] 448:828). ► [protein engineering](#), ► [glyoxal](#), ► [cefotaxime](#); Dwyer MA et al 2004 Science 3004:1967; divergent evolution of enzymes: Yoshikuni Y et al 2006 Nature [Lond] 440:1078.

Enzyme Induction: Requires the presence of the substrate or substrate analog. ► [Lac operon](#), ► [Arabinose operon](#)

Enzyme-Linked Immunosorbent Assay: ► [ELISA](#)

Enzyme Mimic: A catalytic antibody.

Enzyme Mismatch Cleavage (EMC): An EMC uses the resolvase enzyme of bacteriophages to recognize and cut at mismatches in double-stranded DNA that has been amplified by PCR. The PCR-amplified DNA is expected to have matching and nonmatching strands if there was mismatched in the original double-stranded DNA. This way heterozygosity or mutation may be detected after gel electrophoresis. ► [resolvase](#), ► [mismatch](#), ► [mutation detection](#)

Enzyme Replacement Therapy: Gaucher disease is caused by deficiency of the enzyme glucocerebrosidase/glucosylceramidase. In patients, the infusion of macrophages carrying the enzyme one to four times a week or twice a month, significantly improved most of the symptoms (Barton NW et al 1991 New

Engl J Med 324:1464; Weinreb NJ et al 2002 Am J Med 113(2):112). Clinical trials are underway for Fabry disease (Schiffmann R et al 2001 J Am Med Assoc 285:2743), mucopolysaccharidoses (Kakkis ED 2002 Expert Opin Investig Drugs 11:675), Pompe disease (Amalfitano A et al 2001 Genet Med 3(2):132), and other lysosomal storage diseases. Research is underway for the treatment of phenylketonuria with recombinant phenylalanine hydroxylase (Gamez A et al 2004 Mol Ther 9:124). ► [Gaucher disease](#), ► [Fabry disease](#), ► [mucopolysaccharidosis](#), ► [glycogen storage diseases](#), ► [phenylketonuria](#), ► [gene therapy](#), ► [blood-brain barrier](#)

Enzymes: Enzymes, in general, are protein molecules. Some ribonucleic acids and DNAs also have enzymatic functions (ribozymes, DNA-zymes). The protein part of the enzyme is the apoprotein or apoenzyme. Their catalytic function may require cofactors, such as metals (Cu^{2+} , Fe^{2+} , K^{+} , Mg^{2+} , Mn^{2+} , Mo^{3+} , Zn^{2+} , etc.) or organic compounds (vitamins, nucleotides, etc.) called coenzymes, also called the prosthetic group of the enzymes. The complete enzyme (apoenzyme + prosthetic group) is the holoenzyme. Enzymes are organic catalysts; they mediate biochemical reactions without becoming parts of the reaction products, and enhance the reaction rates by $\sim 10^{10}$ to 10^{15} fold. The site(s) of the enzyme molecule interacting with the substrate (the molecule to be acted on) are the active sites of the enzymes. Enzymes carry out gene functions. RNA is transcribed on the DNA and the RNA is translated into a protein. Enzymes are named by adding “ase” to either the name of the substrate or to the name of the reaction, e.g., DNase, phosphorylase. The International Union of Biochemistry (*Enzyme Nomenclature*, 1972, Elsevier, Amsterdam) classified enzymes into six major groups and assigned code names to them. The six groups are 1. *oxidoreductases* (transfer electrons); 2. *transferases* (catalyze molecular group transfers); 3. *hydrolases* (cleave covalent bonds and transfer H and OH, respectively to the products); 4. *lyases* (form or remove double bonds); 5. *isomerases* (rearrange molecules internally); 6. *ligases* (mediate condensations by forming C-C, C-N, C-O and C-S bonds while cleaving ATP). In technical descriptions, enzymes are identified by EC (enzyme classification) numbers where the first digit refers to the number of one of the above groups and the following digits specify more closely the nature of the reaction mediated, thus DNA polymerase I of *E. coli* has the EC number 2.7.7.7, whereas restriction endonuclease Eco RI is 3.1.21.4., bovine RNase is 3.1.27.5 and glucose-6-phosphate dehydrogenase is 1.1.1.49. Some enzymes are modular, i.e., they may have interchangeable components with other enzymes

or may be components in different catalytic complexes. ►protein synthesis, ►inhibition, ►repression, ►induction, ►allosteric control, ►competitive inhibition, ►effector, ►Michaelis Menten equation, ►Lineweaver Burk equation, ►Eadie Hofstee plot, ►regulation of enzyme activity, ►subunits, ►recombination mechanisms, ►restriction endonucleases, ►ribozymes, ►enzymes multifunctional, ►DNA-zyme, ►BRENDA; Nature (Lond) 409 [2001]:225 ff on biocatalysis, action theory: Garcia-Viloca M et al 2004 Science 303:186; kinetics and energetics: Kraut DA et al 2003 Annu Rev Biochem 72:517; nomenclature database: <http://www.expasy.ch/enzyme/>; amino acid interactions, ligands (substrate, cofactors, inhibitors, etc.): <http://precise.bu.edu/>; catalytic mechanisms: <http://mbs.cbrc.jp/EzCatDB/>; <http://www.ebi.ac.uk/thornton-srv/databases/MACiE/>.

Enzymes, Multifunctional: During the 1940s, the then revolutionary one gene-one enzyme theory was proposed. Since then it has been recognized that the attachment of different prosthetic groups and altering of active sites, using different promoter sites, alternate processing, post-translational modifications, etc., may contribute to the production of different proteins from the same DNA sequence (Perham RN 2000 Annu Rev Biochem 69:961).

Eomes (comesodermin): ►eomesodermin

Eomesodermin (Eomes): A transcription factor attaching to a T box (see MAR) and regulating trophoblast and mesoderm development in mice. Eomes and T-bet are 74% identical in their T-box region. T-bet is a key factor of activation of effector CD8⁺T lymphocytes defending against viruses, intracellular microbes, and tumors. Translocation involving human chromosomes 3p and 10q leads to microcephaly and other brain defects (Baala L et al 2007 Nature Genet 39:454). ►trophoblast, ►mesoderm, ►T cell, ►T-bet, ►T-box, ►memory immunological; Pearce EL et al 2003 Science 302:1041.

Eosinophil: The white blood cells (readily stainable by eosin dye) generally display a bilobal large nucleus. They modulate allergic and inflammatory reactions of the animal body and mediate the destruction of parasites(see Fig. E37). ►granulocytes, ►blood

Figure E37. Eosinophil

Eotaxin: A C-C type chemokine. ►chemokines

EP: Effector proteins stimulate the conversion of E.GTP into E.GDP. ►GTP, ►GDP

EP (early pressure): Early pressure in zebrafish gynogenetic embryos is produced by exposing early embryos, fertilized by UV-inactivated sperm, to high hydrostatic pressure immediately after fertilization to suppress the second meiotic anaphase. A heat shock, 15 minutes after fertilization, suppresses the first mitotic division and leads to gynogenesis. ►gynogenesis, ►zebrafish, ►UV

EPA: RAP1.

e-PCR (electronic PCR): An electronic PCR can be used to search for matches to STS primer pairs in the UniSTS database (forward e-PCR) or to estimate the genomic binding site, amplicon size and sets of primer pairs by searching against genomic and transcript databases of some major genetic organisms (reverse e-PCR). ►PCR, ►STS, ►UniSTS, ►amplicon; <http://www.ncbi.nlm.nih.gov/sutils/e-pcr>.

Ependymoma: The brain or spinal chord covering membrane neoplasia.

EPH (ephrin): A family of receptor tyrosine kinases involved in axon guidance and synaps regulation of integrin, cell migration, embryo differentiation and indirectly signals to the cytoskeleton. The EPH proteins guard against mixing of different cell types (rhombomeres) during early embryonal development of animals. They form two subclasses, EphA and EphB. The EphA receptors are connected by ephrin-A ligands (glycosyl-phosphatidylinositol) to the cell membrane. The EphB receptors use ephrin-B ligands. EphB receptors regulate excitatory synapses by interacting with NMDA receptors. Alternative splice forms of a tyrosine kinase receptor control adhesion or repulsion of cells during embryogenesis. These ligands have different names in different organisms and tissues. The Ephrin-A/Eph-A receptor signaling negatively regulates brain size of mice by apoptosis; loss of Eph-A function reduces apoptosis of neural progenitor cells and increases cortical size of the brain and sometimes exencephalic outgrowth (Depaepe V et al 2005 Nature [Lond] 435:1244). EphrinB receptors coordinate migration and proliferation in the intestinal stem cell niche (Holmberg J et al 2006 Cell 125:1151). EphrinB2 specifically binds the attachment glycoprotein of the Nipah virus (paramyxovirus) and facilitates its infection of a wide range of mammals, including humans. In humans, the virus causes encephalitis with a 70% fatality (Negrete OA et al 2005 Nature [Lond] 436:401). ►tyrosine protein, ►kinase, ►receptor, ►tyrosine kinases, ►netrin, ►neurogenesis, ►synaps, ►rhombomeres,

E

Ephedra (ephedrin): A plant alkaloid used as a dietary supplement for weight control. Unfortunately it is not entirely safe because it may cause hypertension, increased heartbeat (tachycardia), stroke and occasionally death. Dietary supplements containing Ephedra were ordered off the markets in November 2004 by the FDA (Federal Drug Administration USA).

Ephelides: ► **freckles**

Ephrim: ► **EPH**

Epiallele: A developmentally changed allele usually without DNA alteration; it may also arise as the result of mitotic gene conversion or recombination. ► **epigenesis**, ► **epimutation**; Rakyen VK et al 2002 *Trends Genet* 18:348.

Epiblast: The precursor of the ectoderm and other embryonal tissues. The epiblast of the inner cell mass of the pre-blastocyst is a good source of stem cell isolation, although the stage of the stem cells may have different developmental potentials (Tesar PJ 2005 *Proc Natl Acad Sci USA* 102:8239). ► **ectoderm**, ► **organizer**, ► **blastocyst**, ► **stem**, ► **cells**

Epiboly: The first embryonic cell movement whereby the upper portion of the yolk bulges in the direction of the animal pole, resulting in the formation of a dome. The blastoderm cells begin spreading dorsally over the yolk until the cell sheet meets at the ventral midline. During zebrafish epiboly, the chimerin family Rac-GAP (Rac-GTPase activating protein) modulates epiboly. Essential modules are involved with GTPase activity and binding of the lipid second messenger diacylglycerol and phorbol esters (Leskow FC et al 2006 *Proc Natl Acad Sci USA* 103:5373). ► **morphogenesis in *Drosophila***, ► **notochord**, ► **RAC**, ► **diacylglycerol**, ► **phorbol**; Marsden M, DeSimone DW 2001 *Development* 128:3635.

Epicanthus: Vertical skin folds near the eyelid; it is a normal characteristic for some oriental human races and some syndromes affect it also. ► **Down syndrome**, ► **ptosis**, ► **Forkhead**

Epichromosomal: Outside the chromosomes; an epichromosomal vector does not integrate into the chromosome and thus does not cause insertional mutation, but it may not be able to replicate continuously.

► **vectors**, ► **insertional mutation**; Rajcan-Separovic E et al 1995 *Hum Genet* 96:39.

Epicotyl: The stem section immediately above the cotyledons of plant embryos and seedlings.

Epidemiology: The study of the distribution, cause and modifying factors of diseases and genetic defects in human and other populations. ► **population genetics**, ► **founder effect**, ► **genetic drift**, ► **inbreeding**, ► **occupational hazard**, ► **mutation detection**, ► **genetic toxicology**, ► **case-case design**, ► **infection**; Ioannidis JP et al 2006 *Nature Genet* 38:3; Human Genome Epidemiology Network (HuGENet): <http://www.cdc.gov/genomics/hugenet/default.htm>, Western Australian resources: <http://www.wager.org.au>.

Epidemiology, genetic: Genetic epidemiology studies the distribution of genetic variations of hereditary diseases, using primarily molecular tools such as blood groups, RFLP, and SNP. ► **blood groups**, ► **RFLP**, ► **SNIP**, ► **linkage**, ► **disequilibrium**, ► **epidemiology**; Bonassi S, William WA 2002 *Rev Mut Res* 511:73.

Epidermal growth factor: ► **EGF**

Epidermis: The nonvascular outer cell layer, derived from the embryonal ectoderm of animals; the surface cell layer of plants. In mouse, epidermal cells deletion of the guanosine triphosphatase Rac1 stimulates terminal differentiation and depletes stem cells required for the maintenance of interfollicular epidermis, hair follicles and sebaceous glands. This effect of Rac1 takes place by negative regulation of c-Myc though p21-activated kinase, PAK2. In this regulation cell adhesion and the cytoskeleton play an important role (Benitah SA et al 2005 *Science* 309:933). In higher animals there is an integument, the stratum corneum (a horny [calloused] layer of dead cells), and in insects, the cuticle for the protection of cell layers beneath. Wounding by microbes provokes an immune response to neutralize the infection and activate nuclear genes involved in protection against pathogens and healing the defect. In plants (*Arabidopsis*), the epidermis controls shoot growth and it is mediated by the presence of brassinosteroid receptor or brassinosteroid synthetic enzymes that are not present in the vasculature (Savaldi-Goldstein S et al 2007 *Nature [Lond]* 446:199). ► **RAC**, ► **PAK**, ► **Myc**, ► **CAM**, ► **cytoskeleton**, ► **brassinosteroids**; Mace KA 2005 *Science* 308:381.

Epidermoblast: Gives rise to the epidermal cells.

Epidermolysis: The dissolution of the skin in spots resulting in blisters (bullae) such as ichthyosis, keratosis, pemphigus, acrodermatitis, porphyria, etc. (see Fig. E38).

Figure E38. Epidermolysis bullosa. (From Bergsma D ed. 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

It is a characteristic symptom of many hereditary skin diseases. The epidermolysis bullosa simplex is encoded in human chromosome 8q24.13-qter and it is caused by mutation in plectin, whereas a similar disease of mouse is associated with a defect in integrin. Junctional epidermolysis bullosa may be due to mutation either in collagen (Col17A1) or laminin protein subunits or in both. Epidermolysis bullosa is a very complex disorder due to defects at 1q32, 1q25-q31, 3p21.3, 10q24, 12q13, 17q11-qter, 17q12-q21. ▶skin, ▶diseases, ▶collagen, ▶intermediate, ▶filaments, ▶plectin, ▶integrin, ▶collagen, ▶laminin; Fine JD et al 2000 J Am Acad Dermatol 42:1051; Ortiz-Urda S et al 2005 Science 307:1773.

Epididymis: A narrow pouch-like structure attached to the testis; it serves for storage, maturation, and forwarding the spermatozoa into the vas deferens during ejaculation. ▶cryptorchidism

Epifluorescence: Epifluorescence is used by special microscopy when the high intensity UV, blue, yellow, or red light is transmitted to the specimen through the objective rather than directly. Only the reflected excitatory light is filtered providing much higher intensity through the eyepieces of the microscope. The techniques generally use appropriate filters and fluorescent dyes for histology, microbiology, and molecular biology.

Epigene conversion: If the gene is introduced into the genome in an additional copy (by transformation of plants) that is hypermethylated, the other copy is silenced by transcription because the methylated promoter is, presumably, imposed on the unlinked promoter. ▶co-suppression, ▶silencer

Epigenesis: The process by which differentiation takes place from undifferentiated cells as programmed by the genome, without any mutational event (base substitution). It is sometimes defined as the mechanism of different types of gene expression from the same nucleotide sequences due to structural changes

in the chromatin and cooperative effect of transcription factors, other regulatory elements and methylation of the gene(s). Typical examples are the different functions of neurons and hepatocytes or plant roots and petals despite the identity of their genome. Epigenetic regulation is somewhat different from the controls of transcriptional activators and repressors that may be subject to great fluctuations. Epigenetic alterations are more stable, involving covalent modifications of the nucleotides and histones—for e.g., by methylation—that are submitted from cell to cell during mitosis and sometimes persist through meiosis. Movement of transposable elements is often considered an epigenetic event despite the fact that it may reorganize and alter the genome. Some mechanisms of gene silencing and activation, such as acting on methyl transferases, histone deacetylases including the action of siRNA are also considered epigenetic (Egger G et al 2004 Nature [Lond] 429:457). It is expected that during meiosis the epigenetic alterations would be erased and, subsequently, reversion take place at the embryonic stage. In fission yeast the mating type conversion genes (*mat*) are, however, transmitted not just mitotically but meiotically too. Similar examples in higher organisms are the paramutant state, imprinting, the position type variegation and paramutation. Meiotic transmission of the epigenetic state has been observed in fission yeast and *Drosophila* that do not methylate DNA much. Hyperacetylation of histone 4 (H4) may be involved in the transmission of the epigenetically activated state. Upregulating genes may have therapeutic value but may have complex and unforeseeable deleterious effects. Epigenetic alterations have decisive roles in carcinogenesis and in the development of various human diseases. CpG island promoter hypermethylation represses tumor suppressor genes, and hypoacetylated and hypermethylated histone H4 transcriptionally silences these genes. Tumor suppressor p21^{WAF1}/CDKN1A and some other tumor suppressors may not even need the CpG hypermethylation for their silencing. In cancer cells H4 lysine 16 residue is acetylated and Lys20 is trimethylated as a general feature of the tumorous condition (Fraga MF et al 2005 Nature Genet 37:391). The epigenetic state of genes can be mapped. Lysine 4 and lysine 27 trimethylation effectively discriminates genes that are expressed, poised for expression, or stably repressed, and therefore reflect cell state and lineage potential. Lysine 36 trimethylation marks primary coding and noncoding transcripts, facilitating gene annotation. Trimethylation of lysine 9 and lysine 20 is detected at satellite, telomeric and active long-terminal repeats, and can spread into proximal unique sequences. Lysine 4 and lysine 9 trimethylation marks imprinting control regions. The chromatin state can be read in an

allele-specific manner by using single nucleotide polymorphisms (Mikkelsen TS et al 2007 Nature [Lond] 448:553). ▶preformation, ▶reaction norm, ▶position effect, ▶imprinting, ▶bivalent, ▶promoter, ▶uniparental disomy, ▶mating type determination, ▶CpG motif, ▶methylation of DNA, ▶PAD4, ▶prion, ▶RIGS, ▶co-suppression, ▶peloric, ▶paramutation, ▶RIP, ▶MIP, ▶RIGS, ▶RNAi, ▶RdRP, ▶histones, ▶histone methyltransferases, ▶histone deacetylases, ▶histone, ▶demethylase, ▶histone variants, ▶p21, ▶histone code, ▶heterochromatin, ▶phenocopy, ▶morphosis, ▶RLGS, ▶reprogramming, ▶CpG, ▶islands, ▶lyonization, ▶insulator, ▶Polycomb, ▶SET motifs, ▶non-coding DNA, ▶noncoding RNA, ▶Beckwith-Wiedemann syndrome, ▶Prader-Willi syndrome, ▶Angelman syndrome, ▶Albright hereditary osteodystrophy, ▶Rett syndrome, ▶immunodeficiency [ICF], ▶ATR-X, ▶Rubinstein syndrome, ▶cancer; Lindroth AM et al 2001 Science 292:2077; Jones PA, Takai D 2001 Science 293:1068; Martienssen RA, Colot V 2001 Science 293:1070; Schreiber SL, Bernstein BE 2002 Cell 111:771; epigenesis in plants: Henderson IR, Jacobsen SE 2007 Nature [Lond] 447:418; epigenesis in mammalian development: Reik W 2007 Nature [Lond] 447:425; epigenetic bases of human disease: Feinberg AP 2007 Nature [Lond] 447:433; human epigenome project: <http://www.epigenome.org/>.

Epigenetic: A phenotypic change that may not be inherited because it is not based on changes in the genome. It is within the range of expression of genes. Much of epigenetic phenomena are based on differential methylation of the DNA during the life of the cell or organism or alteration in chromatin structure. Some of the methylation may be transmitted, however, by either the maternal or both maternal and paternal mouse parents (Rakyan VK et al 2003 Proc Natl Acad Sci USA 100:2538). DNA methylation at *cis*-regulatory sequences determines whether gene expression is on or off. Stable inheritance of these expression states is required in bacterial pathogenesis, cancer, and developmental pathways. In *Escherichia coli*, the *agn43* gene (encoding an outer membrane protein, antigen 43 involved in biofilm formation) exercises control. Systematic disruption of this system shows that a functional switch requires the presence of several, rarely occupied, intermediate states that separate the “on” and “off” states. Cells that leave the on and off state enter different intermediate states, where there is a strong bias that drives cells back to their original state. The intermediate states act as buffers that prevent back and forth switching (Lim HN, van Oudenaarden A 2007 Nature Genet 39:269). ▶reaction norm, ▶cortical inheritance, ▶epimutation, ▶histones,

▶histone code, ▶soft inheritance, ▶RLGS, ▶nucleolar dominance, ▶X chromosome inactivation, ▶paramutation; Surani MA 2001 Nature [Lond] 414:122; Petronis A 2001 Trends Genet 17:142; Richards EJ 2006 Nature Rev Genet 7:395.

Epigenetic Landscape: The course of development of different cell types from the fertilized egg without changes in the base sequences in the DNA. ▶epigenesis

Epigenetic Memory: Cells may propagate for many cell divisions and maintain an “on-state” of gene expression in the absence of conditions that induced them. Thus, cells can inherit the differentiated state of the same cell lineage and may cause developmental abnormalities after somatic cell nuclei are transferred to enucleated oocytes. Normally about 1% of differentiated amphibian cells yield feeding tadpoles and less than 3% of the mammalian cloned embryos develop into live birth. The incomplete reprogramming of the epigenetic state can cause developmental abnormalities and premature death (Ng RK, Gurdon JB 2005 Proc Natl Acad Sci USA 102:1957). Histone 4 K29me is mediated by enzyme PRE-SETZ and Histone 3 K27me is mediated by EZH2 enzymes, respectively. These methyl sites are not demethylated and have good chance for transmission through meiosis (Trojer PO, Reinberg D 2006 Cell 125:213). *Plasmodium falciparum* has about 60 *var* genes for antigens at various locations within their chromosomes; however, parasite isolates contain different complements of *var* genes and, thus, the gene family is enormous with a virtually unlimited number of members. A single *var* gene is expressed by each parasite in a mutually exclusive manner and control of *var* gene transcription and antigenic variation is associated with a chromatin memory that includes methylation of histone H3 at lysine K9 as an epigenetic mark. This epigenetic mechanism contributes to evasion of the host defense system (Chookajorn T et al 2007 Proc Natl Acad Sci USA 104:899). ▶nuclear transplantation, ▶histones, ▶*Plasmodium*, ▶antigenic variation; Ringrose L, Paro R 2004 Annu Rev Genet 38:413.

Epigenetic Shift (epigenetic drift): The identity of monozygotic twins tends to be reduced during the process of aging due to different methylation of DNA, chromatin remodeling, changes in the position of transposable elements, increase in the relative proportion of memory T cells and, to a lesser degree, by somatic mutation. ▶Twinning; Martin GM 2005 Proc Natl Acad Sci USA 102:10413.

Epigenetics: The area of study of epigenesis, epigenetic phenomena, and epimutation. Conrad Waddington argued for the term in 1942 although Theodore

Boveri had already concluded in 1903 that “*alle essentiellen Merkmale...epigenetisch sind und daß die Determinierung ihrer Specialität durch den Kern erhalten*” (i.e., “all traits are epigenetic and the determination of their characteristics is derived from the nucleus”). In modern terms it means the study of the changes in the chromatin (or in prion proteins) which permit different patterns of gene expression from the same nucleotide sequence of the genome. Epigenetic changes do not alter the nucleotide sequence, yet the alterations may be transmitted through mitosis and meiosis. Epigenetics is important for both development and for disease. ►epigenesis, ►imprinting, ►paramutation, ►chromatin remodeling, ►methylation of DNA, ►heterochromatin, ►histones, ►histone code, ►RNAi, ►reprogramming, ►mating type determination in yeast, ►prion, ►stem cells, ►acquired characters, ►developmental-regulator effect variegation; Rubin H 2001 Science 294:2477; Shilatifard A 2006 Annu Rev Biochem 75:243; Ruthenburg AJ et al 2007 Mol Cell 25:15; Cell review issue 2007 Vol 128 ([4]).

Epigenome: The differentiated genome, including epigenetic changes. The epigenetic changes are mediated primarily by methylation/demethylation of cytosine and modification of histones (Bernstein BE et al 2007 Cell 128:669). ►epigenesis; Brena RM et al 2006 Nature Genet 38:1359.

Epigenomics: ►genomics

Epigyny: The plant ovary being embedded in the flower receptacle, with other flower organs above it. ►flower differentiation, ►receptacle

Epilepsy: Suddenly recurring impairment of consciousness, involuntary movements, nervous disturbances occurring simultaneously or separately, caused by acquired or genetic factors. Epilepsy is a very complex paroxysmal disorder affecting 1–2% of the world's population. Some seizures may occur in early infancy while others are triggered by light (photogenic epilepsy) or by reading. According to one study, among 27 monozygotic twins, 10 pairs were both affected (concordant) and 17 pairs were not, and among 100 dizygotic twins, only 10 pairs had it both. Thus some epilepsies appear to have a strong genetic component (heritability, $h^2 > 0.40$). *Grand mal* epilepsy is a severe form of seizures occurring in 4–10% of epileptics and it generally develops fully by adult age. *Petit mal (absence)* epilepsy is a milder form and it is less frequent. In mouse a similar mutation in the γ subunit of a Ca^{2+} ion channel (VS.) is responsible for the *stargazer* epileptic phenotype. The *autosomal dominant nocturnal frontal lobe epilepsy* (ADNFLE, human chromosome 20q13.2-q13.3) is caused by mutation in the neural nicotinic

acetylcholine receptor $\beta 2$ subunit. *Idiopathic epilepsy* is not associated with detectable brain lesions, whereas *symptomatic epilepsy* (acquired epilepsy) may be the consequence of a definable brain injury or disease. Idiopathic epilepsy is caused by mutation in the GABA_A receptor $\gamma 2$ -subunit (Baulac S et al 2001 Nature Genet 28:46). The same molecular defect is responsible for the “childhood absence epilepsy”, CAE and “febrile seizures” (Wallace RH et al ibid. p 49). Recessive single gene mutation can cause infancy-onset mutation in the GM3 gene GM3). Some seizures or spasms are associated with a number of genetic maladies (phenylketonuria, epiloia, Zellweger syndrome, Menke's syndrome, ceroid lipofuscinosis, adrenal hypoplasia, multiple sclerosis, glycogen storage diseases, lysosomal storage diseases, myoclonic epilepsy, porphyria, glutamate decarboxylase deficiency, rickets, galactosemias, Friedreich ataxia, West syndrome, Lesch-Nyhan syndrome). A gene for partial epilepsy was located to human chromosome 10q. *Familial partial epilepsy with variable foci* (FPEVF) was assigned to 22q11-q12. The rare recessive *pyridoxine dependent epilepsy* has been mapped to 5q13; it responds favorably to pyridoxine. The underproduction of γ -aminobutyrate (GABA, 5q31), a molecule with an important role in neurotransmission, may also lead to epileptic seizures and encephalitis. A rare but severe form of childhood epilepsy is caused by autoantibodies that turn against the brain's glutamate receptors. A homologue of this gene is found at 8q24. A voltage-gated sodium ion channel $\beta 1$ subunit gene mutation in human chromosome 19q13.1 is one of the causes of *generalized epilepsy with febrile seizures plus* (GEFS⁺). A second (GEFS⁺) locus was found at 2q24-q33. Febrile seizures were associated also with chromosome 8q13 region. Myoclonus epilepsy with ragged red fibers (MERRF) is determined by mitochondrial defects. The myoclonic epilepsy (EPM1) in human chromosome 21 is based of repeat insertions. *Idiopathic epilepsy* is characterized by seizures, which apparently show no metabolic, structural cause, yet has a relatively high heritability. *Benign familial neonatal convulsion* (BFNC) diseases are attributed to defects in human chromosome 20q13.3, encoding a potassium channel (KCNQ2/KCNQ3). *Benign adult familial myoclonic epilepsy* is at 8q23.3-q24.1. *Familial recessive idiopathic myoclonic epilepsy of infancy* maps to 16p13. About 40 different types of epileptic syndromes have been described. Epilepsy also occurs in animals; in chickens it is controlled by a single recessive gene with reduced penetrance. The *unc (uncoordinated)* mutants of the nematode, *Caenorhabditis* are also affected in GABA-mediated functions. Many famous people, Julius Caesar, Bonaparte Napoleon, the great Russian novelist Fedor

Mikhailovich Dostoyevski, and the famous French novelist Gustave Flaubert suffered from the disease (Gastaut H et al 1984 *Epilepsia* Oct 25[5]:622). (See disease mentioned under the specific entries, ►mitochondrial disease in humans, ►autoimmune diseases, ►seizures, ►glutamate decarboxylase deficiency disease, ►ion channel, ►GABA, ►paroxysmal, ►myoclonic epilepsy; Meisler MH et al 2001 *Annu Rev Genet* 35:567; Haug K et al 2003 *Nature Genet* 33:527; Leppert M F, Singh NA 2003 *Annu Rev Genomics Hum Genet* 4:437; synaptic transmission: Fukata Y et al 2006 *Science* 313:1792; <http://www.epilepsyfoundation.org/gene/>; <http://www.carpedb.ua.edu>).

Epilobium: A herbaceous plant species ($2n = 36$) in the family of *Onagraceae* distributed widely in Europe, Asia, and Africa. It became a favorite organism for the study of nonnuclear inheritance since the early decades of this century. A variety of cytoplasmic mutations were discovered in the different species that were transmitted maternally. The identity of the cytoplasmic genetic material (plasmon) was preserved even when *Epilobium luteum* \times *E. hirsutum* was backcrossed with *E. hirsutum* for 25 generations and less than 3×10^{-8} chance remained for the presence of *E. luteum* genes in the nucleus. Some of the information indicated, however, an interaction between nuclear genes and cytoplasmic genetic elements (plasmon-sensitive genes). Some of the cytoplasmic elements were assigned to the plastids and the others were presumably present in the mitochondria. These nonnuclear genes affected pigment variegation, male and female fertility, and a number of morphological changes of the leaf, plant height, etc. From the developmental patterns of the cell lineages (sector formation and sector size), the number of plasmon and plastome (chloroplast-coded elements) were estimated. It was a tragic fact that after the retirement and death of the primary research worker, Peter Michaelis, the majority of the *Epilobium* mutants were lost because of the lack of an organized system for their maintenance. *Epilobium* species also attracted pharmacological interest. ►*Oenothera*; Michaelis P 1965 *Nucleus* 8:83; Battinelli L et al 2001 *Farmaco* 56[5-7]:341; <http://plantsdatabase.com/genus/Epilobium/>.

Epiloia (tuberous sclerosis, TSC): Epiloia is caused by more than one dominant gene; human chromosomes 9q34.3 (TSC1), 3p26 and 12q23, 16p13.3 (TSC2) have been implicated (see Fig. E39). Its prevalence is about 2×10^{-4} . Characteristic symptoms are seizures, mental retardation, papules on the face, low pigmented spots on the trunk and limbs, etc. Inactivation of either TSC1 or TSC2 results in increased cell size. TSC2 coordinates AMPK and GSK3 mediated

Figure E39. Epiloia

phosphorylation and regulates cell growth (Inoki K et al 2006 *Cell* 126:955). In mutant cell lines the level of Cyclin E and Cyclin A is higher and that disturbs the cell cycle (Tapon N et al 2001 *Cell* 105:345). The symptoms may vary substantially, yet mental retardation is apparent in 50% of the afflictions. Brain nodules may be revealed by tomography for diagnosis even in individuals who are otherwise non-symptomatic. The majority of the cases are due to new mutations, thus sibs may have no risk of recurrence. When the anomaly is present in the pedigree the recurrence risk may approach 50% although the penetrance may be incomplete. The TSC1 encoded protein, hamartin, is about 130 kDa. TSC2 encodes the 200-K protein tuberin. The two proteins apparently affect the insulin-signaling pathway. TSC1-TSC2 inhibit ribosomal protein kinase S6 and activate the eIF-4E-binding protein (4E-BP1), an inhibitor of translation initiation. Phosphorylation of TSC by ERK may inhibit TOR signaling and oncogenic cell proliferation (Ma L et al 2005 *Cell* 121:179). In breast cancer cells, Akt-1 phosphorylates TSC2 resulting in reduced Rho-GTPase activity and reduced focal cell adhesion, motility, and invasion. Overexpression of TSC2 results in increased cell motility and metastasis indicating that oncogenes and tumor suppressors effects are expressed in cellular context. These facts must be considered in therapy (Liu H et al 2006 *Proc Natl Acad Sci USA* 103:4134). ►mental retardation, ►tomography, ►S6 kinase, ►ERK, ►TOR, ►eIF-4E, ►tuberous sclerosis, ►Akt, ►RHO, ►oncogene, ►AMPK, ►GSK3; Dabora SL et al 2001 *Am J Hum Genet* 68:64; Inoki K et al 2002 *Nature Cell Biol* 4:648, [photo by courtesy of Dr. C. Stern, after Dr. V. McKusick].

Epimastigote: ►*Trypanosoma*

Epimers: Stereoisomeric compounds that differ at one asymmetric configuration, e.g., glucose and mannose or ribulose 5'-phosphate and xylulose 5'-phosphate; they are reversibly interconverted by epimerase enzymes. ►enantiomorph

Epimorphosis: A cell-division-requiring regeneration of surface structures of animal cells. ►morphallaxis, ►regeneration in animals

Epimutagenic: A physiological factor that causes epigenetic alteration. ►[epigenesis](#)

Epimutation: An epigenetic change during development without change in the DNA sequence. Usually, the epimutation, based on methylation of certain segments of the DNA, is erased by passing through the germline. Epimutation in the somatic cells may be reverted during aging (Bennett-Baker PE et al 2003 Genetics 165:2055), yet in some instances it may be transmitted through meiosis (Frevel MA et al 1999 J Biol Chem 274:29331).

The somatic epigenetic state of the agouti A^{vy} allele is affected by in utero methyl donor supplementation only when the allele is paternally contributed. Exposure to methyl donor supplementation during mid-gestation shifts A^{vy} phenotypes not only in the mice exposed as fetuses, but in their offspring too. This finding indicates that methyl donors can change the epigenetic state of the A^{vy} allele in the germ line, and that the altered state is retained through the epigenetic resetting that takes place in gametogenesis and embryogenesis. Thus, a mother's diet may have an enduring influence on succeeding generations, independent of later changes in diet (Cropley JE et al 2006 Proc Natl Acad Sci USA 103:17308). Epimutation has also been reported in humans; it is generally difficult to prove its transmission to following generation(s) (Horsthemke B 2007 Nature Genet 39:573). "Heritable germline epimutation" describes an atypical epigenetic state that occurs in all tissues of an individual (hence the adjective "germline") and one that is detected in more than one generation. "Transgenerational epigenetic inheritance" is the direct transfer of epigenetic information across generations. Heritable germline epimutation may or may not be the result of transgenerational epigenetic inheritance (Chong S et al 2007 Nature Genet 39:574). ►[epigenesis](#), ►[epiallele](#), ►[imprinting](#), ►[transgenerational effect](#), ►[methylation of DNA](#), ►[peloric](#), ►[directed mutation](#); Suter CM et al 2004 Nature Genet 36:497.

Epinasty: The downward bending of a plant organ because of the more rapid division of the upper cell layer(s) (see Fig. E40). Hyponasty is the opposite phenomenon.

Figure E40. Epinasty

Epinephrine (adrenaline): An animal hormone, produced by the kidney (adrenal medulla). When it binds to specific transmembrane receptors of the G_s proteins, they may be phosphorylated to the G_{sa} - GTP form facilitating the activation of the adenylate cyclase enzyme which produces 3', 5' cyclic AMP. cAMP mediates the function of protein kinase A, setting into motion a cascade of protein phosphorylations and resulting in the activation of glycogen synthase, phosphorylase b kinase (causing glycogen breakdown), acetyl coenzyme A, carboxylase (required for the synthesis of fatty acids), pyruvate dehydrogenase (oxidation of pyruvate to acetyl-CoA), triacylglycerol lipase (resulting in mobilization of fatty acids in the mitochondria and plant peroxisomes), phosphofructokinase and fructose-2,6-bisphosphatase (involved in glycolysis and gluconeogenesis). ►[G_s](#), ►[adenylate cyclase](#), ►[phosphorylase a](#), ►[β-adrenergic receptor](#), ►[axon guidance](#), ►[neurotransmitter](#), ►[animal hormones](#)

Epiphyseal Dysplasia, Multiple (MED): Human chromosome 20q13.3 dominant defect in the α -chain of type IX collagen that involves early-onset of osteoarthritis, walking defects and short stature. It is a sulfate transporter. A recessive form is caused by mutation in the diastrophic dysplasia (5q32-q33.1) sulfate transporter. There is apparently a dominant MED gene at 2p24-p23 encoding matrilin 3, an oligomeric protein of the cartilage matrix containing a von Willebrand factor A type protein domain. Several different mutations have been identified at multiple loci for collagen and thus cartilage defects. ►[collagen](#), ►[arthritis](#), ►[diastrophic dysplasia](#), ►[von Willebrand disease](#); Chapman KL 2001 et al 2001 Nature Genet 28:393; Czarny-Ratajczak M et al 2001 Am J Hum Genet 69:969.

Episomal vector: ►[yeast episomal vector](#), ►[transformation genetic](#)

Episome (plasmid): The dispensable genetic element in bacteria that can exist in a free state within the cell or be integrated into the main genetic material, comprising a couple of thousand to a few hundred thousands of nucleotides. A typical episome is the bacterial sex plasmid (F); the temperate phages also behave like episomes. Originally, the term was coined for a hypothetical chromatin attached to the *Drosophila* chromosome. Plasmids of prokaryotes and eukaryotes are also considered as episomes. Some plasmids may be diluted during division of the cells but the self-replication-competent plasmids may reach high levels in the cells. ►[mitochondrial plasmids](#), ►[F element](#), ►[plasmids](#); Jacob F, Wollman EL 1958 C.R. Hebd Séances Acad Sci Paris 247:154.

Epistacy: Quantitative interaction among the products of more than one allelic pair. The term, originally suggested by R.A. Fisher in 1918, has been usually replaced by epistasis.

Epistasis: The interaction between products of nonallelic genes, resulting in modification or masking of the phenotype expected without epistasis. The majority of single gene yeast mutations affect the expression of other genes. The segregation ratios in F_2 may be altered depending on the type of epistasis involved. At *recessive epistasis* (a recessive allele of a locus is epistatic to another recessive allele of another independently segregating locus) the phenotypic classes in F_2 are 9:4:3, at *dominant epistasis* 12:3:1, rather than the common 9:3:3:1. Epistasis may be brought about by modification of gene function due to alterations in the signal-transducing pathway. *Synergistic epistasis* reinforces the consequences of other epistatic factors, e.g., deleterious mutations may enhance each other's detrimental effects. *Negative epistasis* reduces fitness in individuals with deleterious mutations; the epistatic genes are more deleterious in combination than separately (Butlin R 2002 Nature Rev Genet 3:311). Epistasis may take place between/among protein modules and form an epistatic network (Segrè D et al 2005 Nature Genet 37:77). *Indirect epistasis*, in contrast, is not an intracellular phenomenon. A pregnant mother with some metabolic defect may exert a deleterious effect on the genetically normal (heterozygous) developing fetus by placental transfer of harmful metabolites. Similarly, breast-feeding by such mothers may elicit the symptoms of the disease in the nursing babies. Such a situation may exist in case of phenylketonuric and myasthenic mothers. The problem of epistasis is of interest for quantitative genetic analysis and it may require sophisticated statistics to separate additive effects from interactions. Epistasis thus has significance for animal and plant breeding, as also for human genetics, to determine the role of genes in the development of cancer and other traits under multiple controls and interaction of drugs. Actually, the majority of genes do not operate independently of each other. Microarray hybridization of mutant transcripts permits quantitative estimation of the phenotypes due to interaction in the expression on a global scale (Van Driessche N et al 2005 Nature Genet 37:471) and on this basis E maps (epistatic interaction maps) can be constructed (Schuldiner M et al 2005 Cell 123:507). ▶[signal transduction](#), ▶[phenylketonuria](#), ▶[myasthenia](#), ▶[modified Mendelian ratios](#), ▶[interaction deviation](#), ▶[synergism](#), ▶[recombinant congenic](#), ▶[two-hybrid method](#), ▶[suppressor gene](#), ▶[cross-talk](#), ▶[genetic network](#), ▶[morphogen](#), ▶[epistacy](#); Bateson W 1907 Science 26:649;

Mcmullen MD et al 2001 Genome 44:667; epistasis in populations: Carlborg Ö, Haley CS 2004 Nature Rev Genet 5:618.

Epistasis group: Non-allelic genes with protein products, which may affect each other's function(s). ▶[complementation group](#), ▶[allelism](#)

Epistatic selection: Consecutively occurring mutations may decrease fitness synergistically. ▶[fitness](#), ▶[selection](#)

Epistemology: The study of the nature and limitations of science.

Epithelial branching: A common theme in organogenesis of epithelial tubes, for the lung, liver, or kidney. The later morphogenesis of these branched epithelia dictates the final form and function of the mature tissue. Epithelial branching requires the specification of branch cells, the out-folding process itself, and, frequently, patterned morphogenesis produces branches of specific shape and orientation. ▶[epithelial cell](#); Hatton-Ellis E et al 2007 Proc Natl Acad Sci USA 104:169.

Epithelial cells: Epithelial cells form a tightly organized cover over the surface of organs or bodies (see Fig. E41). The architecture of the epithelial tissues is maintained by intercellular adhesion mediated by E-cadherin molecules and a synaptogamin-like protein, Btsz (Pilot F et al 2006 Nature [Lond] 442:580). Tuba protein modulates the expression of CDC42 GEF and regulates the junctional configuration of epithelial cells (Otani T et al 2006 J Cell Biol 175:135). Mice homozygous for a missense mutation in interferon regulatory factor 6 (*Irf6*), the homolog of the gene mutated in the human congenital disorders Van der Woude syndrome and Popliteal pterygium syndrome, have a hyperproliferative epidermis that fails to undergo terminal differentiation, resulting in soft tissue fusions rather than keratinizing epithelia (Richardson RJ et al 2006 Nature Genet 38:1329). ▶[cadherin](#), ▶[synaptogamin](#), ▶[CDC42](#), ▶[GEF](#), ▶[Van der Woude syndrome](#), ▶[Popliteal pterygium syndrome](#), ▶[polycystic kidney disease](#)

Figure E41. Epithelium

Epithelioma: An autosomal dominant benign or cancerous human skin lesion, encoded in the long arm of human chromosome 9. ▶kin diseases

Epitope: The binding site on the antigen for the paratope of the antibody, the antigenic determinant. The polymorphic (private) epitopes are specific for one MHC, whereas the monomorphic (public) epitopes may be shared by more than a single MHC allele. The cryptic epitopes are usually expressed at very low levels, but they may be induced to overexpression. Immunodominant epitopes are the ones commonly binding to the antibodies. Multimeric epitopes are multivalent arrays of peptide:MHC complexes on the surface of the antigen-presenting cells (APCs). The cross-linking of MHC class II molecules and the resulting clustering of peptide:MHC/T cell receptor (TCR) greatly enhances both APC and T cell activation. Therefore, multimerized T cell epitopes increase the immunological potency of soluble peptides and can promote either antigen-specific T cell activation or tolerance through activation-induced cell death in vitro at much lower concentrations than the monomeric peptide (Piaggio E et al 2007 Proc Natl Acad Sci USA 104:9393).

The α -galactosyl epitope (Gala1-3Gal β 1-4GlcNAc-R) is expressed on the surface of most mammalian cells (except humans and Old World primates) and is the most common factor of tissue rejection. This epitope is present on several potentially pathogenic viruses, bacteria, and protozoa. Retroviral vectors also carry this epitope and it appears to be the major cause for triggering the complement cascade against them. The α -1,2-fucosyl transferase (H-transferase) may reduce the α -galactosyl residues on the viral and cellular surface and thus reduce the complement-mediated immune reaction. The elimination of the α -galactosyl epitope either by gene knockout or by increasing the H-transferase expression may facilitate xenotransplantation. ▶antibody, ▶MHC, ▶antigen, ▶paratope, ▶xenograft, ▶gene therapy, ▶complement, ▶knockout, ▶epitope tagging; <http://www.rostlab.org/services/epitome/>; epitope peptide segments: <http://140.121.196.30/remus.asp>.

Epitope Screening: If an antibody is available for a protein it can be used to screen expression libraries of the antigen with the antibody. The antigen-containing cells are plated, then transferred to nitrocellulose filter replicas, and subsequently submerged in a solution of the antibody. The epitope-containing colonies tightly bind the antibody and while incubating the filter reveal the position of the complex by a second, radiolabeled antibody that binds to the first one. This procedure is of medical significance for the development of immunological defense systems. ▶antibody,

▶antigen, ▶epitope, ▶radioactive label, ▶phage display

Epitope Spreading: An expansion of specific antigen responses to additional determinants of the same protein (intramolecular epitope spreading) or to targets present in different proteins (intermolecular epitope spreading). Epitope spreading may enhance the damage of the autoreactive immune responses. ▶immune system, ▶autoimmune diseases, ▶immune tolerance; Robinson WH et al 2003 Nature Biotechnol 21:1033.

Epitope Tagging: An immunochemical/immunocytochemical method that employs a short polynucleotide, encoding a 6 to 10 amino acid epitope, inserted into a gene, which is then transfected into a cell. This epitope already has a known antibody and when it is expressed in a transgenic cell it facilitates the tracking of the transgene tagged. It is superior as far as specificity to natural immunogens is concerned. Inserting tandem epitopes improves sensitivity. Generally, either the N or the C ends of the proteins are labeled. For identification, Western blots, immunoprecipitation, immunofluorescence, electron microscopy and other methods are used. Epitope tagging has wide applicability in basic proteomics and eventually to clinical problems. Some epitope-antibody combinations are commercially available. (See individual terms under separate entries, Jarvik JW, Telner CA 1998 Annu Rev Genet 32:601; Heintz N 2000 Hum Mol Genet 9:937; Ferrando A et al 2000 Plant J 22:553).

Epizootic: A serious disease of insects or other animals occurring occasionally, but one which spreads rapidly and involves high morbidity.

EPO: Erythroid progenitor cell regulator affecting, primarily, megakaryocyte differentiation. ▶TPO, ▶megakaryocyte, ▶erythrocyte

Eponym: The designation of a phenomenon or principle by the name of person(s) who discovered it or who was associated with it as a proband, e.g., Punnett square, centi Morgan, Hogness box, Abraham Lincoln hemoglobin, Lepore hemoglobin. (See www.whonamedit.com).

Epothilone: A water-soluble polyketide produced by myxobacteria (*Sorangium cellulosum*) in low quantity. It is a spindle fiber poison and is a potential anticancer drug, similar to taxol but more effective. The epothilone gene has been cloned and it can be produced more efficiently by transgenic other bacteria such as *Streptomyces coelicolor*. It has also been synthesized by laboratory methods. ▶taxol, ▶myxobacteria, ▶polyketide; Chen H et al 2001 Chem Biol 8:899.

Epoxide: An epoxide contains a three-membered (oxirane) ring, e.g., ethylene oxide, and they are highly reactive (see Fig. E42).

Figure E42. Epoxide ring

Epoxide Hydrolase Deficiency (1q42.1): Results in the inability to detoxify arene oxide (phenytoin/hydantoin type drugs) causing cell death, birth defects, congenital heart disease, cleft lip/palate, microcephaly, and genital/urinary, eye and limb anomalies (see Fig. E43).

Figure E43. Hydantoin

Eppendorf: Although this company merchandises other types of laboratory tools, generally, its name is synonymous for the conical polypropylene microcentrifuge tubes of 1.5-mL capacity. Several companies market such 0.5 to 1.5-mL tubes in equal quality.

Eppin: A epididymis/testis-expressed, alternatively spliced, cysteine-rich protease inhibitor protein encoded at human chromosome 20q12-q13.2. It appears to be a promising immunocontraception agent. ▶[immunocontraceptive](#); Richardson RT et al 2001 Gene 270:93.

EPS: Exopolysaccharide.

EPS8: Transduces signals between Rac and RAS. (See Rac; RAS; signal transduction; E3B1).

Epsin (EPS): A clathrin-associated protein binding the adaptin subunit of AP2. EPS also has a ubiquitin interaction motif too. It seems to transmit signals from the endocytotic pathway to the nucleus. ▶[clathrin](#), ▶[AP1](#), ▶[adaptin](#), ▶[endocytosis](#), ▶[ENTH](#); Drake MT et al 2000 J Biol Chem 275:6479.

Epstein-Barr Virus (EBV): A 172-kbp linear DNA herpes virus with multiple direct repeats of 0.5 kb at both ends. Within the cells the EBV may make up to 100 circular, nonintegrated copies or it may integrate into the chromosomes. Some of its RNA genes are transcribed by RNA polymerase III and use upstream elements for regulation. Herpes viruses cause infectious mononucleosis, Burkitt's

lymphoma, nasopharyngeal (nose-throat) carcinoma, Marek's disease (an avian tumor), etc. About 90% of the human populations harbor EBV. EBV infects and immortalizes B lymphocytes with the aid of the EBNA1 and EBNA2 (Epstein-Barr virus nuclear antigen) genes and may be used for the (sometimes inefficient) production of monoclonal antibodies. Replication of EBV is apparently preceded by nucleosomal destabilization brought about EBNA1. EBNA2 is also a transactivator of other genes without binding to DNA. Responsive promoters are targeted through the CBF1 DNA binding transcriptional repressor protein. CBF1 binds to a consensus of GTGGGAA at a considerable distance from the EBNA2-responsive cellular promoters. EBNA2 counters transcriptional repression by CBF1. EBV is the most effective tumorigenic virus of humans and it targets the B lymphocytes and transforms them into active immunoglobulin-producing immunoblasts. More than 90% of the infections lay dormant because of the immunological surveillance of the T cells. In Hodgkin's disease and nasopharyngeal cancer cell, EBV is detectable. In case of a mutation in the cells, EBV displays the X-linked lymphoproliferative syndrome (XLP, Xq24-q25) upon infection. The syndrome includes infectious mononucleosis, acquired hypogammaglobulinemia and malignant lymphoma. The XLP/SH2D1A gene encodes a 128 amino acid protein with a single SH2 domain. The XLP/SH21A gene product appears to be the same as SAP (SLAM-associated protein). SLAM (signaling lymphocyte activation molecule, alias CDw150) is a glycosylated transmembrane protein involved in the activation of B and T cells and in the interaction between B and T cells. The EBV antigen stimulates the proliferation of CD8⁺ and CD4⁺ T lymphocytes. The CTLs keep the virus under control until its proliferation is evoked by some conditions. Within the EBV protein network 52 proteins are linked via 60 interactions and 40 EBV proteins and 112 human proteins are connected by 173 interactions as detected by the yeast two-hybrid assay (Calderwood MA et al 2007 Proc Natl Acad Sci USA 104:7606).

EBV can be used as lymphoid-tissue-specific genetic vector. This specificity depends on the presence of the CD21 complement receptor type II protein. The CD21 ligand is a gp350/220 glycoprotein. The vectors form only 2 to 4 copies in mammalian cells. They can carry 35-kb inserts and can be used as a shuttle vector. The EBV establishes latency in the target cells, making it a desirable genetic vector. The engineered EBV minireplicons need nontransforming (EBNA2-defective) helper cell line packaging. The safety of using EBV-based vectors for gene therapy may not be completely assured. ▶[Herpes](#), ▶[Burkitt's lymphoma](#), ▶[Hodgkin's disease](#), ▶[lymphocytes](#),

►CTL, ►shuttle vector, ►carcinoma, ►cancer, ►oncogene, ►CBF, ►complement, ►Duncan syndrome, ►hypogammaglobulinemia, ►lymphoma, ►mononucleosis, ►complement, ►SLAM, ►SAP, ►heterohybridoma, ►lymphoproliferative diseases; Khanna R, Burrows SR 2000 Annu Rev Microbiol 54:19; Avolio-Hunter TM et al 2001 Nucleic Acids Res 29:3520; Grinstein S et al 2002 Cancer Res 62:4876.

Epstein Syndrome: Macrothrombocytopathy. ►Alport syndrome

EQ (encephalization quotient): The comparison of brain weight relative to body weight. Although relatively larger brain weight is characteristic for humans, the brain weight alone may not reflect cognitive abilities among hominids. ►brain human

Equational Division: ►mitosis

Equational Separation of Chromosomes: The separation takes place in mitosis when the sister chromatids go to opposite poles during anaphase. Similarly, the separation of the chromosomes at anaphase I of meiosis may be equational in case of recombination or in the absence of mutation. In heterozygous autopolyploids, when crossing over takes place and the *Aa* and *aA* chromatids go to the same pole, the separation is equational. When the distance between a gene and its centromere is at least 50 map units (or more) maximal equational segregation occurs. Such a separation may permit the formation of *aa* gametes in an *AAAa* (triplex) and increases the frequency of *aa* gametes in duplex (*AAaa*) and simplex (*Aaaa*) individuals. ►mitosis, ►meiosis, ►autopolyploidy, ►reductional separation

Equatorial Plane: The middle region of a dividing cell nucleus where the chromosomes congregate before anaphase begins and where the nucleus will divide into two. Note, sometimes it is called “plate” but there is no physical plate there at that stage. ►mitosis

Equatorial Plate: ►equatorial plane

Equilibrium: A state without a net change.

Equilibrium Centrifugation: The centrifugation is continued in a density gradient until each macromolecule (subcellular organelles) reaches a position corresponding to its density. ►density gradient centrifugation, ►ultracentrifugation

Equilibrium Constant (K_{eq}): The concentrations of all reactants and products at equilibrium under specified conditions. ►dissociation constant

Equilibrium Dialysis: Known quantities of an antigen and an antibody are placed in a dialysis bag. Only those small antigens can pass the bag membrane that cannot react with the antibody. This way, the number

of specific binding sites can be determined on the basis of the antibody inside and outside the bag. ►antibody, ►antigen, ►immune reaction, ►valence, ►dialysis

Equilibrium Dissociation Constant (K_d): Expresses the strength of interaction between two molecules where (AB) is the concentration of the complex and (A) and (B) is the concentration of the separate molecules (K_a). Its reciprocal (K_d) is the equilibrium association constant.

$$K_d = \frac{(A)(B)}{(AB)} \quad K_a = \frac{(AB)}{(A)(B)}$$

Equilibrium of Heterozygotes: Both homozygotes in a random mating population are equally disadvantaged as compared to the heterozygotes and heterozygote equilibrium takes place relative to homozygotes. ►Hardy-Weinberg theorem, ►genetic equilibrium

Equilibrium of Mutations: The occurrence of a number of mutations in a random mating population has the same consequence as immigration, i.e., the frequency of the allele may increase. Unless the new mutation has substantial selective advantage, its survival (fixation) or death (extinction) is equally likely. If the mutation is frequent and random elimination (drift) is insignificant, maintenance of the mutant allele may be assured, even when it does not have a selective advantage. If a mutation from *A* to *a* is a regular event, the frequency of *a* may increase at the expense of *A*

$$qn + 1 = qn + \mu(1 - qn) \quad \{1\}$$

where q = frequency of the recessive allele, and $(1 - q)$ = frequency of the dominant allele, n = the number of generations and μ = mutation rate.

After a number of generations (n), the initial frequency of the recessive allele (q_0) may increase to q_n by the acquisition of the same mutant alleles ($A \rightarrow a$) as represented:

$$e^{-n\mu} = (1 - q_n)/(1 - q_0) \quad \{2\}$$

and hence

$$-n\mu = \ln[(1 - q_n)/(1 - q_0)] \quad \{3\}$$

If, e.g., $q_0 = 0.05$ (as we hypothesize for an example), the number of generations required to double its frequency to $q_n = 0.10$ can be computed if the value of μ (= mutation rate) is known, e.g., $\mu = 10^{-5}$. According to {3}, $\ln[(1 - 0.10)/(1 - 0.05)] = \ln[0.90/0.95] = \ln 0.94737 = 0.05407 = -n\mu$. When 0.05407 is divided by 0.00001 (the mutation rate given above, 10^{-5}), we get

5,407. This means that under the conditions specified by this hypothetical example, 5,407 generations are required to double the frequency of the recessive allele. Since this change depends not on the number of years but on the number of generations, species with many generations annually may change more rapidly than the ones with long times to sexual maturity and gestation. Therefore, it is easier to test these mathematical models with bacteria or *Drosophila* or mice than with humans or elephants.

The rate of change of allelic frequencies in a random mating population can be expressed as:

$$\Delta q_n = \mu(1 - q_n) \quad \{4\}$$

where Δ indicates change in the frequency of the recessive allele (q). Thus the rate of change {4} for the hypothetical experiment is 10^{-5} (0.90) = 0.000009 . The larger the number of alleles, which can mutate, the larger is the chance for the change. One must take into account also the fact that mutations may revert. Accordingly:

$$\Delta q = \mu p - r q \quad \{5\}$$

where μp represents the mutation $A \rightarrow a$, and/or stands for backmutation $A \leftarrow a$ (r = reversion).

At mutational equilibrium

$$\hat{q} = \mu / (\mu + r) \quad \{6\}$$

and

$$\hat{p} = r / (\mu + r) \quad \{7\}$$

where \hat{q} and \hat{p} represent the equilibrium frequencies of the recessive and dominant alleles, respectively.

It is evident if p is larger than q , a larger r is required to keep equilibrium with a smaller μ , e.g., if $p = 0.8$ and $q = 0.2$ ($p + q$ is always 1) and $\mu = 0.00001$, r must be 0.00004 to make $0.8 \times 0.00001 = 0.2 \times 0.00004$. Usually in nature the frequency μ (forward mutation) is larger because $A \rightarrow a$ change may occur by more mechanisms than base substitution alone (e.g., deletion, frame shift, etc.) whereas reversion (r) is expected to take place mainly by nucleotide replacement. Therefore, in the maintenance of allelic equilibrium, selection usually plays a major role.

► **allelic frequencies**

Equivalence Group: A group consisting of cells with equal differentiatonal potential at a particular time.

ERAB (endoplasmic reticulum associated binding protein, a putative hydroxysteroid dehydrogenase): Binds to the amyloid- β peptide and appears to cause neuronal dysfunction in Alzheimer's disease. ► **Alzheimer's disease**; He XY et al 2001 Eur J Biochem 268:4899.

ERAD: Stands for endoplasmic reticulum-associated degradation of aberrant or unneeded proteins by the proteasome. ► **proteasome**, ► **endoplasmic reticulum**; Molinari M et al 2003 Science 299:1397; Oda Y et al 2003 Science 299:1394.

ERBA: The genes present in multiple copies in both the human (chromosome 17q22-q23 or 17q11-q12) and the mouse genomes. ERBA was held responsible for the potentiation of ERBB1 and the protein is a receptor for thyroid hormones and functions in the nucleus as a transcription factor. It has the highest expression in the nervous system and, unlike other thyroid receptors, not in the liver. It is related to the avian erythroblastic leukemia virus oncogene and it is involved in leukemia and other cancers in humans, including some translocations. ► **erbB**, ► **ERBB1**, ► **oncogenes**, ► **hormones**, ► **TRE**, ► **hormone response elements**, ► **regulation of gene activity**; Andersson ML, Vennstrom B 2000 Oncogene 19:3563.

erbA: A retroviral oncogene which produces a transcription factor (member of the steroid receptor family).

erbB: An avian erythroleukemia oncogene (receptor for EGF and other cellular and viral proteins). Its overexpression may confer resistance to anticancer chemotherapy and radiation treatment. Herceptin and taxol may block erbB. Erb-specific tyrosine kinase inhibitors may also reduce its effect on chemoresistance. ErbB3 receptor-binding protein Ebp1 down-regulates the androgen receptor and may be effective against hormone-refractory prostate cancer (Zhang T et al 2005 Proc Natl Acad Sci USA 102:9890). ► **avian erythroblastoma**, ► **ERBB1**, ► **herceptin**, ► **taxol**, ► **prostate cancer**, ► **immunostimulatory DNA**; Olayioye MA et al 2000 EMBO J 19:159.

erbB1: An oncogene (human chromosome 7p12-p22, mouse chromosome 7) encodes the glycoprotein, epidermal growth factor receptor (EGFR), and a transmembrane protein tyrosine kinase. The protein has two subunits, one contains phosphotyrosine and phosphothreonine, and the other contains, in addition, phosphoserine. ERBB2 has been assigned to human chromosome 8p22-p11. The synonyms of ErbB2 are NEU and HER2. Probably ErbB2 is a normal growth factor but when its expression is enhanced it becomes a protooncogene. The amplification of its expression was detected in adenocarcinomas and gastric cancer. The ErbB2 product is present in neuroblastomas, breast and ovarian cancers. The anti-ErbB2 monoclonal antibody (trastuzumab) is recommended for metastatic tumors overexpressing ErbB2. ErbB3 is a related (mammary) oncogene in human chromosome 12q13. Regulation of ErbB2-induced mammary tumorigenesis by protein tyrosine kinase 1

occurs through the attenuation of both the MAP kinase (MAPK) and Akt pathways (Julien SG et al 2007 Nature Genet 39:338). ▶EGF, ▶oncogenes, ▶glycoprotein, ▶protein kinase, ▶proto-oncogene, ▶breast cancer, ▶neuroblastoma, ▶Heregulin, ▶Herceptin, ▶cyclin D, ▶MAPK, ▶Akt; Friedman LM et al 2005 Proc Natl Acad Sci USA 102:1915.

ERBBA: Two human genes in chromosome 19 (locus EAR2, with preferential expression in the liver) and chromosome 5 (locus EAR3) encode steroid and thyroid hormone receptors. The homologous retroviral gene is *erb*. ▶animal hormones, ▶retrovirus

ERC (extrachromosomal rDNA circle): Repeated sequences in ribosomal DNA (rDNA) may recombine and yield extrachromosomal circles. It has been suggested that accumulation of these circles may result in aging.

ERC (entorhinal cortex): The part of the central nervous system where neuritic degeneration occurs in Alzheimer's disease. (See Du AT et al 2001 J Neurol Neurosurg Psychiatry 71:441).

ERCC: ▶excision repair, ▶RAD25

ERDA1: Expanded repeat domain CAG/CTG with 50 to 90 repeats at 17q21.3. ▶trinucleotide repeats; Bowen T et al 2001 Psychiatr Genet 10:33.

Erectile Dysfunction (ED): A complex and widespread disorder causing impotence. Numerous environmental, metabolic, neurological, and disease factors may be the underlying causes. Several prescription drugs have been developed that correct the anomaly with a variable success rate for the male population. Gene therapies are under study in animal models using primarily adenoviral and plasmid vectors for the transfer of nitric oxide synthase, calcitonin gene-related peptide, brain-derived neurotrophic factor, vascular endothelial growth factor, and potassium ion channel genes. Another possibility is the transfer of genetically modified autologous cells into the corpus cavernosum of the penis. Gene therapy may eliminate the potential side effects of drugs, but it does not have yet clinically approved methodology for human use. The drug Viagra (Sildenafil citrate 1-[[3-(6,7-dihydro-1-methyl-7-oxo-3-propyl-1*H*-pyrazolo[4,3-*d*]pyrimidin-5-yl)-4-ethoxyphenyl] sulfonyl]-4-methylpiperazine citrate) and other similar medications may be prescribed for alleviation of the problem. ▶gene therapy, ▶Peyronie disease; Anastasiadis AG et al 2004 In Seftel AD et al (eds) Male and Female Sexual Dysfunction Mosby, St. Louis, MO, USA, p 183.

eRF: Recognizes stop codons in mRNA and terminates translation, stimulates peptidyl-tRNA cleavage and

release. In prokaryotes there are two RFs, RF1 and RF2, and in eukaryotes there are eRF1 and eRF3. Eukaryotic eRF1 recognizes all three termination codons (UAA, UGA or UAG). In prokaryotes, RF1 recognizes UAA and UAG and RF2 recognizes UAA and UGA. In eukaryotes, eRF3 binds to the C-terminal domain of eRF1 and their cooperation realizes the release of the peptidyl tRNA bond (Alkalaeva EZ et al 2006 Cell 125:1125). eRF3 is one of the factors that controls yeast prion PSI conformation (Wilson MA et al 2005 Proc Natl Acad Sci USA 102:10244). ▶stop codon, ▶prion, ▶tRNA, ▶release factor; Ohta M et al 2001 Plant Cell 13:1959.

erg: A unit of energy or work in dyne acting through a distance of 1 cm. ▶dyne unit of force

ERG: A DNA-binding protein, oncogene, encoded in human chromosome 21q22.

Ergodic Rule: Rare events are more likely to be found when the population size is large.

Ergosterol: The most common sterol in some fungi. It is D₂ provitamin and it is used as an antirachitic drug (for prevention of certain bone deficiency problems). ▶cholesterol

Ergot: Dry sclerotia (compact dry mycelial mass) of *Claviceps purpurea* fungus on rye ears (and some other grasses) containing a large number of alkaloids and peptide alkaloids, some of which promote the contraction of the uterus (oxytocic) and are highly toxic (see Fig. E44). Lysergic acid is one of the main alkaloids of ergot which affects the nervous system, causes confusion. It has been used as a psychomimetic and was supplied to the defenders of the soviet political "conception" trials to admit to crimes they did not commit. ▶alkaloids, ▶psychomimetic; Mukherjee J, Menge M 2000 Adv Biochem Eng Biotechnol 68:1.

Figure E44. Ergot

ERK: A family of extracellular signal-regulated protein kinases. ERK5/BMK1 is required for epidermal growth factor and nerve growth factor to induce cell proliferation. ERK kinases are important for histone (H3) phosphorylation and activation of transcription. ERK activation depends on an oxysterol-binding protein (OSBP) through the cholesterol-binding scaffolding of this phosphatase (Wang P-y et al

2005 Science 3007:1472). ►signal transduction, ►SAPK, ►EGF, ►MAP kinase; Chen RH et al 1992 Mol Cell Biol 12:915; Adachi M et al 2000 J Cell Biol 148:849; Howe AK et al 2002 Current Opin Genet Dev 12:30.

ERM (ezrin-radixin-moesin): A protein cofactor complex, in its active state, of GTPase reactions. It affects the cytoskeletal system and anchors filaments to the cell surface. It may enhance metastasis in sarcomas. The ERM-like protein, merlin, appears to be a suppressor of meningiomas and schwannomas. Protein 4.1, containing ERM, is also a potential suppressor of metastasis (Wong SY et al 2007 Proc Natl Acad Sci USA 104:12784). ►cytoskeleton, ►ezrin, ►GTPase, ►merlin, ►neurofibromatosis, ►meningioma; Bretscher A 1999 Curr Opin Cell Biol 11:109.

ERP: A transcription factor of the ETS family. ►transcription factors, ►ETS

Erp1: An inhibitor of the anaphase-promoting complex. ►CSF

Erp61: An endoplasmic reticulum stress protein with functions similar to PDI. ►PDI, ►Erp72

Erp72: An endoplasmic reticulum protein with thiorodoxin- and PDI-like functions. ►thio-redoxin, ►PDI

ERR (extra radiation risk): Expresses the increased cancer or other risk compared to the unexposed population. ►risk, ►EAR

Error Catastroph: A high rate of mutation—beyond a certain threshold—that may drive a species to extinction (Eigen M 2002 Proc Natl Acad Sci USA 99:13374). Lower doses of mutagens may also accomplish viral extinction because of the replicative competition by defectors (Grande-Pérez A et al 2005 Proc Natl Acad Sci USA 102:4448). ►mitotic catastrophe

Error in Aminoacylation: Approximately 3×10^{-4} is the rate of charging a tRNA with the wrong amino acid in prokaryotes and eukaryotes, 10^{-5} in yeast to 10^{-4} and 10^{-3} in higher forms. Several aminoacyl-tRNA synthetases carry out editing functions by hydrolyzing the misactivated aminoacyl adenylates and aminoacyl-tRNAs. DNA aptamers are also involved in editing functions. Amino acids larger than the cognate amino acid are eliminated in a single step. Amino acids smaller than the critical ones are selected against a second step of screening. This is called the “double-sieve model”. ►ambiguity in translation, ►error in replication, ►aptamer, ►editing,

►aminoacyl tRNA synthetase; Parker J, Holtz B 1984 Biochem Biophys Res Commun 121:482; Mori N et al 1985 Biochemistry 24:1231; Jakubowski H, Goldman E 1992 Microbiol Rev 56:412; Nordin BE, Schimmel P 1999 J Biol Chem 274:6835.

Error in Communication: The accidental substitution of a symbol by another.

Error in Replication: Leads to base replacement and thus mutation. The rate of replicational errors of the different DNA polymerases varies but it is partly compensated for by the editing function of the 3'→5' exonuclease activity of the polymerases. The error rate of α subunit of DNA polymerase III of *E. coli* is about 10^{-5} , but it is reduced by about two orders of magnitude by exonuclease subunit ϵ . The base substitution error of the *E. coli* DNA polymerase III holoenzyme is within the range 5×10^{-6} to 4×10^{-7} . The repair polymerase, Pol I of *E. coli* also has an error rate of about 1×10^{-5} , but the 3'→5' exonuclease activity again reduces the errors by two orders of magnitude. The T7 DNA polymerase has an error rate of 10^{-3} to 10^{-4} , but the repair system lowers it to 10^{-8} to 10^{-10} . The RNA polymerases of RNA viruses do not have proofreading and editing functions and their error rate may vary within the 10^{-3} to 10^{-4} range per nucleotide. The mitochondrial DNA polymerase γ has a base substitution error of $\sim 3.8 \times 10^{-6}$ to 2.0×10^{-6} . This appears to one or two orders of magnitude higher than in the nucleus of mammals. The proofreading rate of the exonuclease depends a great deal on the availability of replacement nucleotides and therefore the difference in the final fidelity may not be so much. ►editing, ►proofreading, ►reverse transcriptases, ►DNA replication mitochondria, ►mutation rate; Kunkel TA, Bebenek K 2000 Annu Rev Genet 69:497; Johnson AA, Johnson KA 2001 J Biol Chem 276:38090; Johnson AA, Johnson KA 2001 J Biol Chem 276:38097; Pesole G et al 1999 J Mol Evol 48:427.

Error in Transcription: Error in transcription is higher (10^{-3} to 10^{-5}) than in replication because the DNA-dependent RNA polymerases do not have editing functions. The consequence of an error in RNA is not serious as relative to mutation in DNA. The yeast protein SII and the *E. coli* proteins GreA and GreB used to be credited for stimulating the cleavage of RNA with misincorporated bases. Experimental data indicate that neither of these proteins is indispensable and their proofreading value appears low. The nucleotide proximal to the 3' end of the nascent transcript stimulates the hydrolysis of the penultimate phosphodiester bond and this hydrolysis is enhanced

in case of misincorporation of a base(s). Thus, the transcript assists proofreading and assures fidelity of transcription (Zenkin N et al 2006 Science 313:518). ▶[error in replication](#), ▶[ambiguity in translation](#), ▶[RNA polymerase](#), ▶[mutation rate](#), ▶[misincorporation](#); Paolini-Giacobino A et al 2001 Hum Genet 109:40; Shaw RJ et al 2002 J Biol Chem 277:24420.

Error in Translation: ▶[ambiguity in translation](#)

Error, Systematic: A basic mistake, bias, or misunderstanding of the collection or analysis or interpretation of data.

Error Types: Type I (α), rejecting a true hypothesis; and type II (β), accepting a wrong hypothesis on the basis of statistical analysis. ▶[power of a test](#), ▶[significance level](#)

Error Variance: The variance arising from agents, conditions beyond the ability to control an experiment, and with which the apparent effect of any controlled factor must be compared to obtain meaningful evaluation. ▶[analysis of variance](#)

Error-Free Repair: ▶[DNA repair](#)

Error-Prone Repair: ▶[SOS repair](#), ▶[DNA repair](#), ▶[mutasome](#), ▶[Y-family DNA polymerases](#); Goodman MF 2002 Annu Rev Biochem 71:17.

Erucic Acid (13-eicosenoic acid): A monoethenoid acid in the seeds of *Cruciferae* (rapeseed, mustard, horseradish, etc.) and *Tropaeolaceae* plants. It may constitute 50–80% of the fatty acids in these plants. It has poor digestibility but, even worse, it accumulates in the muscles and livers of the animals (humans) and causes serious and irreversible pathological changes. In the newly developed varieties of rapeseed (canola, *Brassica napus*) the erucic acid content has been reduced to 0.3%, thus making this plant a valuable oil-seed crop, particularly in cooler climates where soybeans do not fare well. The mutation blocks the conversion of oleic acid (18:1) to eicosenoic acid (20:1) and erucic acid (22:1). ▶[fatty acids](#), ▶[canola](#); Hans J et al 2001 Plant Mol Biol 46:229.

ERV: ▶[endogenous retrovirus](#)

Erwinia: A group of gram-negative enterobacteria. It is a pathogen for a variety of plant species. *Drosophila* appears to be a vector.

Erythralgia: An autosomal dominant disease with intense burning pain in the feet and hands, redness, heat-sensation, and swelling. A susceptibility locus

was found at 2q31-q32. ▶[pigmentation defects](#); Drenth JPH et al 2001 Am J Hum Genet 68:1277.

Erythroblast: A nucleus-containing erythrocyte or, in a loose sense, immature red bloods cell.

Erythroblastoma: A tumor-type mass of nucleated red blood cells.

Erythroblastosis: The circulating blood contains immature red blood cells.

Erythroblastosis Fetalis (neonatorum): When red blood cells of the developing fetus enter the maternal blood circulation of immunogenic mothers an immunization reaction may be generated. It may be particularly intense when the mother is Rh-negative and the fetus has Rh-positive blood. The antibodies formed by the mother then may enter the fetal blood supply and cause increased bilirubin production (causing nerve damage) and agglutination, and lysis of the fetal blood resulting in intrauterine death or severe anemia unless the newborn's blood is replaced immediately after delivery. Today, monitoring, especially in the later stages of the pregnancy, for bilirubin or Rh-antibody accumulation may prevent the development of erythroblastosis. If the tests are positive, and before Rh-antibodies accumulate, the mother may be given an anti-Rh γ -globulin that can be transferred through the placenta to the fetus. This affords protection against erythroblastosis. Erythroblastosis may be caused also by infection by the avian retrovirus, AEV, and ABO blood group incompatibilities. The latter is quite common but its effects are usually mild. ▶[Rh blood type](#), ▶[SU antigen in pigs](#); Stockman JA 3rd, de Alarcon PA 2001 J Pediatr Hematol Onc 23[6]:385.

Erythrocyte (red blood cell): Erythrocytes are disk-shaped (doughnut-shape), biconcave cells (see Fig. E45). Their average numbers in human males is ~5,400,000 and in females ~4,800,000/mL of blood after puberty. The numbers may vary by as much as 15% depending on altitude or other conditions. In animals the numbers may be different; in pigeons it is ~2,400,000 in dogs it is ~6,650,000. Their red color is due to the red oxygen carrier molecules, hemoglobin they contain. The erythroblasts expel the nuclei and express phosphatidylserine on the surface and thus attract the engulfing macrophages, which destroy the nuclei (Yoshida H et al 2005 Nature [Lond] 437:754). The mature erythrocytes no longer contain nuclei or nuclear DNA. Primarily, DNaseII of the macrophages mediates the enucleation during development. ▶[blood](#), ▶[leukocyte](#), ▶[hemolytic disease](#), ▶[sickle cell anemia](#), ▶[survivin](#), ▶[TIF1- \$\gamma\$](#) ; Orkin SH, Zon LI 1997 Ann Rev Genet 31:33.

E

Erythroderma, Ichthyosiformis, Non-Bullous (ALOX, 17p13.1): Result of mutations in lipoxygenase. ▶ichthyosis, ▶Kid syndrome, ▶lipoxygenase; Jobard F et al 2002 Hum Mol Genet 11:107.

Erythrokeratoderma Variabilis (1p34-p35): A dominant hyperkeratosis with transient red patches, encoded by gene GJB3, responsible for connexins 31/30.3 component of gap junctions (see Fig. E46). A conditional mouse mutant that carries the human F137L mutation in the Cx31 mouse gene, which was described to act in a transdominant negative manner, is an animal model for the disease. The phenylalanine residue at position 137 is highly conserved in several human and mouse connexin genes (Schnichels M et al 2007 Hum Mol Genet 16:1216). ▶connexins, ▶Charcot-Marie-Tooth disease, ▶deafness, ▶skin diseases, ▶gap junctions

Figure E46. Erythrokeratoderma variabilis. Sharp red keratotic spots on the human back

Erythroleukemia: Erythroleukemia is based on an autosomal dominant gene causing neoplastic growth of the immature and mature red blood cells, increase in the size of liver and spleen, and acute anemia. It is considered to be a malignant disease. ▶leukemia

Erythromycin: A group of three antibiotics produced by *Streptomyces erythreus*/*Saccharopolyspora erythraea*. The sequenced circular genome of this soil bacterium comprises 8,212,805 base pairs and predicted to encode 7,264 genes (see Fig. E47). The bacterium is resistant to several antibiotics and contains 17 lactamase genes and two macrolide esterases (Olynyk M et al 2007 Nature Biotechnol 25:447). Erythromycin inhibits amino acid chain elongation on the ribosomes. ▶antibiotics. The *ery* (erythromycin resistance) gene is the most distal marker to *ap* (attachment point) in the chloroplast DNA of *Chlamydomonas reinhardtii* according to recombination tests in cytohybrids (heterozygous for

Figure E47. Erythromycin

ctDNA). Oral erythromycin therapy, when combined with the use of cytochrome-450 3A, increases the concentration of the antibiotic and may cause sudden heart failure (Ray WA et al 2004 New England J Med 351:1089). ▶chloroplast genetics, ▶chloroplast mapping, ▶nonribosomal peptide

Erythropoietin (EPO): A highly specific erythrocyte stimulating glycoprotein factor (M_r 51,000), produced mainly in the kidneys and acting in the bone marrow. It was isolated from anemic sheep but is now also produced by recombinant DNA technology. It is also used as a medication to avoid the need for blood transfusion in patients prone to anemia. The EPO receptor (EPOR) is a protein of the cytokine receptor family. It is formed as a dimer with an extracellular ligand-binding, a short, single pass transmembrane segment and a cytoplasmic domain without kinase activity. Its signaling relies on the Jak/STAT pathway. EPO/EPOR regulates caspases, which in turn control the fate of GATA-1 and apoptosis with the aid of FAS. EPO may induce tumor regression and antitumor immune response in murine myeloma. Cross talk between Janus kinase and NF- κ B signaling cascades results in neuroprotection by erythropoietin. ▶growth factors, ▶megakaryocyte, ▶hematopoiesis, ▶signal transduction, ▶FAS, ▶GATA, ▶apoptosis, ▶CIS, ▶polycythemia, ▶Jak kinases, ▶NF- κ B; Spivak JL et al 1991 Blood 77:1228; Digicaylioglu M, Lipton SA 2001 Nature [Lond] 412:641; Leist M et al 2004 Science 305:239.

ES: An embryonic stem cell; cells that can proliferate in an undifferentiated state but can give rise to differentiated cells as well and can be returned to an embryo to become part of it. These pluripotent cells are taken from blastocyst stage embryos. They are functionally similar to the meristem cells of plants. ▶totipotency, ▶pluripotency, ▶stem cell

ESA1: A histone acetylase that can activate transcription if targeted to specific promoters. ▶histones; Reid JL et al 2000 Mol Cell 6:1297.

ESAG: An expression site associated genes. ▶Trypanosoma

ESC: An embryonic stem cell. ▶ [stem cell](#), ▶ [SSC](#)

Escape Commitment: After initiation of transcription by RNA polymerase II and synthesis of four nucleotides, the polymerase proceeds to elongation with an *escape commitment* and leaving the promoter. ▶ [transcription factors](#)

Escherichia coli: ▶ [E. coli](#)

ESE (exon splicing enhancer): ca. 6–8-nucleotide sequences within exons that promote efficient splicing. They generally bind SR proteins with arginine/serine-rich tract. ▶ [NAS](#), ▶ [exon](#), ▶ [splicing](#), ▶ [SR motif](#); Woerfel G, Bindereif A 2001 Nucleic Acids Res 29:3204; Tian H, Kole R 2001 J Biol Chem 276:33833.

Ess1: ▶ [parvulins](#)

Essential Amino Acids: Essential amino acids cannot be synthesized de novo by vertebrates and must be provided in the diet: arginine (in young), histidine, isoleucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. The sensing of the lack of indispensable amino acids in the food/feed resides in the mammalian brain anterior piriform cortex. Uncharged transfer RNA induces phosphorylation of eukaryotic translation initiation factor eIF2 α with the aid of the GC nonrepressing 2 kinase (GCN2). This mechanism determines appropriate food selection (Hao S et al 2005 Science 307:1776). ▶ [high-lysine corn](#), ▶ [kwashiorkor](#), ▶ [amino acid metabolism](#), ▶ [transfer RNA](#), ▶ [eIF-2A](#)

Essential Athrombia: ▶ [thrombopathia](#)

Essential Fatty Acids: Essential fatty acids are required by mammals although they cannot synthesize them (linoleate [18:2 cis-D⁹, D¹²], and α -linolenate [18:3 cis-D⁹, D¹², D¹⁵]) because they are unable to introduce additional double bonds beyond the C-9. ▶ [fatty acids](#)

Essential Hypertension: ▶ [hypertension](#)

Essential Gene: An essential gene cannot be dispensed of without lethal consequences. In *Saccharomyces cerevisiae* yeast more than 80% of the genes are nonessential (Tong AHYY et al 2001 Science 294: 2364).

EST: ▶ [expressed-sequence tag](#). (See Gene Indices: <http://www.tigr.org/tldb/tgi/>).

EST1: A telomerase subunit. ▶ [telomerase](#)

EST Genome: Predicts genes on the basis of homology and aligns ESTs, cDNAs or mRNAs. ▶ [gene prediction](#), ▶ [expressed-sequence tag](#); <http://www.litbio.org>.

Established Cell Line: An established cell line of animals consists of fused cells (with one component being myeloma cancer cells) and is capable of indefinite growth without senescence. ▶ [immortalization](#), ▶ [HeLa](#)

Ester: An ester is formed when the OH end of an alcohol is combined with the COOH end of an acid leading to the removal of H₂, e.g., R–O–CO–R. Nucleotides may form ester linkages during chain elongation. ▶ [phosphodiester bond](#), ▶ [nucleotide chain growth](#)

Esterases: Esterases are enzymes involved in hydrolysis of ester bonds. Some proteolytic enzymes catalyze the reaction (see Fig. E48). In biochemical systems the esters may be phosphate-, glycerol-esters and many other molecules. Esterase A-4 (ESA4) is encoded in human chromosome 11q13-q22, ESD was located to 13q14.11; other human variants exist.

Figure E48. Esterases

Estradiol (estrogen): A steroid hormone produced by the animal (human) ovaries and placenta. It regulates secondary sexual characters and female estrus and implantation (see Fig. E49). 17 β -estradiol and raloxifene indirectly activate the estrogen-response element. The β -estradiols are carcinogenic through their metabolites (4-hydroxyesterone, 16 α -hydroxyesterone, semiquinone) by contributing to reactive oxygen and lipid compounds. Estrogen-like substances in the environment pose reproductive hazards to humans and wildlife. Estradiol (17 β) susceptibility in mice may vary by a factor of 16 or more among different strains. Although estrogen does not appear to be mutagenic in most of the standard bioassays, it generates DNA-estrogen adducts, and damages DNA

by free radicals. It produces 8-hydroxyguanine and may induce chromosomal aberrations. Estrogens may act as cancer promoters in cases where cancer cells are already present. Some estrogens or estrogen-like compounds are not steroids, e.g., diethylstilbestrol, hexestrol, the flavone and isoflavone phytoestrogens (coumestrol, genistein), mycoestrogens, and some alkylphenols, arylphenols and the nonaromatic pesticides like dieldrin, endosulfan, chlordane, some carbamates and the herbicide atrazine. Some pesticides such as DDT, methoxychlor are estrogenic pollutants. Similarly, the industrially used polychlorinated biphenyls (PCB), automobile exhaust, and Agent Orange, dioxin, etc., may be considered as endocrine disrupters and pose environmental hazards to humans and animals.

Figure E49. Estradiol

Estrogens act through the estrogen receptors and various ligands and other cooperative molecules. They may regulate + and – the transcription of many different genes (breast cancer, prolactin, dopamine, plasminogen activator, peroxidase, renin, etc.). All estrogen receptor and RNA polymerase II binding sites were mapped on a genome-wide scale, identifying the authentic *cis* binding sites and target genes, in breast cancer cells (Carroll JS et al 2006 Nature Genet 38:1289). Estrogens may have post-transcriptional and post-translational regulatory influence too. Estrogens affect the cholinergic activity in the brain and when this function diminishes by advanced age, learning and memory are impaired. Estrogens are involved in many metabolic processes. 17 β -hydroxysteroid dehydrogenase 2 and cytochrome P₄₅₀ mono-oxygenases metabolize estrogens. The latter enzymes may produce carcinogenic catechol estrogen. The anti-estrogen, tamoxifen, also appears carcinogenic to the liver and on prolonged use, to the endometrium of the uterus. Some of the estrogens appeared mutagenic in various types of assays. Several diseases (breast, endometrial, cervical prostate cancers, and thyroid diseases) increase hydroxylation of estradiol whereas osteoporosis and obesity may decrease hydroxylation. In pregnancy, the level of estrogens rises rapidly and the maintenance of an appropriate level is required for fetal development. It has been suggested that estrogens regulate the level of 5-hydroxy-tryptamine/serotonin in the brain and the lower supply of estrogens may thus be a contributing

factor to menopausal and postpartum (after-child-birth) depression. Estrogens may control glucose transport to the brain and may protect against neurodegeneration, such as is associated with aging (Alzheimer's disease). Gonadal hormones show protective effects against heart disease by contributing to the integrity of the vascular wall. Estrogens and antiestrogens modulate the immune system in various ways. A low level of estrogen is normally also present in mammalian males. Its deficiency due to mutation in the aromatase gene lowers the fertility of the male mice, but its role in the human male is less obvious although increase in estrogen may cause gynecomastia. Human males with aromatase deficiency show increased levels of estradiol. Under normal conditions, in males, the 17 β -estradiol level is higher than in postmenopausal women. ▶animal hormones, ▶estrogen response element, ▶steroid hormones, ▶antiestrogens, ▶nitric oxide, ▶androgen, ▶gynecomastia, ▶choline, ▶depression, ▶Alzheimer's disease, ▶aromatase, ▶tamoxifen, ▶raloxifene, ▶dioxine, ▶phytoestrogen, ▶targeting vector, ▶abortion spontaneous; Petterson K, Gustafsson JÅ 2001 Annu Rev Physiol 63:165; estrogen sensitive genes: <http://research.i2r.a-star.edu.sg/kberg>.

Estriol: A 16 α -hydroxylation product of estradiol. ▶estradiol

Estrogen: ▶estradiol, ▶animal hormones

Estrogen Receptor (ER): An estrogen receptor is dimeric (ER α + ER β) and to become functional, ER α is phosphorylated at Ser¹¹⁸ by a mitogen-activated protein kinase (MAPK) in the presence of an epidermal growth factor (EGF) and insulin-like growth factor (IGF). The dimeric ER associated with the proper ligands can bind to the estrogen receptor element in the chromosome and activate transcription of the estrogen receptive genes. The ERs can bind also to the AP1 transcriptional activator protein. ER α bound through the Jun and Fos oncoproteins to an AP1 site is activated by estradiol-17 β . In contrast, ER β bound estradiol-17 β inhibits transcription. The antiestrogens tamoxifen and raloxifene are transcriptional activators of ER β at the AP1 site. These pieces of information indicate that the two ERs differ in their signaling properties depending on the response element and the ligand. The practical significance of the finding is that this may provide a clue to why tamoxifen is an inhibitor of breast cancer but at the same time carcinogenic to the uterus, whereas raloxifene may be beneficial for the chemotherapy of breast cancer without a risk to the uterus. There is some recent observation that after a few years (2–5 years) raloxifene may alter the cellular machinery and promote tumorigenesis. Amplification of the

ESR1 estrogen receptor alpha gene (6q25) was detected in 20.6% of breast cancers by tissue microarray analysis of more than 2,000 clinical breast cancer samples. Ninety-nine percent of tumors with ESR1 amplification showed estrogen receptor protein overexpression, compared with 66.6% cancers without ESR1 amplification (Holst F et al 2007 Nature Genet 39:655). ▶estrogen, ▶breast cancer, ▶MAPK, ▶MAPKK, ▶EGF, ▶IGF, ▶tamoxifen, ▶raloxifene, ▶phytoestrogen; Shang Y et al 2000 Cell 103:843; Klinge CM 2001 Nucleic Acids Res 29:2905; Ciana P et al 2003 Nature Med 9:82.

Estrogen Response Elements (ERE): ERE are generally located about 200–300 bp upstream of the transcription initiation site. Despite their diversity they generally share a low homology consensus. For example, the *Xenopus* vitellogenin and the chicken ovalbumin gene carry the dyad: GGTCANNNTG^A_TCC. ▶hormone response elements, ▶regulation of gene activity, ▶animal hormones, ▶raloxifene, ▶tamoxifen; Driscoll MD et al 1998 J Biol Chem 273:29321; Shang Y, Brown M 2002 Science 295:2465.

Estrus: The recurrent sexually receptive periods of female mammals (except humans) accompanied by a sexual urge (heat); it is induced by cyclic ovarian hormonal activity (oestrus).

ET Cloning: The transformation of *E. coli* by using homologous recombination with the aid of a plasmid expressing the products of gene *RecE*, exonuclease VIII, and RecT. The gene to be transferred is flanked by about 40 nucleotides. ▶e *RecE*, ▶RecT, ▶transformation-associated recombination; Muylers JP et al 2000 Genet Eng 22:77.

Eta: ▶osteopontin

Ethanol: A common laboratory sterilizing agent used in 70–80% aqueous dilutions. Yeast synthesizes it from Glucose → Glyceraldehyde3-phosphate → 1,3-Diphosphoglycerate → Pyruvate → Acetaldehyde → Ethanol. From acetaldehyde it can make Acetate → Acetyl phosphate → Acetyl Coenzyme A and enters the Citric acid cycle. ▶alcohol, ▶alcoholism

Ethenobases: Ethenobases are metabolites of vinyl chloride through the action of the cytochrome P450 system which produces chloroethylene oxide, leading to the formation of several carcinogenic adducts. Among these are ethenobases (see Fig. E50). Ethenodeoxyguanine pairs with adenine and despite the relatively small amounts formed it is primarily responsive for the mutagenic/carcinogenic effects in the liver and brain. ▶environmental mutagens; Morinello EJ et al 2002. Cancer Res 62:5183.

Figure E50. Ethenobases

Ethernet: The wiring and software required to share data through the Internet and local talk.

Ethics: The rules of animal and human behavior based on genetic and instinctive or social and moral traditions. The Gene Letter URL (<http://www.geneletter.org>) is a source for current problems and information on genetics (gene-related ethics). Physicians frequently face the problems of applying legal medical procedure (abortion, sedation to terminally ill, contraception to adolescents) to what they have moral or religious objections to. Among the polled 2,000 physicians, 63% believe that it is ethically permissible for doctors to explain their moral objections to patients and 86% believe that physicians are obligated to present all options to patients; 71% agree to refer them to another clinician who does not object to the requested procedure (Curlin FE et al 2007 New England J Med 356:593). The code of ethics of the American Society of Human Genetics: Boughman JA 2006 Amer J Hum Genet 79:1136). ▶behavior genetics, ▶ethology, ▶genetic privacy, ▶bioethics, ▶informed consent, ▶nuclear transplantation, ▶embryo research, ▶misconduct scientific, ▶publication ethics, ▶morality, ▶forbidden knowledge; Febr. 8 2007 comments in the New England Journal of Medicine; <http://www.ornl.gov/hgmis/elsi/elsi.html>; <http://www.nhgri.nih.gov/ELSI/>.

Ethidium Bromide (EB): A polycyclic fluorescent dye. Its fluorescence increases about 50 fold when it intercalates between DNA bases, and the sensitivity of the staining is so high that 2.5 ng DNA is detectable. It is used for revealing of DNA in agarose or polyacrylamide gels and buffers (0.5 mg/mL). The UV light absorbed by DNA at 254 nm is transferred to EB that itself has two absorption maxima at 303 and 366 nm and emits red-orange fluorescence at 590 nm maximum. DNA of more than 250 ng/mL can quantitatively be measured spectrophotometrically. The detection of

single-strand DNA or RNA is much less effective by EB. Intercalation into closed circular DNA is much less efficient than into linear DNA. Therefore, EB-stained plasmid or organellar DNA can be separated by buoyant density centrifugation from linear DNA by becoming of lesser density. EB-stained gels can be destained with water or by 1 mM MgSO₄ for 20 min. From the DNA, EB can be removed by washing several times with an equal volume of water-saturated 1-butanol or isoamylalcohol. EB is a powerful mutagen and must be handled carefully with gloves. The used solutions after dilution to no more than 0.5 mg/L require decontamination by 1 vol. 0.5 M KMnO₄ and careful mixing of 1 vol. 2.5 N HCl for several hours, followed by neutralization with 1 vol. 2.5 N NaOH. This procedure reduces mutagenicity to 3×10^{-3} of the untreated solutions.

Ethnicity: A human population related by biological features, identifiable by anthropometric, cultural, linguistic, biochemical, serological, molecular characteristics, SNPs and gene frequencies. The identification may not use all of these methods, depending on the nature of the genetic distances in the comparisons. The various ethnic groups and isolated communities provide valuable information for population genetics research. Protection of the privacy of individuals (Nature Genet 23:275), however, deserves serious consideration. The HGDP (Human Genome Diversity Project) aims to survey the world population for genetic diversity at the DNA level. The idea is to study disease susceptibility/resistance genes, evolution, population genetics, etc. Mapping by admixture linkage disequilibrium (MALD) is a potential analytical statistical method. Some analysts of the problems of ethnicity consider the study of ethnic differences to lead to racial discrimination (Duster T 2005 Science 307:1050).

Specific genetic variation among populations contributes appreciably to differences in gene expression phenotypes. Populations differ in the prevalence of many complex genetic diseases, such as diabetes and cardiovascular disease. The data collected on European, Chinese, and Japanese populations indicate allele frequency differences at regulatory polymorphisms to account for differences in prevalence of complex diseases (Spielman RS et al 2007 Nature Genet 39:226). ►genetic distance, ►Jews and genetic diseases, ►thalassemia, ►sickle cell anemia, ►Duffy blood group, ►MALD, ►SNPs, ►low-density lipoprotein, ►admixture in populations, ►myocardial infarction, ►Amish; Guglielmino CR et al 2000 Ann Hum Genet 64:145; Pastinen T et al 2001 Hum Mol Genet 10:2961; Arab genetic diseases: Teebi AS et al 2002 Hum Mut 19:615; Finnish diseases: Sipilä K, Aula P 2002 Hum Mut 19:16; ethnicity/

Ethological Isolation: A type of sexual isolation. Males or females refuse to mate for some “psychological” reason(s). ►sexual isolation

Ethology: The study of behavior. ►behavior genetics, ►ethics, ►aggression, ►instinct, ►morality

Ethyl (–CH₂CH₃): An alcohol radical.

Ethylene (C₂H₄): The simplest plant hormone yet it controls a wide variety of morphogenetic and developmental processes, from stem and root growth, seed germination, to fruit ripening, senescence, and sex determination. Ethylene is synthesized as a side branch of the Yang cycle. The key enzymes in ethylene synthesis are ACC synthase and ACC oxidase. A multigene family encodes ACC synthase and it is regulated by hormonal, physical, and environmental signals. In *Arabidopsis*, a series of mutants are available that determine constitutive ethylene response and are overproducers. The ethylene insensitive mutations include a histidine kinase (*ein1*, *etr1*), *ain* is ACC-insensitive, *ctr1* is a putative serine/threonine kinase similar to the members of the MAPK. *EIN-2* has a central role in the pathway, encoding an integral membrane protein. It is a transducer of ethylene and stress responses. Gene *ERS* (ethylene response sensor) has some structural similarity to ETR (ethylene response resistance) but its role is upstream in the pathway. The order of gene action has been determined for most of the numerous mutations. Ethylene plays a key role in plant signaling and, from practical points of view, in fruit ripening and disease resistance. Several of disease and stress resistance genes and other genes controlling differentiation contain GCC box repeats that are also ethylene response elements. The ethylene insensitive *ETR1* gene of *Arabidopsis*, when transferred to yeast, conveyed ethylene binding in this fungus too. The ethylene nonresponding mutation *hookless1* seems to be a regulator of auxins. The *RTE1/GR* genes of *Arabidopsis* and of tomato, respectively, are specific repressors of insensitivity to an ethylene receptor *etr1* (Klee H 2006 Proc Natl Acad Sci USA 103:7537). ►plant hormones, ►Yang cycle, ►fruit ripening, ►SAR, ►hypersensitive reaction, ►hormone-response elements, ►MAPK, ►MAPKK; Bleecker AB, Kende H 2000 Annu Rev Cell Dev Biol 16:1; Johnson PR, Ecker JR 1998 Annu Rev Genet 32:227; Wang KL-C et al 2002

Plant Cell 14:S131; Wang K L-C et al 2004 Nature [Lond] 428:945; Alonso JM, Stepanova AN 2004 Science 306:1513; Bonaventura LM, Alonso JM 2006 Mol Biosyst 2:165.

Ethylene Oxide (C_2H_4O): A colorless, explosive gas used as a sterilizing agent for instruments, textiles, certain types of food, and soil. It is hazardous to handle; an irritant to mucous membranes and the lung and may cause pulmonary edema at higher concentrations. ▶sterilization

Ethyleneimine: ▶EI

Ethylmethanesulfonate (EMS, $CH_3SO_2OCH_2CH_3$): An alkylating mutagen and carcinogen. Its prime target for mutagenesis is the alkylation of the O⁶ position of guanine although it alkylates prefer the 7 position of guanine, but this rarely leads to base substitution. It alkylates all other nucleic acid bases too, and may cause strand scission by depurination. It is one of the most useful chemical mutagens for a wide range of organisms. ▶alkylation, ▶mutagens, ▶carcinogens, ▶depurination, ▶hydrogen pairing

Etiolated: Plants grown in the absence of light display elongation and lack of the typical leaf pigments (chlorophyll and carotenoids). The chloroplasts do not develop and the plastids only reach the etioplast stage (thylakoid membrane system incomplete). The leaves are not fully expanded. ▶photomorphogenesis, ▶phytochrome, ▶de-etiolation

Etiology: The study of cause(s) of disease and its development. Chemical etiology investigates the origin and cause(s) of the development of molecules.

Etioplast: An etioplast lacks the typical chloroplast pigments and displays a prolamellar body. The etioplast-chloroplast transition is a light-dependent process catalyzed by protochlorophyllide oxidoreductase A (PORA). ▶etiolated, ▶prolamellar body, ▶proplastid, ▶chloroplasts; Philipp K et al 2007 Proc Natl Acad Sci USA 104:678.

ETL (economic trait loci): ETL determine phenotypes that are important for practical agriculture.

ETO (eight twentyone): A translocation involving human chromosome 8q22 and 21q22.3 involved in myelogenous leukemia. ▶leukemia; Erickson P et al 1992 Blood 80:1825.

ETOPE: An evolutionary test of predictive exons (Nekrutenko A et al Nucleic Acids Res 31:3654).

Etoposide: A synthetic cytostatic compound; it inhibits topoisomerase II, cancer and nucleoside transport and CDK2. It may promote the function of nucleotidyl transferase and gene conversion in somatic mammalian cells. Etoposide may induce chromosomal

aberrations and aneuploidy. When rubbed to the skin of rats treated by chemotherapy hair loss was prevented in 50% or more of the animals. Genome-wide, 63 genetic variants were identified that contribute to etoposide-induced toxicity through their effect on gene expression. These include genes that may play a role in cancer (Huang RS et al 2007 Proc Natl Acad Sci USA 104:9758). ▶cytostatic, ▶aneuploid, ▶topoisomerases, ▶terminal deoxynucleotidyl transferase, ▶CDK, ▶camptothecin; Jacob S et al 2001 Cancer Res 61:6555.

ETS (external transcribed spacers): ETS are located between pre-tRNA gene clusters and at other genes controlling growth and development:

ETS - 5' - 18S- ITS - 5.8S - ITS - 28S) - ETS

The ETS family members usually bind to different protein monomers or dimers. ▶ITS, ▶SAP, ▶PU.1, ▶GABP, ▶spacer DNA; Borovjagin AV, Gerbi SA 2001 Mol Cell Biol 21:6210.

ETS Oncogenes: ETS-1 was located to human chromosome 11q23-q24. It is involved in acute monocytic leukemia (AMoL) when interferon β gene (IFB-1, chromosome 9p22) is translocated to it. ETS-1 and ETS-2 genes are physically contiguous in birds. The homologous two genes are coordinately expressed and the proteins are both in the cytoplasm and nucleus. In humans, ETS-2 genes are in chromosomes 21q22, 1-q22.3 and their expression is not coordinate; the ETS-1 protein is cytoplasmic whereas the ETS-2 is nuclear. ETS-1 can be phosphorylated posttranslationally in an unstructured region in multiple ways; the phosphorylation fine-tunes DNA binding, transcription and signaling (Pufall MA et al 2005 Science 309:142). Translocation t(8;21)(q22; q22) is common in patients with acute myeloid leukemia (AML-M2). The breakage point in the latter cases is not within the ETS-2 sequences. The ETS-2 gene lacks the TATA box and CAAT box, and alternative elements substitute for them. The ELK oncogenes display homology to the ETS oncogenes. This family of transcription factors has about 35 known members and regulates various aspects of growth, development, and lymphocyte pool maintenance. PEA3, a member of the ETS family of proteins, binds to the 5'-AGGAAG-3' DNA motif and suppresses the expression of the HER-2 oncogene. ETS opposes p16^{INK4a} in cooperation with Id1 during senescence. ERM, an ETS family protein, is required for the maintenance of spermatogonial stem cell niche (Chen C et al 2005 Nature [Lond] 436:1030). ▶leukemia, ▶interferon β -1, ▶oncogenes, ▶ELK, ▶SAP, ▶ERP, ▶lymphocytes, ▶HER; Blair DG, Athanasiou M 2000 Oncogene 19:6472.

Eubacteria: The majority of bacteria belong to this subkingdom of prokaryotes; the other subkingdom is *Archaeobacteria*.

Eucaryote: eukaryote; karyon [καρυον] is a Greek word and it is more appropriate to spell it with k.
►prokaryote

Euchromatic: Chromosomal regions containing euchromatin. ►euchromatin

Euchromatin: Euchromatin does not absorb the common nuclear stains during interphase and is normally transcribed into mRNA. In the human genome, the euchromatic fraction varies a great deal among the chromosomes. In chromosome 2 an almost 160 Mb sequence is less than 60% euchromatic whereas a more than 30 Mb sequence in chromosome 21 is almost entirely euchromatic. ►heterochromatin; <http://www.euchromatin.net/>; Yu A et al 2001 Nature 409:951.

EUCIB: ►European Collaborative Interspecies Backcross, a cooperative workgroup for plants.

Euclidean Distance: Calculations are used to construct dendrograms, evolutionary trees or comparisons. In the formula (see diagram) x and y represent observations in a set of multivariate data. ►dendrogram, ►evolutionary tree, ►multivariate analysis

$$d_{xy} = \sqrt{\sum_{i=1}^q (x_i - y_i)^2}$$

Eudicot: Common dicotyledonous plants.

EUG: A 65-kDa yeast protein in the endoplasmic reticulum with disulfide isomerase activity. ►PDI, ►Mpd

Eugenics: The application of genetic principles to the breeding of the human race with the purpose of improvement. *Positive eugenics* wishes to enrich the frequency of “favorable” genes whereas *negative eugenics* wants to eliminate the “undesirable” genes by selective breeding. The word eugenics was coined by Sir Francis Galton in 1883, unaware of Mendel’s discoveries, but his statistical data indicated that about 25% of the sons of eminent fathers were also eminent. From this he concluded that heredity plays a role in talent, intellect, and behavior. These fields are highly controversial because of the lack of scientific bases for the objective measurement of “desirable” and “undesirable” and the potentials of exploitation for political or unethical goals. The eugenics movements generally emerged during economic downturns in an effort to find scapegoats for the ills of societies, and the support generally

came from people without any understanding or training in genetics. By 1917, in 16 states of the USA, laws were approved for compulsory sterilization of the feeble-minded, insane, rapists, criminals and other “hereditary unfit” individuals. Actually, by 1935, about 30,000 sterilizations were carried out on the basis of these state laws. With the rise of scientific population genetics, it became obvious that this type of negative selection is ineffective. According to the Hardy–Weinberg theorem, if the frequency of the homozygous recessive “undesirable” individuals is $1/20,000$ (5×10^{-5}) then at genetic equilibrium the frequency of that gene is $\sqrt{0.00005} \cong 0.0071 = q$ and the frequency of the carriers (heterozygotes) is $2 \times p \times q = 2 \times 0.9929 \times 0.0071 \approx 0.014099$, i.e., about $1/71$. In other words, about 99.3% of this “undesirable” allele will be present in the heterozygotes of the population and about $1/71$ individual will have a 50% chance to pass it on to their children. If all the “undesirable” individuals are prevented from reproduction by sterilization the frequency of their “bad” gene (q_n) will change in 100 generations to:

$$q_n = \frac{q_0}{1 + 100q_0} = \frac{0.0071}{1 + [100 \times 0.0071]} \cong 0.004152$$

Thus, the initial gene frequency of 0.0071 will be reduced to about 0.004152 and the number of carriers by about 41% to $1/121$ in about 3,000 years. Also, behavioral traits are under the control of multiple genes, scattered in the genome, and each of them contributes partly to the phenotype. Furthermore, characters as these are under polygenic control and are greatly affected by environmental influences. Thus, the negative eugenic measures are biologically ineffective and ethically unacceptable in enlightened societies. Nevertheless, in the name of eugenics, Hitler’s regime exterminated six million Jews and millions of others of different ethnic groups, as well as sterilized more than 250,000 people. Negative eugenics, although it is quite ineffective as shown above, still may have some justification in some forms chosen by the individuals at high genetic risk of disease. The simplest humane and intellectually and ethically correct solution is refraining from reproduction. Therapeutic abortion is counterproductive because it may increase the number of carriers although the “defective” individuals (homozygotes) are eliminated.

Positive eugenics has some biological and ethical problems too because human values cannot be adequately assessed. Certain measures may, however, be acceptable and are practiced in societies without naming them as eugenics. For example, adequate scholarship to college students may facilitate their

support of a family and thus, presumably, intellectually better individuals may not be prevented from procreation because of economic hardship. Also, reproduction at a younger age may reduce chromosomal defects (see ►[Down's syndrome](#)). The Nobel-laureate geneticist H. J. Muller advocated positive eugenics throughout his career. He considered it a necessity to fight genetic load through *germinal choice*, meaning that spousal love should be separated from procreational role in marriage. He suggested the reliance of gene banks for artificial insemination of the women and recommended systematic screening of the sperm donors on the basis of health, intellect, and social consciousness. The sperm of the selected individuals were supposed to be stored frozen and used only some years after their death to make an objective and reliable assessment of their value. Although such a program may appear reasonable, problems in value judgment remain. Muller believed that in a true socialist political and social system these problems could be overcome. His own disenchantment with the Marxist society of the USSR proved, however, otherwise. Some general fears of intervention in the human system of reproduction are still not completely dissolved. Will the controlled insemination reduce the gene pool? Is it conceivable that the selection may foster the increase of some so far unforeseen genetic defects either by lack of recognition or by hitchhiking (linkage)? Is there a risk that political systems impose their selfish will upon the biologically desirable systems of reproduction? The problems of positive eugenics may not, however, be ignored. The progress in medical technologies prevents the selection against formerly inferior traits. The uses of medication, prosthetics, somatic gene therapy, etc., are devices of contraselection. Perhaps, the replacement of genes of the germline involved in clinically proven defects may offer a solution. The methodology now appears clear in principle, but the consequences are still untested. Thus, the “brave new world” is not yet at hand, primarily because our values cannot be defined in a simplistic manner. Eugenics must be separated from the racist views that discredited the field. Multiracial and multicultural societies offer unique advantages in their diversities for the betterment of life. Biologists must find the facts but the application of the principles discovered requires the democratic decisions of the ethicists and the societies. Will ethicists know enough biology? ►[gene therapy](#), ►[eutelegensis](#), ►[Hardy-Weinberg theorem](#), ►[sterilization in humans](#), ►[genetic counseling](#), ►[Galtonian inheritance](#); Kempthorne O 1997 *Genetica* 99:109; Li CC 2000 *Hum Hered* 50:22; Micklos D, Carlson E 2000 *Nature Rev Genet* 1:153; Gillham NW 2001 *Annu Rev Genet* 35:83; a historical display

on origin and flaws: <http://www.galton.org/>; <http://vector.cshl.org/>.

Euglena: A green (has chloroplast) flagellate protozoon, $n = 45$. (See Sheveleva EV et al 2002 *Nucleic Acids Res* 30:1247; <http://www.plantbiology.msu.edu/trie-mer/Euglena/Index.htm>).

Eukaryotes: Organisms with enveloped cell nucleus, mitosis, and meiosis, such as fungi, plants, and animals. The evolutionary origin of eukaryotes cannot be determined with certainty (see Fig. E51). Genomic data indicate that genes involved in transcription and translation and other processes of information are most likely descended from archaea, whereas genes involved in cellular metabolism such as synthesis of amino acids, cell envelope and lipid synthesis suggest eubacterial (proteobacteria, cyanobacteria, bacilli) origin. Conditioned reconstruction techniques used in connection with Markov-based quartet methods may overcome the problems with horizontal gene transfer and indicate that the eukaryotic genomes arose through the fusion of two different prokaryotic genomes, represented on the left and right sides of the figure. Thus, the evolution of eukaryotes indicates a ring of life, rather than the common evolutionary tree. ►[evolutionary tree](#), ►[archaea](#), ►[life form domains](#); Rivera MC, Lake JA 2004 *Nature [Lond]* 431:152; models of the origin of eukaryotic cells: de Duve C 2007 *Nature Rev Genet* 8:395; euGenes information system: <http://iubio.bio.indiana.edu/eugenet/>.

Figure E51. Eukaryotes

Eulerian Path: A mathematical solution for a DNA fragment assembly in a novel way. It is named after the mathematician L. Euler (1707–1783) who solved basic problems of sets like the Venn diagrams. ►[Venn diagram](#); Pevzener PA et al 2001 *Proc Natl Acad Sci USA* 98:9748.

Eunuch: A person whose testes have been removed by castration thereby preventing sexual functions. If this takes place early in childhood it reduces the expression of the secondary sexual characters.

E

Eunuchs were used in the Middle East and North Africa as guardians of the harems and chamberlains. The Chinese emperors employed hundreds of them in the Forbidden City as counselors. In Italy, until 1871, the “castrati” dominated the operatic stages and church choirs because these male sopranos and contraltos had high-pitched voices of a great range. The removal of the testes contributed to the increased development of the vocal folds and this combined with their greater capacities of the chest and lungs facilitated finer expression than expected from women who were banned from such roles on “moral” grounds. Medicine calls males eunuchs if their sexual function is diminished by underdevelopment of the genitalia or mutation in the sex hormone genes.

►castration

Euphenics: Corrective measures for genetically determined defects with the aid of nongenetic means (e.g., spectacles, prosthetics, insulin, etc.). ►eugenics

Euploid: Cells or organisms with one or more complete genomes, the full basic set(s) of chromosomes. ►aneuploid

Eusocial: The altruistic behavior of the sterile worker class in social insects supporting the fitness of the colony by tending to the needs of the reproductive casts. Ants, termites, bees, and wasps are eusocial insects. ►altruistic behavior, ►fitness, ►social insects; Wilson EO, Hölldobler B 2005 Proc Natl Acad Sci USA 102:13367.

Euteleogenesis: A form of positive eugenics where selected sperm sources are used for voluntary artificial insemination. The expected impact on improving IQ has been defined as: $\bar{x}_1 = p \frac{\bar{x} - M}{2} h^2 + M$ where \bar{x} = the mean IQ of the sperm donors, p = percentage of females involved, M = mean, h^2 = heritability. ►eugenics, ►heritability, ►human intelligence

Eutely: In some species of nematodes (*Caenorhabditis* and relatives) all individuals have the same cell number and all organs in all individuals show identical cell numbers. There are, however, some exceptions to this rule. ►*Caenorhabditis elegans*; Azevedo RBR, Leroi AM 2001 Proc Natl Acad Sci USA 98:5699.

Euthanasia: The method of causing “painless” death practiced on handicapped, seriously incapacitated, or fatally ill persons. Infanticide and late-term abortion are very cruel forms of euthanasia. These are morally unacceptable procedures in the majority of enlightened societies. The morality of euthanasia has been questioned even when it takes the form of a suicide although it may prevent the sufferings of terminally ill individuals. In the majority of countries, the law does not permit euthanasia, even in case of

severe illness. Euthanasia has no eugenic consequence because the objects are not expected to reproduce due to age or illness. Various scientific organizations issued guidelines for the humane and ethical principles for euthanasia of experimental animals (Demers G et al 2006 Science 312:700). In the Netherlands in 2002, after three decades of debate and research, the Euthanasia Act was passed to regulate the ending of life of people by a physician at the request of a patient who was suffering unbearably without hope of relief. A similar law was adopted in Belgium. The Oregon Death with Dignity Act legalizing physician-assisted suicide was enacted into a law in 1997. In 2005, 1.7% of all deaths in the Netherlands were the result of euthanasia, as compared with 2.6% in 2001. 0.4% of all deaths were the result of the use of lethal drugs, not at the explicit request of the patient. In 73.9% of all cases of euthanasia or assisted suicide in 2005, life was ended with the use of neuromuscular relaxants or barbiturates. Physicians also sometimes administered deep sedation when they had the explicit intention of hastening death (van der Heide A et al 2007 New England J Med 356:1957).

Eutherians: Eutherians are true placental mammals, but not the marsupials and monotrenes. ►marsupials, ►monotrene, ►X chromosome

eV: ►electron volt, ►Volt

Eva: A program that continuously and automatically analyses protein structure prediction servers “in real time”. (See <http://cubic.bioc.columbia.edu/eva/>).

Evans' Blue (direct blue): A strong oxidant and suspected carcinogen. It can be used for the isolation of intact protoplasts, which do not stain by it, whereas the damaged ones appear blue-green. ►protoplast

Eve Foremother of Molecular mtDNA: An evolutionary hypothesis attempting to trace the origin of the human race on the basis of mitochondrial DNA. Mitochondrial DNA in humans is transmitted only through the females and because of the uniparental transmission recombination cannot reshuffle the base composition of the mtDNA. Because of technical and computational difficulties, the assumption—that a single woman's descendants populate the earth—could not unequivocally be placed to Africa, and the investigators remained divided concerning the notion that all humans descended from a single female or even from a single group of females. Most likely, “Eve” represented a human population of 10,000 to 100,000 living about 150 to 200 kya (kiloyears ago). Some recent studies (based on the decline of linkage disequilibrium) indicate the possibility that paternal mitochondria may be transmitted during

fertilization and recombination may alter the maternal mtDNA sequences in larger blocks. ▶mtDNA, ▶genetic drift, ▶effective population size, ▶out-of-Africa, ▶Y chromosome, ▶F_{ST}, ▶mutation rate, ▶paternal leakage, ▶mitochondrial genetics, ▶archaeogenetics; Owens K, King M-C 1999 Science 286:451; Richards M, Macaulay V 2001 Am J Hum Genet 68:1315; Malhi RS et al 2002 Am J Hum Genet 70:905.

Eversporting: Organisms that carry unstable gene(s) and display somatic or germinal variegation. Many of the eversporting conditions are caused by the presence of transposable elements. ▶transposable elements, ▶transposons, ▶retrotransposons, ▶retroposons

Evi Oncogenes: Integration sites for retroviral insertions in human chromosome 3q24-q28, translocated to chromosome 5q34, resulting in nonlymphocytic leukemia. The Evi-1 mouse gene may cause murine leukemias. Its protein product has numerous zinc-finger domains and is presumably a transcription factor. The Evi-2A gene is in the proximal part of the long arm of human chromosome 17. The Evi-2B is in the same chromosome about 15 kb apart. Its product is apparently a transmembrane protein with surface receptor function. A homolog of these genes is associated with murine myeloid leukemia. The Evi-1 oncogene stabilizes the Emi1 inhibitor of the anaphase-promoting complex (Eldridge AG et al 2006 Cell 124:367). ▶leukemia, ▶oncogenes, ▶SMAD, ▶Evi, ▶Emi1

Evicting Plasmid: An evicting plasmid is incompatible with another type of plasmid and if selection is favoring the evicting plasmid (e.g., carries a gene for antibiotic resistance) the other plasmid can be eliminated. These operations can be used for the construction of particular genetic vectors. ▶vectors

Evidence Code: The evidence code indicates the type of evidence used for the annotation of a gene(s). ▶annotation

Evidence Viewer: An evidence viewer displays the alignments to human genome contigs of RefSeq and GenBank transcripts and ESTs supporting gene models. It points out mismatches between transcripts and genomic sequences are highlighted. It aligns transcripts exon-by-exon, including flanking genomic sequence for each exon. ▶EST, ▶exon, ▶mismatch, ▶RefSeq; <http://www.ncbi.nlm.nih.gov/Web/Newsltr/Summer03/index.html>.

Evocation: The induction of differentiation. ▶differentiation

Evo-Devo: A new term for evolutionary developmental biology. It studies the effect of development on the

direction of evolution, the relation between micro- and macroevolution, developmental genes across phylogenetic boundaries, etc. (See Arthur W 2002 Nature [Lond] 415:757).

EvoFold: A general comparative genomics method based on phylogenetic stochastic context-free grammars for identifying functional RNAs. Functional roles of RNAs are difficult to identify directly but their role can be assessed by comparative genomic surveys carried out among different genera and/or species (Pedersen JS et al 2006 PloS Comput Biol 2(4):e33). ▶AlioldZ, ▶RNAz, ▶RNA structural

Evolution: A process and theory of the biological and physical change that brings about the variety of the living world and its environment at the global and cosmic range. Biological evolution is based on changes in gene frequencies or function brought about by mutation, horizontal gene transfer, rearrangement by transposable elements, selection, migration, adaptation and fixed by reproductive isolation. The general evolutionary theory integrates all ideas about the nature, origin, and future of the universe. Evolutionary concepts can be supported by molecular, cytological, archeological, and other logical facts although the processes cannot be verified experimentally because of the lack of repeatability. Organic evolution is concerned with the origin, development, and relationship of living organisms of past and present. According to the most widely accepted current views, evolution came about in three major pathways: 1. Bacteria (including among others Proteobacteria and Cyanobacteria); 2. Eukarya (animals, fungi, plants); and 3. Archaea (Euryarchaeota, Crenarchaeota). The Proteobacteria became symbionts in Eukarya and evolved into mitochondria. The mechanism of replication, transcription, and translation of the Archaea group is more similar to those of the Eukarya than to that of the Bacteria. Cyanobacterial symbionts in plants developed into chloroplasts. Evolutionary studies are greatly facilitated by the genome-wide sequence information. The majority of protein-coding genes have homologs across widely different taxa. From nucleotide sequence data safe information on function cannot always be obtained. Comparison of gene sequences and regulatory elements reveal a great deal about the relationship of the species (Kellis M et al 2003 Nature [Lond] 423:241). In *Drosophila* some genes with substantial homology to chitinase genes actually encode imaginal disk growth factors. Genes with clear phenotypes or high level of expression are more likely conserved across phylogenetic boundaries.

A new phase occurred in evolution during the pre-Cambrian epoch when phylum and superphylum characters (*kernels* of genetic organization) emerged and subsequently conserved basic body plans of

higher organisms (such as bilateral and anterior-posterior organization). Subsequently, class and order characters determined morphological characters and size of body parts by acquiring new regulatory and metabolic systems. Different organisms share many of these regulatory networks. Through differentiation of gene batteries new functions potentiated speciation as seen in the modern living world (Davidson EH, Erwin DH 2006 *Science* 311:796).

E

Evolution is frequently contrasted with the views of creation as described in the Bible and holy books of other religions. The science of evolution is concerned with facts that can be experimentally studied with the available technological tools and has no room for faith, while the primary criterion of religion is the faith in its teaching. Thus, it is improper to compare these principles because they are not of the same nature and they are not required to support or exclude each other. The philosopher K.R. Popper defined the scientific method as “the criterion of potential satisfactoriness is thus testability, or improbability: only a highly testable or improbable theory is worth testing and is actually (and not merely potentially) satisfactory if it withstands severe tests—especially those tests to which we could point as crucial for the theory before they were ever undertaken.” At another place he says “...I refuse to accept the view that there are statements in science which we have, resignedly, to accept as true merely because it does not seem possible, for logical reasons, to test them.” Thus, testability and refutability are the most basic cornerstones of evolution. Evolution is using the methods of cytogenetics, population genetics, molecular biology and geological fossil records of the past to establish the relationship, origin and variation in the living world. Ideas about evolution that are not supported by the methods referred to above are just ideas but not science. With the progress of sequencing DNAs, RNAs and proteins, evolutionary studies are shedding light on mechanisms common to a wide range of organisms and assist in the solution of problems in health-related areas as well as improving the productivity of economically important organisms. Evolution is generally believed to be a *stochastic* (random) process in finite (small) populations and drift plays out the differences. In case the population is infinitely large, evolution may be *deterministic* (predictable on the basis of selective values) and selection has major importance. ▶Hardy-Weinberg theorem, ▶duplication, ▶reductive evolution, ▶orthologous loci, ▶paralogous loci, ▶genomics, ▶gene evolution, ▶genome evolution, ▶genome projects, ▶mutation, ▶migration, ▶selection, ▶speciation, ▶microevolution, ▶macroevolution, ▶phylogeny, ▶fossil records, ▶population genetics, ▶evolutionary trees, ▶evolutionary distance,

Evolution and Base Substitutions: Base substitutions are generally estimated on the basis of number of changes per site per 10^9 years. Accordingly, the rates in various genomes are: mammalian nuclear 2–8, angiosperm nuclear 5.4, mammalian mitochondrial 20–50, angiosperm mitochondrial 0.5, angiosperm cpDNA single copy regions 1.5, angiosperm cpDNA inverted repeats 0.3. The high mutation rate of mammalian mtDNA may be the result of the deficiency in excision, photoreactivation and recombinational repair, as well as the low level of selection, and the ability of mtDNA's tRNAs to recognize all four synonymous codons within a family of amino acids. Base substitution rates in fungi as well as in plant mtDNAs are much smaller than in mammalian mtDNAs. Molecular evolution is generally interpreted on the basis of common descent of the nucleotide sequences. The orthogonal theories must accommodate the apparent facts of horizontal transfer by way of symbiosis and infections in both prokaryotes and eukaryotes. ▶base substitutions, ▶diversity, ▶evolution, ▶evolutionary distance, ▶nongenic DNA sequences, ▶Jukes-Cantor estimate, ▶parallel substitution, ▶orthologous loci, ▶plasmids, ▶retroviruses, ▶retrotransposons, ▶retrotransposons; Salse J et al 2002 *Nucleic Acids Res* 30:2316.

Evolutions and Duplications: Molecular evidence indicates that duplications have played important roles in evolution (see Fig. E52). Duplication may arise by unequal crossing over between similar genes and may occur repeatedly. The example in the diagram shows the molecular consequences of an unequal crossing over in the DNA at the level of the protein products. Human haptoglobins have two α and two β chains and when an unequal crossing over takes place, duplication is also detectable in the protein product. Genes encoding multiple protein subunits or members of complex genomes are less likely to be maintained by evolution (Yang J et al 2003 *Proc Natl Acad Sci USA* 100:15661). ▶unequal crossing over, ▶cluster homology region, ▶duplication, ▶deletion, ▶polyploidy in evolution; Ohno S 1970 *Evolution by Gene*

Evolution, Convergent: Homologous changes occur among distantly related organisms. ►[evolution parallel](#)

Evolution, Cost of: Evolution proceeds by replacing old alleles with new ones and the replacement may also sacrifice some individuals. This is the way the cost is paid. ►[genetic load](#)

Evolution, Directed: Directed evolution involves in vitro synthesis of proteins or polynucleotides with new functions. ►[mutation directed](#); Xia G et al 2002 Proc Natl Acad Sci USA 99:6597.

Evolution in vitro: Mutations in RNA molecules can occur in vitro during cell-free replication and may improve their catalytic and amplification rate. evolution, prebiotic.

Evolution, Non-Darwinian: Non-Darwinian evolution is supposed to take place by the fixation of neutral mutations in contrast to Darwinian evolution that postulates evolution by survival of the fittest. Because of the degeneracy of the genetic code, many mutations will leave the phenotype or function unaltered. There is no reason why these neutral mutations would not be fixed. Although it must be remembered that the codon usage in different genes and/or organisms is not identical, and the codon selection may have an adaptive nature. Also, there is no reason to doubt that certain amino acid substitutions have no effect on protein structure and function and thus appear without selective effect. Rapid evolution is favored by the fixation of neutral changes. If neutral mutations are fixed, there is no need for concomitant elimination of the old genotypes. Random genetic drift may also lead to changes in gene frequencies and possibly to evolution. ►[neutral mutation](#), ►[beneficial mutation](#), ►[drift](#)

[genetic](#); Matsuda H, Ishii K 2001 Genes Genet Syst 76[3]:149; King JL, Jukes TH 1969 Science 164:788.

Evolution of Amounts of DNA: There is tendency toward increased amounts of genetic material in the more highly evolved organisms. Viruses have generally less DNA than bacteria and microorganisms have smaller genomes than higher eukaryotes ►[genome](#). It is not entirely clear, however, why the total size of the genome varies by orders of magnitude among higher eukaryotes and, e.g., amphibians and several plants have much more DNA than humans. This is frequently called the C value paradox. ►[C amount of DNA](#), ►[C value paradox](#), ►[genome](#), ►[duplication](#), ►[deletion](#)

Evolution of Metabolism: <http://compbio.mcs.anl.gov/puma2/>.

Evolution of Organelles: The cytoplasmic organelles of eukaryotes, mitochondria, and plastids contain DNA but the base composition of this DNA displays very little similarity to that of the nucleus. The organellar DNA is usually circular versus the nuclear that is linear. The ribosomes in the organelles bear more similarities to prokaryotic ribosomes, being also 70S, in contrast to the ribosomes in the cytosol that are 80S. Several mitochondrial codons do not conform to the universal code words (►[mtDNA](#)) and no organisms are known that would have the same nuclear codon dictionary. Plastids use the universal codons. The mitochondrial genome probably has polyphyletic origins with major similarity to purple non-sulphur photosynthetic bacteria. The plastid genome may have derived from non-cyanobacterial oxygenic bacteria and it may be closest to *Prochloron*. The plastid genome is also most likely descended from more than a single species. It is assumed that

these organelles were captured by means of endocytosis of some lower organisms, perhaps repeatedly during evolution. The double membranes wrapping the cytoplasmic organelles may have their origin part from the ancestral donor part from the plasmalemma of the recipient cells. In the Euglenoids the plastids have triple membranes, suggesting that this is the relic of double endocytotic events. The size of the mitochondrial genome is very variable among the various organisms. In mammals, it is about 16 kbp but in the muskmelon it may be up to 2,400 kbp and in the majority of other plants varying generally between 200 and 500 kbp and thus exceeding those of the plastids, which are rather conservatively between 120 and 270 kbp. The amount of intergenic nuclear DNA in vertebrates is 0.65, in invertebrates 0.64 and in plants 0.68%. In the mitochondria of animals it is only 0.05 to 0.10, whereas in plant mitochondria the intergenic DNA fraction is ~ 0.72 . The mitochondrial mutation rate in animals is about 9–25 times higher than in the nuclei; in plant mitochondria the rate is however only 0.05 times higher than in the nuclei. In unicellular eukaryotes the mutation rates are about the same in the nuclei and mitochondria. The high level of free oxygen radical, the high rate of replication, and the loss of nucleotide excision repair and reduced mismatch repair cause the high mutation frequency in animal mitochondria. There is no general explanation for the differences in mutation rates of plant mitochondria (Lynch M et al 2006 Science 311:1727).

The transcriptional machinery in plastids and mitochondria resembles that of prokaryotes. Some of the chloroplast genes have upstream elements similar to the promoter sequences of bacteria. The plastid RNA polymerase is not inhibited by rifampicin whereas this antibiotic blocks transcription in prokaryotes. Both plastids and mitochondria have genes for rRNAs and tRNAs and these also resemble more the prokaryotic ones than that of eukaryotes in the cytosol. More than a dozen of the plastid genes and about three of the mitochondrial genes have introns, an uncommon feature of prokaryotes. Less than one third of the ribosomal proteins in the plastids are coded within this organelle, the rest is of cytosolic origin. This and other facts indicate that the acquisition of the organelles was followed by loss of some functions that could be taken care of by genes in the nucleus. There is also a regular import of proteins into the organelles from the cytosol, aided by the transit peptides of the nuclear-coded proteins. Nuclear genes encode the photosynthetic rubisco protein small subunits whereas the large subunits are transcribed and translated of plastid DNA. Also, organellar gene functions, including mutability, are regulated by nuclear genes. It appears that some DNA

sequences have homologs among the nucleus, plastids and mitochondria, indicating the availability of some DNA transfer mechanism(s). ▶mitochondria, ▶mtDNA, ▶chloroplast, ▶chloroplast genetics, ▶organelles, ▶ribulose1, ▶6-bisphosphate carboxylase-oxidase, ▶organelle sequence transfers, ▶*Rickettsia prowazekii*; Margulis L, Bermudes D 1985 Symbiosis 1:101; Delihans N, Fox GE 1987 Ann NY Acad Sci 503:92; Takemura M 2001 J Mol Evol 52:419; Sato N 2001 Trends Plant Sci 6:151; Selosse M et al 2001 Trends Ecol Evol 16:135; Wallace DC. 2007 Annu Rev Biochem 76:781.

Evolution of Proteins: The amino acid sequence in the proteins reflects the coding sequences in the DNA or RNA genetic material. Although the genetic code has synonymous codons, the primary, secondary, tertiary and quaternary structure reveals important information how proteins function. Adaptive evolution relies primarily on the expression of genes rather than on their structure, although the latter is important for tracing the path of this evolution. Certain proteins such as cytochrome c (coded by the nucleus but present in the mitochondria) reveals similarities and differences in the amino acid sequence in the widest range of eukaryotes and displays similarities even to bacterial cytochrome c2. Such analyses carried out two to three decades ago have shown that similar functions require similar structures. Furthermore, the similarities within apparently related groups are greater than among those that are more distant by any type of classification. Protein domains, which are essential for functions evolve at a restricted rate and are rather well conserved by physiological necessity and alterations are subject to negative selection. About 50,000 different protein family domains could be recognized in 2005 on the basis of three-dimensional structures (Lee D et al 2005 Proteins 59:603).

These studies brought recognition to the fact that some gene loci are *orthologous*, i.e., they seem to be directly connected by descent across phylogenetic groups whereas other genes, arising by duplication, (*paralogous loci*) may show greater difference in the primary structure because the ancestral copy of the gene could continue providing the needed function while the duplication was more free for (adaptive) evolutionary experimentation. Proteins may evolve by recruitment of new domains or by rearrangement of domain organization. New catalytic properties can now be created on existing protein scaffolds in the laboratory using biochemical techniques. Proteins encoded by linked genes appear to evolve at similar rates due apparently to the force of stabilizing selection. It is not entirely certain that organic evolution proceeds through the same path yet the

new enzymes are functional and technology provides means for the generation of enzymes not found in nature but which may have the advantage for biotechnology. It appears that indispensability (i.e., importance of presence for survival) and the level of expression affect evolution although their effects are independent from each other (Wall DP et al 2005 *Proc Natl Acad Sci USA* 102:5483). Highly expressed proteins, involved with networks evolve slowly, and a high level of expression is better correlated with their evolutionary rate than their function (Drummond DA et al 2005 *Proc Natl Acad Sci USA* 102:14338). ►homology, ►ribozymes, ►protein families, ►proteome, ►PRINTS; Altamirano MM et al 2000 *Nature [Lond]* 403:617; Williams EJ, Hurst LD 2000 *Nature [Lond]* 407:900; Gerlt JA, Babbitt PC 2001 *Annu Rev Biochem* 70:209; Aravind L et al 2002 *Current Opin Struct Biol* 12:392; Kinch LN, Grishin NV 2002 *Curr Opin Struct Biol* 12:400; Davis BK 2002 *Progr Biophys Mol Biol* 79:77; Fay JC 2003 *Annu Rev Genomics Hum Genet* 4:213; Orengo CA, Thornton JM 2005 *Annu Rev Biochem* 74:867; Pál C et al 2006 *Nature Rev Genet* 7:337; <http://www.ebi.ac.uk/goldman-srv/pandit/>, distant similarity search; <http://crick.mbu.iisc.ernet.in/~CASCADE/CascadeBlast.html>; software: <http://www.pantherdb.org/>, analysis of evolution of non-conventional structure and protein fold: <http://sisyphus.mrc-cpe.cam.ac.uk>; prokaryotic protein family definitions built to aid in high-throughput annotation of specific protein functions: <http://www.tigr.org/TIGRFAMs>.

Evolution of Recombination: The evolution of recombination is influenced by the physiological needs of the organisms such as improvement of genetic repair, chromosome distribution in mitosis and meiosis, etc. Alternatively, the breakage of linkage to disadvantageous genes may have adaptive value. The evolution of sexual reproduction aids both of these mechanisms. Under conditions of high (deleterious) mutations the increase in recombination frequency may be beneficial, and the reduction of linkage disequilibrium is expected. ►linkage disequilibrium

Evolution of Sexual Reproduction: In an asexually reproducing strain, two advantageous mutations must occur sequentially to be maintained by evolution. In a sexual population the advantageous mutations can occur in independent lineages because recombination can permit their incorporation. Also, sexual reproduction has an advantage in facile elimination of deleterious mutations. (See Felsenstein J 1974 *Genetics* 78:737; J Arjan GM et al 2007 *Nature Rev Genet* 8:139).

Evolution of the Genetic Code: The genetic code is practically universal with the exception of a few mitochondrial codons. Furthermore, the structures of tRNAs reveal much greater similarities than expectable on the basis of random assembly of the nucleotides. The most plausible interpretation of these facts is that these nucleotide sequences developed by an evolutionary process from common ancestral sequences and also indicate a relation of descent of eukaryotes from prokaryotes. It seems that the most archaic genetic code existed in RNA in the RNA world. The ancestral triplets probably escaped from the amino acid-binding sites and acquired new functions as codons and anticodons (escaped triplet theory, Yarus M et al 2005 *Annu Rev Biochem* 74:179). The original sequences were probably relatively short although they probably contained meaningless tracts mixed with useful ones. For the development of well-organized nucleotide sequences specifying an ancestral gene, mechanisms were required for the recognition and correction of errors. This ability probably evolved when the first DNA sequences appeared. Modern DNA polymerases are generally endowed with synthetic, proofreading and editing (endonuclease) functions. This was indispensable for the development of larger and conservative genetic molecules. The first codon probably specified those amino acids, which were most abundant among the molecules formed under abiotic conditions. It was suggested that the earliest codons were of the GNC type (where N is any base). This idea is supported by the fact that G=C base pairs having three hydrogen bonds are more stable than the A = T pairs and under simulated prebiotic conditions, glycine (GGC), alanine (GCC), aspartic acid (GAC) and valine (GUC) are produced in relative abundance. It is conceivable that these four amino acids formed the first protein involved in replication. The next three amino acids might have been glutamic acid, serine, and phenylalanine. These seven early amino acids could later have served as precursors of others, first through abiotic pathways; later the synthesis might have been facilitated by enzymes. The earliest codons might have been somewhat ambiguous aggregates of nucleotides. Later, each amino acid probably shared its codon with its daughter amino acid(s). The successive subdivision of codon domains is still reflected in the similarities of the codons among structurally related amino acids. Apparently, the expansion of the amino acid repertoire took place in parallel with the evolution of the code. Eventually, the assignment of all 64 codons was completed.

In the primordial dictionary, probably only the first two bases were required for the specification of an amino acid. Today, in most of the degenerate codon

domains, still, the first two positions are identical. Codons beginning with C specify amino acids derived from α -ketoglutarate; those starting with A encode amino acids of oxaloacetate metabolic origin; and those starting with U encode amino acids synthesized from pyruvate. Codons starting with G encode amino acids (glycine, alanine, aspartate, glutamate) formed by direct reductive amination of α -keto acid. Codons with U at the 2nd position specify the most hydrophobic amino acids and those codons, which have A at the 2nd place, encode the most hydrophilic amino acids. Simple amino acids might have been synthesized in covalent linkages with dinucleotides and the phosphates of the dinucleotides might have enhanced synthetic reactions (Copley SD et al 2005 Proc Natl Acad Sci USA 102:4442).

With the acquisition of new amino acids and new codons, the stability, specificity and efficiency of the primordial proteins adaptively changed. The archaic, ambiguous codons with lesser precision must have been then eliminated, culminating in the development of a codon dictionary common to prokaryotes and eukaryotes, as we know it today. Through functionally improved enzymes, faster and more reliable replicational processes emerged. As the efficient and precise replication, transcription and translation began, the prebiotic synthesis was no longer needed in this era, about 3 billion years ago. Some investigators have doubted the idea that high G + C content was required for origin of the code under high temperature. Also, it was suggested—on the basis of evolutionary calculations on ribosomal RNA—that life may not necessarily have arisen in a hot environment, but the high G + C content of thermophilic microbes might have been due to adaptive evolution.

Universality of the genetic code has been recently attributed to communal evolution permitting to share genetic information by horizontal gene transfer at the early stages. This processes led to the emergence of innovation-sharing protocols. In a following phase individual (Darwinian) evolution could proceed in a vertical manner. Thus, collective evolution was facilitated by utility of the mechanisms of translation in a Lamarckian sense (Vetsigian K et al 2006 Proc Natl Acad Sci USA 103:10696).

Evolution of the Karyotype: The chromosome number is a rather good characteristic of related species. Cytotaxonomists define homologies among taxonomic groups on the basis of the karyotype, the morphology of the chromosomes at (generally) metaphase. Some important landmarks of the chromosomes (chromomeres, band, knobs) can be better visualized at prophase (pachytene). Some chromosomal aberrations (inversions) are identified also at anaphase. Salivary gland (polytenic) chromosomes reveal a great deal of morphological information on the chromosomes. With the introduction of the “banding techniques” (Giemsa, C-banding) various taxonomic groups can be rather well defined. Various chromosomes or chromosomal segments can be identified by in situ hybridization with DNA probes “painted” with fluorochromes of various colors (such as fluorescein isothiocyanate [FITC, green], Spectrum Orange [red], 4',6'-diamidino-2-phenyl indole [DAPI, blue fluorescence in UV], biotin derivatives, etc.), and the genomes in amphiploids can be distinguished. Although the number of chromosomes may vary even in closely related taxonomic groups because of centromeric fusion or fission of telochromosomes and bi-armed inversions, by analysis of the natural banding pattern of salivary gland chromosomes, inversions could be traced among related species (see Fig. E53).

By analysis of the natural banding pattern of salivary gland chromosomes, inversions could be traced among related species. Acrocentric chromosomes may undergo Robertsonian translocation changes in chromosome numbers by making from two acrocentrics one bi-armed chromosome (quite common in mice).

If, for e.g., chromosome arms A and B as well as A and D, and similarly, D and C as well as C and B are fused in diploid cells, at meiotic metaphase I, the configuration (see Fig. E54) is displayed.

Such a situation may lead to sterility, reproductive isolation, and eventually speciation. Although inversion heterozygosity may lead to sterility depending on the frequency of crossing over in the inverted

Figure E53. Conversion of metacentric chromosome into telochromosome

Figure E54. Tracing the origin of chromosomal inversions

segment, many wild populations contain various types of inversions. Paracentric inversions do not affect the fertility of the females (either in plants or animals) because the inversion bridge prevents the incorporation of the crossover chromosomes into the eggs (►inversions paracentric). Chromosomal inversions can frequently be traced in the polytenic chromosomes. Inversions may occur repeatedly and may partially involve the same chromosomal segment each time (see Fig. E55).

Figure E55. Robertsonian translocation ring

The serial origin of such inversions can be detected. Molecular analysis of *Drosophila* chromosomes confirms the cytological evidence that extensive reshuffling has taken place during evolution. ►inversions, ►chromosome painting, ►comparative chromosome painting, ►comparative genomic hybridization, ►chromosome banding, ►telochromosome, ►microinversions, ►Robertsonian translocation, ►acrocentric, ►reproductive isolation, ►polyteny, ►duplication, ►deletion, ►karyotype, ►karyotype evolution; Ranz JM et al 2001 Genome Res 11:230; Nurminsky D et al 2001 Science 291:128; Gonzalez J et al 2002 Genetics 161:1137; Posada D et al 2002 Annu Rev Genet 36:75; mammalian chromosome evolution—comparative maps: Murphy WJ et al 2005 Science 309:613.

Evolution, Parallel: Parallel evolution involves homologous features among closely related organisms. ►evolution convergent

Evolution, Prebiotic: Before living cells appeared on earth, organic molecules must have been formed. In

1953, Stanley Miller and Harold Urey showed that when mixtures of ammonia, methane, hydrogen, and water were exposed to electric sparks (simulating stormy conditions of the early atmosphere), carbon monoxide, carbon dioxide, amino acids, aldehydes and hydrogen cyanide were generated during the experiments lasting for several weeks. Later, more extensive experiments revealed hundreds of organic molecules under such simulated abiotic conditions. It was of particular significance that more than ten different amino acids, various carboxylic acids, fatty acids, adenine, sugars, etc., could be obtained in abiotic experiments with increased sophistication. HCN and heavy metal ions present in the early earth environment and in laboratory simulation could promote polymerization. Carbonyl sulfide ($O=C=S$, a volcanic, inflammable gas with potential health hazards) forms peptides from amino acids under mild conditions, at room temperature with high efficiency (Leman L et al 2004 Science 306:283). Thus the conclusion appeared logical that primitive macromolecules could be formed de novo and the macromolecules required for life could eventually evolve. Amino acids, under anaerobic aqueous conditions at 100°C and pH 7 to 10—in the presence of NiS, FeS and CO, and H₂S or CH₃SH as catalysts—coprecipitate and form peptides. ►origin of life, ►spontaneous generation unique and repeated, ►abiogenesis, ►evolution in vitro, ►evolution of proteins, ►evolution of the genetic code; Brack A 1999 Adv Space Res 24:417.

Evolution, Retrograde: ►retrograde evolution

Evolutionary Clock (molecular clock): The evolutionary clock measures the time required for 1% amino acid replacement in a protein in a million years (MY). It is based on the assumption that mutations are neutral and occur at random and the amino acid changes reflect the time elapsed since a particular event. The molecular clocks may be biased because of selection. A better procedure is to determine the rate of nucleotide substitution in homologous genes because mutation in synonymous codons does not lead to amino acid replacement. The rate of protein evolution is frequently expressed as the accepted number of point mutations per 100 residues in the protein. This parameter is generally symbolized with the acronym PAM. The rate of amino acid substitution per site per year was estimated to be, on average, 10^{-9} , which is frequently referred to as the “pauling” unit of molecular evolution (named after the Nobel-Laureate chemist, Linus Pauling). Individual proteins evolve at very different rates (see Table E1). Perhaps better comparisons can be made if enzymes rather than other proteins are used. There are differences in

Table E1. Amino acid substitution rates

| Proteins | Amino acid substitutions per residues per million years |
|-------------------------|---|
| Fibrinopeptides | 90 |
| Pancreatic ribonuclease | 33 |
| Hemoglobins | 14 |
| Cytochrome C | 3 |
| Histone 4 | 0.06 |

substitution rates among different organisms. Mitochondrial base substitutions involve similar differences. The data may be biased if orthologous and paralogous loci cannot be safely distinguished. From the comparison of enzymes it appears that eukaryotes and eubacteria shared common ancestors about 2 billion years ago. The divergence of plants and animals took place about 1 billion years ago. The similarity of fungi to animals is somewhat better than to plants. The molecular evolutionary clocks cannot adequately estimate evolution because of the highly different rates of amino acid or base substitutions in individual proteins and genes, respectively. Recently, multiprotein sequences have also been used with promise for improved estimates. In addition, there is no comforting proof that the molecular clocks ticked uniformly through the ages. Another problem is the not infrequent discrepancy between the molecular and the paleontological estimates. It appears that the molecular clock (mutation) depends on the metabolic rate of the organisms and also on the prevailing temperature and these factors should be considered in the estimations (Gilloly JF et al 2005 Proc Natl Acad Sci USA 102:140). The rate of evolution of the molecular clock is in decreasing order: human > chimpanzees > gorillas > orangutans (Elengo N et al 2006 Proc Natl Acad Sci USA 103:1370). Unfortunately, the evolutionists do not have many choices.

In a somewhat similar manner the progression of a cancerous tumor can be reconstructed. Colorectal tumors may be caused by the loss of genes controlling mismatch repair (MMR). The loss of MMR also involves the expansion of microsatellite sequences. Microsatellites are expanded during cell divisions and thus the expansion—relative to the noncancerous or nonexpanded state—indicates the number of cell divisions since the loss of MMR. The mass spectrometric method of deamidation of glutaminy and asparaginy residues in peptides has also been developed as molecular timers. ▶racemate, ▶orthologous, ▶paralogous, ▶Eve foremother, ▶Y chromosome, ▶microsatellite, ▶colorectal cancer,

Evolutionary Distance: Evolutionary distance can be numerically estimated on the basis of allelic differences (amino acid differences in proteins, RFLPs, nucleic acid base sequences, etc.). It must be remembered that evolution may proceed either by divergence or convergence of whatever criteria are used (see Table E2). When larger number of loci is used the greater the accuracy of the estimate. There are several procedures in the literature. Here the method of Nei (Molecular Population Genetics, Elsevier/North Holland, 1975) will be illustrated. The normalized identity of alleles in populations is determined by dividing the arithmetic means of the products of allelic frequencies by the geometric means of the sum of squares of the homozygote frequencies in each population to be compared.

$$I = \frac{\{[p1 \times p2] + [q1 \times q2]\}/L}{\sqrt{\{[p1^2 + q1^2] \times [p2^2 + q2^2]\}/L^2}}$$

where *I* is the index of identity, *p* and *q* are allelic frequencies in the two populations and *L* is the number of loci studied (including even those with single allele representation). The evolutionary (genetic) distance is then calculated from the natural logarithm of *I*, i.e., *D* = -log_e*I*. This type of calculation is meaningful and reliable if a minimum of 25 loci is compared. It can be used with any type of alleles, including even proteins of different electrophoretic mobilities. An example for the procedure is given in table. By using the procedure outlined, the human racial distance and the number of years of divergence have been estimated (after M Nei, AK Roychoudhury 1974 Amer J Hum Genet 26:421) and it turned out to be minimal:

The evolutionary distance can be estimated more precisely on the basis of nucleotide sequence and replacements (Kimura M 1980 J Mol Evol 16:111): The pyrimidine ⇌ pyrimidine and the purine ⇌ purine substitutions are designated as *P* and the pyrimidine ⇌ purine or purine ⇌ pyrimidine transversions are represented by *Q*. The evolutionary distance *K* is

$$K = -(0.5)\log_e[(1 - 2P - Q)\sqrt{1 - 2Q}]$$

The standard error of *K*:

$$s_k = \frac{1}{\sqrt{n}} \{ \sqrt{[a^2P + b^2Q] - [aP + bQ]} \}$$

Table E2. Evolutionary distance

| Human races | Genetic distance | Years of divergence |
|--------------------------------------|------------------|---------------------|
| Caucasoid - African Negroid | 0.023 | 115,000 |
| Caucasoid - Oriental Mongoloid | 0.011 | 55,000 |
| African Negroid - Oriental Mongoloid | 0.024 | 120,000 |

where $a = \frac{1}{1-2P-Q}$ and $b = 0.5 \left[\frac{1}{1-2P-Q} + \frac{1}{1-2Q} \right]$

In a sequencing study of the 438 nucleotide β -globin genes of chicken and rabbit the P value was $58/438 = 0.132$ and $Q = 63/438 = 0.144$, and after the appropriate substitutions the evolutionary distance thus appeared to be 0.347 ± 0.0329 .

The time of divergence (in million years) varies according to the specific gene and taxonomic category considered, e.g., in Echinodermata–Chordata, Annelida–Chordata for ATPase: 786 and 1059, for cytochrome: 883 and 1078, for cytochrome oxidase I: 1160 and 1465, for cytochrome oxidase II 608 and 773, for 18S RNA: 1288 and 1214, respectively. ▶DNA sequencing, ▶array hybridization, ▶amino acid sequencing, ▶evolutionary tree, ▶genetic distance, ▶minimum evolution method, ▶four-cluster analysis, ▶neighbor joining method, ▶evolutionary tree, ▶least square methods, ▶transformed distance, ▶Fitch–Margoliash test, ▶DNA likelihood method, ▶protein-likelihood method, ▶nucleotide diversity, ▶ F_{ST} , ▶ $[\delta\mu]^2$; Tamura K, Nei M 1993 Mol Biol Evol 10:512, <http://warta.bio.psu.edu/DED/>.

Evolutionary Substitution Rate: Estimates the number of mutations leading to an evolutionary divergence in a million years: $\sum \frac{(d_{ij}-2d_{ik})}{n_i n_j} \times \frac{1}{t_j}$ where d_{ij} and d_{ik} are the number of the DNA base substitutions per number of sites in genotypes i and j and between genotype i and evolutionary tree node k , respectively; $n_i n_j$ are the number of pairwise comparisons, t is the time in million years when the i genotype was deposited in the rock stratum and the k is the node furthest from the common root. ▶evolutionary tree, ▶evolutionary distance, ▶PAUP

Evolutionary Tree: Displays the descent of organisms from one another. Initially trees were constructed on the bases of morphological traits, and later on the basis of chromosome numbers and pairing affinities in hybrids and chiasma frequencies. The former criteria are not well quantifiable; the latter features are applicable to only relatively closely related forms because of the sexual isolation among distant species.

The numbers of substitutions at large or all comparable sites of macromolecules provide the most accurate information.

Evolutionary trees based on nucleotide sequences are more reliable than those based on proteins because silent genes are not included in the proteins. Since DNA sequences are available in several organisms, nucleotide sequence alignment and percentage of homologies are frequently used. Caution may be necessary to interpret evolutionary trends because the similarities or differences can be brought about either by convergence or divergence or lateral transfer. In prokaryotes lateral gene transfer—based on >220,000 proteins in 144 organisms—can obscure the line of descent in some instances (Beiko RG et al 2005 Proc Natl Acad Sci USA 102:14332). From the nucleotide sequences in the DNA, the amino acid sequence in the protein can be relatively easily inferred on the basis of the genetic code with some caution. Before nucleotide sequencing became practical in the late 1970s, amino acid sequencing was available and many of the evolutionary trees constructed were based on protein primary structure.

An evolutionary tree of mammals has been constructed on the basis of molecular clocks of seven proteins (see Fig. E56). The right end of the tree was fixed by paleontological information on marsupial divergence from the placental mammals, an estimated 120 million years ago. The nodes of divergence are based on the putative nucleotide substitutions in the seven coding genes. (After Fitch WM, Langley CH 1976 Fed Proc 35:2092).

From 300,000 protein sequences, the *Tree of Life* has been constructed for the evolution of all

Figure E56. Evolutionary tree

Figure E57. Possible amino acid substitutions

E

organisms although large gaps still remain because not enough data is available in the databases (Driskell AC et al 2004 Science 306:1172).

Since amino acids have up to six synonymous codons, there is no simple way from the amino acid positions in the protein to determine the nucleotide sequence in the gene. Furthermore, as evolutionists rely on the principle of *maximal parsimony*, i.e., they suppose that the actual evolution took place in the simplest possible way (what may not be true). Let us assume that the nucleotide sequence A C C A is the result of evolution (see Fig. E57). Through two mutational events (indicated by →) the original sequence may have changed the following ways:

Let us assume that in three different taxa (or orthologous loci) at a particular site, valine, leucine and serine are found (see Fig. E58). Valine has four code words (GTT, GTC, GTA, GTG), leucine has six (TTA, TTG, CTT, CTC, CTA, CTG), and serine has six as well (TCT, TCC, TCA, TCG, AGT, AGC). A single mutation may replace the first G of the valine codon by T and a second mutation may lead to a T→C change at the second nucleotide and thus in place of a valine residue serine may occur. From the four valine triplets only two may result in serine codons via two mutational events.

Figure E58. Possible routes from valine to serine

There are many ways to construct evolutionary trees and each has advantages and disadvantages under a particular condition (see Fig. E59). Evolutionary trees of genes may not be the same as phylogenetic trees because individual genes evolve at different rates. The evolutionary trees constructed by different methods appear different depending on type and number of markers used (Kolaczowski B, Thornton JW 2004 Nature [Lond] 431:980). A ring of life may best represent the evolution of eukaryotes. (<http://www.astrobio.net/cgi-bin/h2p.cgi?sid=1191&ext=.pdf>). ▶evolutionary distance, ▶phylogenetic tree, ▶gene tree, ▶microarray hybridization, ▶population tree, ▶indel, ▶rooted evolutionary tree, ▶unrooted evolutionary tree, ▶eukaryotes, ▶DNA sequencing, ▶lateral transmission, ▶amino acid sequencing, ▶METREE, ▶patristic distance, ▶PAUP, ▶heuristic search, ▶exhaustive search, ▶four-cluster analysis, ▶least square methods, ▶Euclidean distance, ▶transformed distance, ▶branch length, ▶Fitch–Margoliash test, ▶DNA likelihood method, ▶protein likelihood method, ▶neighbor joining method, ▶UPGMA, ▶bootstrap, ▶homoplasy, ▶lateral transfer; Miyamoto MM, Ctacraft J 1992 Phylogenetic Analysis of DNA Sequences, Oxford Univ. Evolvability: The ability to evolve. Evolvability in viruses is generally considered an adaptive response to natural selection. In RNA virus φ6 the experimental

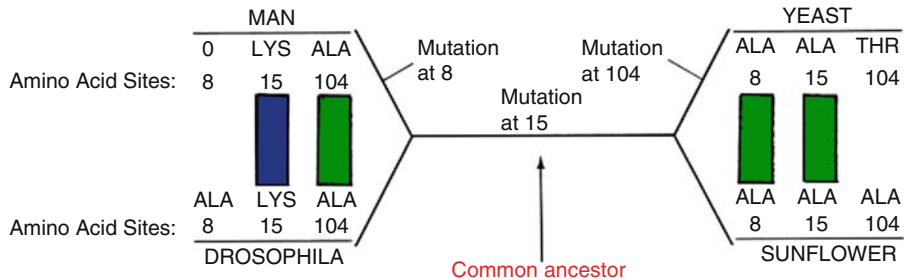

Figure E59. An over-simplified example for construction of a protein evolutionary tree. Mutation at site 15 separates the left from the right. Mutation at site 8 distinguishes man from *Drosophila* and site 104 yeast from sunflower. (Constructed after Dayhoff, M et al. 1972 Atlas of Protein Sequence and Structure Vol.5 Natl. Biomed. Res. Found. Washington, DC)

data indicate that advantageous genes favor the accumulation of advantageous mutations in their vicinity. Pigliucci, M 2008 *Nature Rev. Genet.* 9:75, ► [hitchhiking](#)

Evoprinter: A software for the detection of evolutionarily conserved DNA sequences in a species (Odenwald WF et al 2005 *Proc Natl Acad Sci USA* 102:147000).

Ewing Sarcoma: ► [EWS](#), ► [sarcoma](#), ► [neuroepithelioma](#)

EWS: Ewing sarcoma oncogene; a binding protein, encoded at human chromosome 22q12. In Ewing sarcoma translocations t(11;22)(q24;q12) are common but several other types also occur. ► [FLI](#), ► [gene fusion](#)

Ex Vivo: An operation carried out outside the body, but the manipulated organ or gene is returned to the body. For example, genetically engineered cells are introduced into a specific tissue as a means of gene therapy. ► [in vivo](#), ► [in vitro](#), ► [gene therapy](#)

Exact Test: ► [Fisher's exact test](#), ► [association test](#), ► [G test](#)

Exaggeration: A recessive mutation in one chromosome and a deficiency for the same site in the homologous chromosome results in a more extreme mutant phenotype than homozygosity for the same recessive mutation. (Mohr OL 1923 *Indukt Abstamm-Vererb-Lehre* 30:279).

Exaptation: When an adapted function is modified to become useful for a different biological function. An originally nonadaptive feature may become adaptive during evolution. A short interspersed repeat (SINE) of a 410-million-years-old coelacanth evolved into an enhancer of mammals; a 200-bp ultraconserved region is practically identical in an exon of the messenger RNA processing genes PCBP2 of modern day mammals and the “living fossil” Indonesian coelacanth *Latimeria menadoensis* (Bejerano G et al 2006 *Nature [Lond]* 441:87). ► [coelacanth](#)

Exchange Pairing: Chromosomes that have paired and recombined in meiosis are distributed normally to the pole. ► [distributive pairing](#), ► [chromosome pairing](#)

Exchange Promoting Protein (EP): Increases the separation of GDP from the bound form (E.GDP) in signal transduction. ► [GDP](#), ► [E.GDP](#)

Excimer (excited dimer): Excitation by light can raise the energy levels and two molecules can occupy, as a dimer, the same level of molecular orbital. Vertical base stacking, and not base pairing, determines the fate of singlet electronic states. In ultraviolet irradiated A≈T DNA in B form double helix excimers

are limited to one of the strands and enable repairing the damage by using the undamaged strand as a template (Crespo-Hernández CE et al 2005 *Nature [Lond]* 436:1141). ► [base stacking](#), ► [pyrene](#), ► [platelet-derived growth factor](#)

Excinucleases: ► [DNA repair](#)

Excipient: A molecule added to proteins for protection from degradation during storage.

Excision: The release of a phage, insertion element, episome or any other element or DNA sequence from a nucleic acid chain. In *precise excision*, for the affected or involved sequence, the “wild type” DNA is copied from the homologous DNA strands and thus substituted for the stretch. Any interruption of this repair copying may result in retaining some parts of the inserted piece and thus resulting in *imprecise excision*. ► [transposable elements](#), ► [transposons](#), ► [T-DNA](#), ► [insertion elements](#), ► [episome](#)

Excision Repair (dark repair, NER, BER): The removal of damaged DNA segments followed by localized replacement (unscheduled DNA synthesis). In excision repair, a DNA glycosylase excises the damaged base and then the abasic deoxyribose is removed by AP endonucleases. In nucleotide excision repair, an enzyme system hydrolyzes the phosphodiester bonds on both sides of the damaged single-strand tract and the sequence including the defect (12–13 nucleotides in prokaryotes, and 27–29 nucleotides in eukaryotes) is removed by excinucleases. Subsequently, the gap is refilled by repair polymerase and the ends are religated. The gap filling process by DNA polymerases δ and ϵ is highly accurate involving $\sim 10^{-5}$ errors. These enzymes correct incorporation errors by 3'→5'-exonuclease function. The first 15 nucleotides are added by pol α and β but they, by lacking exonuclease function, start the replication much less faithfully. DNA pol β by repairing single-nucleotide gaps makes errors in the range of $3-5 \times 10^{-3}$. Fortunately, DNA ligase III refuses to join mismatched ends and a mammalian exonuclease (homolog of the bacterial Pol III subunit encoded by DnaQ) then may correct the wrong base. Similarly, in prokaryotes Pol III is endowed by both 3'→5' and 5'→3' editing functions. Another solution to avoid the DNA damage without excision is provided by the yeast DNA polymerase ζ (and its homolog in humans) that can bypass pyrimidine dimers and other adducts and may incorporate in their place the correct nucleotides. The Rev1 (human hREV1) protein encodes a template-dependent deoxycytidylic acid transferase that can mediate translesion and insertion of a base opposite to a gap. The DNA polymerase η

can insert two adenylic residues opposite to a thymine dimer and thus saves the otherwise damaging situation. Excision repair genes have been identified in many organisms, including mammals. XPA (human single-strand binding protein [HSSB]) and its homologs (Rpa in yeast) are essential binding proteins for nucleotide exchange repair. The damage-binding proteins (DDB or UV-DDB) generally recognize defective areas caused by photo-adducts. These proteins may recruit others such as XPC (human) and some similar proteins of yeast (Rad4 and Rad23). The transcription complex TFIIH is composed of several subunits required for repair (XPB and XPD in humans) and in yeast (Ss12 and Rad3). TFIIH contains also kinases (CDK2). The human excision repair genes were identified by genetic transformation of UV-sensitive Chinese hamster cells with human DNA (excision repair cross-complementing genes, ERCC). Gene ERCC3 (human chromosome 2q21) appears to be at the locus responsible for xeroderma pigmentosum type II (B) and it controls an early step of excision repair involving a DNA helicase function; it is also associated with the basal transcription factor TFIIH. ERCC1/XPF (*RAD10*) endonuclease appears to be in human chromosome 3 and it is involved with xeroderma pigmentosum F. ERCC2 is in human chromosome 19, ERCC4 in chromosome 16, and ERCC5 (rad2) in chromosome 13q22. Excision repair gene UV-135 (ERCC2) appears to be in human chromosome 13 and UV-24 in chromosome 2. Transcription factor TFIIH is also involved in nucleotide excision repair in transcriptionally not active DNA, in cooperation with Rad 2 and Rad4. Pol δ and pol ϵ in cooperation with PCNA (proliferating cell nuclear antigen) and RFC (replication factor) auxiliary proteins may carry out repair synthesis.

Excision Repair Bioassays: Excision repair bioassays are essentially biochemical procedures. The mutagen may cause the formation of cyclobutane rings, alkylation

of bases, formation of covalent adducts between bases and the reactive chemical, depurination of the DNA, interstrand cross-links in the DNA, cross-links between DNA and protein, breakage of the phosphodiester bonds, intercalation of the mutagen between DNA bases, etc. The defects are detected in the extracted DNA cleaved by acids (formic acid or trifluoroacetic acid). The acid hydrolysis does not give as reliable results as the use of DNase or phosphodiesterase enzymes. The free bases and the pyrimidine dimers are analyzed by one-dimensional or two-dimensional paper or thin-layer or column or Sephadex or Dowex chromatography. By similar procedures the alkylated bases can be identified. Identification of adducts has been attempted by using radiolabeled mutagens and detecting the sites of the adduct formation. This procedure, however, is not completely reliable. The use of single-strand specific nucleases may detect the consequences of strand breakage resulting in strand separation liable to digestion by these nucleases. DNA breakage has also been evaluated by centrifugation of the extracted DNA in 5–20% alkaline sucrose-gradients where the intact DNA peaks closer to the bottom of the centrifuge tube while the damaged one floats at the lower sucrose concentration areas. A different type of approach is to provide radioactively labeled bases after the mutagenic treatment and monitor the extent of repair replication that is supposed to be increased if the mutagen damages the DNA. The extent of repair is reflected by the increase in radioactivity in the DNA. Adding bromodeoxyuridine (BrDU) to the mutagen-treated DNA can assess extensive repair replication. Incorporation of BrDU increases the buoyant density of the DNA and that is detectable upon separation by ultracentrifugation. Another variation is the exposure of BrDU containing DNA tracts to irradiation by 313 nm UV-B. The patches containing the analog are cleaved by this and thus reveal, by photolysis, the original sites of damage. ►unscheduled DNA synthesis, ►ultracentrifuge, ►ultraviolet light, ►buoyant density, ►bioassays in genetic toxicology, ►mutation detection, ►site-specific mutation; Rédei GP et al 1984 In Chu EHY, Generoso WM (Eds.), Mutation Cancer and Malformation, Plenum, New York p 689; Pavlov YI et al 2006 Int Rev Cytol 255:41.

Excision Vector: An excision vector carries the prokaryotic *Cre* gene (see Fig. E60). If a mouse is transformed by *Cre* and its mate carries a gene closely flanked by loxP, then their F₁ offspring (or any heterozygote) may evict the targeted gene as shown on the diagram. ►*Cre*, ►targeting genes, ►homologous recombination

Figure E60. Excision vector

Excitation: Illumination with ultraviolet light may raise transiently the orbital electrons of an atom to a higher level of energy. Such excitation may lead to electron loss and may be sufficient to cause mutation although the level of energy may drop back to ground level. ▶ultraviolet light, ▶electron

Excitatory Neurotransmitters: Excitatory neurotransmitters open cation channels and facilitate the influx of Na^+ to depolarize postsynaptic membranes. ▶acetylcholine, ▶glutamate, ▶serotonin, ▶neurotransmitter

Excited State: An energy rich atom or molecule after the absorption of light energy.

Excitotoxicity: Natural and man-made compounds with glutamic acid resemblance may excite the central nervous system and cause excessive Ca^{2+} influx across the postsynaptic membrane resulting in neural death by mitochondrial permeability transition. Excitation of the neurons is essential for brain activity but its excess is toxic and must be protected against. The cannabinoid receptor (CB1) provides a homeostatic mechanism. Kainic acid and several other compounds have the opposite effect. ▶cannabinoids, ▶synapse, ▶kainate; Marsicano G et al 2003 Science 302:84.

Exclusion Mapping: Exclusion mapping can be used to eliminate a certain DNA tract from being linked to a particular gene. (See <http://www.wardsystems.com/products.asp?p=genehunter>).

Exconjugant: Ciliates (*Paramecia*) may pair (conjugate) and the paired cells mutually fertilize each other followed by separation of the two, now diploid cells, the exconjugants. ▶*Paramecium*

Exencephaly: An overgrowth of mid-brain neural tissue (the brain may be outside the cranium) caused by a defect in protein p53. ▶p53, ▶neural-tube defects, ▶Gadd45

Exergonic Reaction: An exergonic reaction releases free energy.

Exflagellation: The transformation of the nonmotile *Plasmodium* male gametocyte into the very motile male gamete in the mosquito, triggered by xanthurenic acid, a derivative of tryptophan. ▶malaria, ▶*Plasmodium*

Exhaustive Search: A procedure of constructing an evolutionary tree by analyzing several individuals to calculate the length of the branches of evolutionary trees. ▶heuristic search, ▶PAUP, ▶evolutionary tree

Exine: The outer layer (of pollen grains).

Exobiology: Exobiology inquires about the possibilities of extraterrestrial life forms. So far no firm evidence exists in spite of several claims. Biogenic hexa and octahedral magnetite crystals in Martial meteorites is one recent suggestive indication. ▶astrobiology, ▶extraterrestrial; Thomas-Keprta KL et al 2001 Proc Natl Acad Sci USA 98:2164; Friedmann EI et al 2001 *ibid.* 2176; Cohen J, Stewart I 2001 Nature [Lond] 409:1119.

Exocarp: The outer layer of the fruit wall, the peel of citrus fruits, the skin of peaches.

Exocrine: The secretory glands that release substances (enzymes, hormones, etc.) through ducts in an outward direction. ▶endocrine

Exocyst: A protein complex that marks the docking position of transporting vesicles on the surface of the plasma membrane. Also involved in the control of cell separation during cytokinesis. ▶cytokinesis; Kee Y et al 1997 Proc Natl Acad Sci USA 94:14438, tethering complexes: Koumandou VL et al 2007 BMC Evol Biol 7(1):29.

Exocytosis: The secretion of molecules from the cell into the medium or transfer of molecules into membrane-enclosed storage compartments in the cell. Exocytosis is one the mechanisms by which cytotoxic T lymphocytes (CTL) release, in a Ca^{2+} -dependent process, perforin and granzymes to lyse the target cells. An antibody to host antigens can activate human endothelial cell exocytosis and leukocyte trafficking. By triggering vascular inflammation, antibody activation of exocytosis may play a role in transplant rejection (Yamakuchi M et al 2007 Proc Natl Acad Sci USA 104:1301). ▶exocytotic vesicles, ▶perforin, ▶granzymes, ▶apoptosis, ▶SNARE, ▶syntaxin; Lin RC, Scheller RH 2000 Annu Rev Cell Dev Biol 16:19.

Exocytotic Vesicles: Exocytotic vesicles serve as vehicles for transport by exocytosis. ▶exocytosis

Exogamy: Exogamy is cross-fertilization.

Exogenic heredity: Exogenic heredity is based not on biological inheritance but on cultural transmission of traditions, scientific information, laws, ethics, values, etc.

Exogenote: When the bacterial genetic material recombines, the recipient genome is called endogenote and

the corresponding segment of the donor genome is an exogene. ► [conjugation bacterial](#)

Exogenous: The influences which come from outside.

Exogenous Evolution: The evolution of cells of higher organisms by inclusion of prokaryotic cells such as plastids and mitochondria. ► [autogenous evolution](#)

E

Exon: Segments of eukaryotic mosaic genes that are represented in the mature mRNA and are translated into a protein. The exon intron boundaries are usually conserved, e.g.:

5'-ACTGCAGtaagg...tttcctctctctagTGGGCG-3' DNA
 exon intron exon

All coding genes have exons but introns are exceptional in prokaryotes, and yet they occur in the plastid and mitochondrial genes. The parts of the RNA genes that are retained in the mature transcripts are also called exons. The length of individual exons is usually short, 10 to 300 nucleotides. The total average exon size per genes in mouse is about 2,300 and in humans ca. 3,400, although large differences exist among the different genes. Generally, the human genes display many short exons (average 50 codons) and are separated by long introns up to 10 kbp larger. The splice sites of exons may vary. In humans, more than 1/3 of the exons may not be translated. The largest exon number, 234, was found in the human *titin* mRNA, whereas the average is about 7–9. In human chromosome 11 there are 296 single-exon genes whereas 80.53% of the genes have an average of 9.39 exons (Taylor TD et al 2006 Nature [Lond] 440:497). Exons comprise approximately 1% of the human genome. The exons can be *constitutive* if they are always spliced and included into the mRNA. Some exons, the *cassette exons*, are included in a facultative manner, i.e., they are regulated. The size of particular exons may vary because both the 5' and 3' splice sites may vary as alternative promoters, and alternative polyadenylation sites are used with alternative splice sites. Splicing of the primary transcript is mediated by small ribonuclear proteins (snRNP) located at the exon-intron boundaries, but the DNA-dependent RNA polymerase II is tethered to the transcript and to the spliced exons to protect the continuity of the message (Dye MJ et al 2006 Mol Cell 21:849). Exons are apparently evolving from introns and thus contribute to gene evolution (Zhang XH-F et al 2006 Proc Natl Acad Sci USA 103:13427). ► [introns](#), ► [spliceosome](#), ► [alternative splicing](#), ► [branch-point sequence](#), ► [mosaic genes](#), ► [titin](#), ► [gene](#), ► [exon junction complex](#), GeneAlign exon prediction: <http://genealign.hccvs.hc.edu.tw/>.

Exon Connection: A method for isolating genes by following the steps: 1. Isolate RNA from a cell line;

2. Obtain cDNA; 3. Use PCR with primers of suspected adjacent exons; 4. Clone the product of PCR; 5. Sequence is tested for connection of exons; 6. Southern blot is performed with the probe generated; 7. Identify and isolate the whole gene. ► [exon](#), ► [cDNA](#), ► [PCR](#), ► [DNA sequencing](#), ► [gene isolation](#), ► [introns](#); Bardos J et al 1997 Int J Cancer 73:137.

Exon Definition: In pre-mRNAs with large introns the splicing machinery searches for closely spaced splice sites in a polar fashion. When such a pair is found U1 and U2 snRNPs and other splicing proteins, 3'-factors (U2AF, SC35) and 5'-recognizing factors (ASF, SF2) bind to the transcript. This definition is then followed by exon juxtaposition into an orderly fashion rather than random scrambling and joining of U4/U5/U6 snRNPs (Berget SM 1995 J Biol Chem 270:2411). ► [spliceosome](#), ► [intron](#), ► [exonscrambling](#), ► [exon skipping](#)

Exon Junction Complex (EJC): A 335-kDa protein complex (approx.) deposited 20–24 nucleotides upstream of the splice junction (see Fig. E61). DEXH/D proteins are instrumental in separating the RNA from the EJC protein complex. The complex includes SRm160 and RNPS1 coactivators of splicing and SRm160 enhances the processing of the 3'-end. RNPS1 and Y14 are also implicated in nonsense-mediated decay. Protein Aly/REF is supposed to mediate the nuclear export of the mRNA. MAGOH (post-splicing processing factor) facilitates sub-cytoplasmic localization of the mRNA. The stable core complex of EJC includes four proteins (eIF4AIII [a DEAD-box protein], Barents [Btz]/MLN51 localization factor, Mago and Y14 [RNA localization factors]), mRNA and ATP (Bono F et al 2006 Cell 126:713). ► [exon](#), ► [intron](#), ► [spliceosome](#),

Figure E61. Structure of the exon junction complex. Btz (magenta) stretches around eIF4AIII helicase (green). These two proteins interact with RNA (black). ATP (gray) is at the interface of the helicase domains. Mago (rust) and Y14 (turquoise) bind mainly to domain 2 of the helicase. Courtesy of Fulvia Bono and Elena Conti.

►NAS, ►nonsense-mediated decay, ►DEXH/D; Wiegand HL et al 2003 Proc Natl Acad Sci USA 100:11327; Wilkinson MF 2005 Trends Genet 21:143, exon junction core complex: Andersen CB et al 2006 Science 313:1968.

Exon Parsing: Determining the exact boundaries of exons or genes.

Exon Scanning: Molecular testing the gene for mutation. ►single strand conformation polymorphism, ►denaturing gradient gel electrophoresis, ►DNA sequencing

Exon Scrambling: In eukaryotes the exons may be spliced correctly but in a different order from that in the genomic DNA. This scrambling is believed to be mediated by loops in the pre-mRNA and makes possible the alternative processing of the transcripts. These exons are not polyadenylated. ►exons, ►exon definition, ►introns; Caldas C et al 1998 Gene 208(2):167.

Exon Shuffling: Exons of the same gene may be processed and thus expressed in more than one pattern and may be recruited for the synthesis of more than one protein. It has been suggested that the role of introns in the earliest cells during evolution was to facilitate the assembly of new genes by exon shuffling. Exon shuffling is most common in vertebrates but it has also been detected in the cytosolic glyceraldehyde-3-phosphate dehydrogenase gene of plants. The ubiquitous retrotransposons of eukaryotic cells may move exons and promoters into other genes and thus generate new composite genes with different function(s). The L1 retrotransposons may be copied into the genes. They can also mobilize the L1 flanking 3' sequences into the genes. The combination of different exons by recombination or genetic engineering may produce enzymes with potential advantage. Protein domains bordering the encoding exons are more numerous and widely distributed in the genomes indicating that these domains were amplified and interchanged more often than other domains during evolution (Liu M et al 2005 Nucleic Acids Res 33:95). ►exon, ►intron, ►retrotransposon, ►LINE, ►3' transduction; Pathy L 1996 Matrix Biol 15:301; Kolkman JA, Stemmer WPC 2001 Nature Biotechnol 19:423.

Exon Skipping: The out-splicing of an exon, i.e., skipping the inclusion into the mRNA. Exonic splicing enhancers can suppress exon skipping (Ibrahim EC et al 2005 Proc Natl Acad Sci USA 102:5002). Exon skipping causes several human diseases. Exon-specific activators of the serine/arginine rich (SR) type may correct disease-associated skipping (Cartegni L, Krainer AR 2003 Nature Struct Biol 10:120). In certain instances exon

skipping may alleviate the disease symptoms by the elimination of a defective exon—resulting from mutation—as long as the deletion does not affect the proper in-frame sequence of the truncated mRNA (see Fig. E62). Exon skipping may be induced by antisense RNA technology. ►splicing, ►alternative splicing, ►exonic splicing enhancer, ►antisense RNA, ►antisense technologies; Harper SQ et al 2002 Nature Med 8:253; Sherratt TG et al 1993 Am J Hum Genet 53:1007.

Figure E62. Exon skipping

Exon Theory: The exon theory has suggested that split genes arose by aggregation of exons during prebiotic or early evolution. Convincing experimental evidence is still lacking.

Exon Trapping: In physical mapping identifies “candidate genes” in transcribed sequences. By the use of an appropriate (commercially available) vector and a transfection technique an exon is inserted into an intron adjacent to the exon targeted. The transcript then appears longer and can be identified by Northern blot. ►candidate gene, ►physical mapping, ►Northern blotting, ►exon, ►trapping promoters; Wapenaar MC, Den Dunnen JT 2001 Methods Mol Biol 175:201.

Exonic Splicing Enhancer: The binding site for serine/arginine-rich splicing proteins and which facilitates the assembly of the pre-spliceosome (Shen H et al 2004 Mol Cell 13:302). ►spliceosome

Exonization: ►Alu family

Exonuclease: An enzyme that digests a polynucleotide chain beginning at either the 5' (RecJ) or the 3' terminus (Exo I, VI, X) or from both ends (ExoVII). Among these only ExoX degrades double-strand DNA. Exonucleases may degrade misaligned tandem repeats and thus favor DNA stability (Feschenko VV et al 2003 Proc Natl Acad Sci USA 100:1134). ►Ball, ►recombination mechanisms, ►endonuclease, ►restriction enzymes, ►mismatch repair, ►RecA-independent recombination; Grunberg-Manago M 1999 Annu Rev Genet 33:193; Shevelev IV, Hübscher U 2002 Nature Rev Mol Cell Biol 3:364.

Exonuclease I: Degrades DNA single-strands 3'→5'.

Exonuclease III: A multifunctional enzyme; in *E. coli* it works as a DNA-repair endonuclease, as an exonuclease 3'→5', phosphomonoesterase, and ribonuclease. ▶endonuclease, ▶exonuclease, ▶phosphomonoesterase, ▶ribonuclease

Exonuclease V: Digests double-stranded DNA and displays DNA-dependent ATPase activity; it is encoded by the *recBCD* complex of *E. coli*.

Exonuclease VII: A heterodimer; cuts single-stranded DNA from both 3' and 5' ends without requirement for Mg²⁺.

Exonuclease λ: Encoded by phage λ, binds to the free end of a DNA duplex, and degrades one strand in 5'→3' direction releasing about 3,000 5'-mononucleotides at a rate of about 12/sec. The 3' overhangs participate in genetic recombination with the assistance of the bacterial RecA protein. Alternatively, two homologous single-strands may anneal without Rec and form double-stranded recombinants. ▶recombination mechanisms, ▶lambda phage

Exoribonucleases: Exoribonucleases are enzymes which digest RNA from the terminus. They belong to six superfamilies and occur in all organisms. In *E. coli* 3'→5' the exoribonucleases are polynucleotide phosphorylase, RNase II, RNase D, RNase BN, RNase T, RNase PH, RNase R and oligoribonuclease. Eukaryotes also have similar enzymes. All eukaryotes also have 5'→3' exoribonucleases apparently absent from *E. coli*. ▶exosome; Deutscher MP, Li Z. 2000 *Progr Nucleic Acids Res Mol Biol* 66:67; Zuo Y, Deutscher MP. 2001 *Nucleic Acids Res* 29:1017; Gagliardi D et al 2001 *J Biol Chem* 276:43541.

Exoskeleton: The hard shell of the body (insects, crustaceans, etc.) including the vertebrate nails, hoofs, hair and other epidermal structures are considered as exoskeleton. ▶chitin

Exosite: An anion-binding site on the surface of a protein molecule. ▶anticoagulation

Exosome: A putative segment of DNA associated with, but not integrated into, the chromosome, yet it can express its genetic information. Exosomes may play a role in the quality control of mRNA. Either the hypopolyadenylated or hyperpolyadenylated molecules are permitted to exit from the nucleus and may be translated in case the nucleolytic complex of the exosome is defective. ▶episome, ▶RNA surveillance, ▶nonstop decay, ▶microRNA; Fox AS et al 1971 *Proc Natl Acad Sci USA* 68:342; Hilleren P et al 2001 *Nature [Lond]* 413:538.

Exosome: A complex of exoribonucleases, RNA-binding proteins and helicases in prokaryotes and

eukaryotes degrading RNA in the 3'→5' (or 5'→3') direction. In yeast, each of the 11 components is essential for viability. The complex—present in the cytoplasm and in the nucleus—trims rRNA primary transcripts and mRNA and degrades some other RNAs. Other eukaryotes may have somewhat different types of exosomes. The function(s) of exosomes is/are not fully understood and the views of the various investigators are not unanimous. According to some the exosomes are transporters of infectious agents such as prions or HIV virus. Some believe they reinforce/bolster the immune system, while others find it hard to confirm these ideas. ▶RNA processing, ▶mRNA degradation, ▶exoribonuclease; Suzuki N et al 2001 *Genetics* 158:613; Estavez AM et al 2001 *EMBO J* 20:3831; Brouwer R et al 2001 *Arthritis Res* 3:102; Koonin EV et al 2001 *Genome Res* 11:240; structure of the 9-subunit eukaryotic exosome: Liu Q et al 2006 *Cell* 127:1223.

Exosomes: Dendritic cells constitutively secrete 50–90 nm diameter vesicles that present antigens. They may stimulate antitumor responses by the ca. two dozen proteins. Exosomes may fuse with the membranes of other cells and thus serve as transfer vehicles for different proteins. Exosomes uptake may be followed by endocytosis. Exosomes and proteasomes have similar degradative functions although their composition and substrates are different (Lorentzen E, Conti E 2006 *Cell* 125:651). ▶endocytosis, ▶proteasome; Thery C et al 2001 *J Immunol* 166:7309; Denzer K et al 2000 *J Cell Sci* 113:3365.

Exostosis (EXT, diaphyseal aclasis): Autosomal dominant (EXT1, human chromosome 8q24.1-p13, EXT2 in 11p11.1, EXT3 in 19p) phenotypes involving growth of extra cartilage or bony projections at the end of bones (mainly on hands and fingers but rarely on the head, except the ear). EXT1 in chromosome 8 encodes a transmembrane glycoprotein and affects the cell surface of heparan sulfate glycosaminoglycans (see Fig. E63). Exostosis is generally accompanied by short stature. EXT2 encodes α-1,4-*N*-acetyl hexosaminyltransferase. The incidence of such defects in Western populations is about 1–2 × 10⁻⁵ and the estimated rate of mutations is 6–9 × 10⁻⁶. Their chance for bone cancer is increased to 0.5–2% of the cases. A deletion at 11p11.2 causes oval defects of a nerve/vein opening in the parietal bones (of the head) called Potocki-Shaffer syndrome. The highly homologous EXTL (EXT-like, EXTL1, 1p36.1, EXTL2, 1p12-p11) genes encode α1,4-*N*-acetyl glucosaminyl transferase involved in the biosynthesis of heparan sulfate and heparin. ▶stature in humans, ▶limb defects in humans, ▶Langer-Giedion syndrome, ▶Ehlers-Danlos syndrome, ▶fibrodysplasia, ▶metachondromatosis, ▶cancer, ▶heparan sulfate,

Figure E63. Exostosis, horse leg

► [glycosaminoglycan](#); Cheung PK et al 2001 Am J Hum Genet 69:55.

Exophthalmus (exophthalmos): A protrusion of the eyeball; it is frequent in goiter.

Exothermic Reaction: An exothermic reaction releases heat.

Exotoxin: Toxins secreted outside the cells (body) such as the protein toxins of several bacteria, e.g., *Clostridium botulinum* nerve toxin, etc. The diphtheria, pertussis, cholera and other toxins target either the α -subunit of the heterotrimeric G proteins, actin, Rho/Rac and eEF2. The ADP-ribosylating toxins share a common structural core containing the NAD⁺ binding site. The eEF2 elongation factor contains a single diphthamide residue (a modified histidine at site 699); diphthamide occurs only in this protein. Exotoxin A and diphtheria toxin inactivate eEF2 and interfere with protein synthesis (Jørgensen R et al 2005 Nature [Lond] 436:979). ► [toxins](#)

Expanded DNA: ► [xDNA](#)

Expansins: Plant cell wall proteins (ca. 26-K molecular mass) that facilitate the elastic growth of cell walls, loosening the stigmatic surface to aid penetration of the grass pollen tube, and fruit ripening. They may have a role as allergens. (See Shie MW, Cosgrove DJ 1998 J Plant Res 111:149; Pien S et al 2001 Proc Natl Acad Sci USA 98:11812).

Expansion Card: A circuit board that can be inserted into some computers and permits the user to perform some special, additional functions.

ExPaSy (Expert Protein Analysis System): Links to the Glaxo Institute of Molecular Biology, Geneva, 2-dimensional electrophoretic database to the SWISS-PROT protein sequence database. ► [laser desorption MS](#), ► [electrospray MS](#), ► [MELANIE II](#), ► [SWISS-PROT](#), ► [databases](#)

Expectation-Maximization Algorithm: Frequently used for studying the association of a certain haplotype with predisposition to disease. In population studies it may be necessary to estimate the linkage phase, the haplotype frequency and the role of a number of factors such as sampling error, sample size, allelic frequencies, deviations from the Hardy-Weinberg equilibrium, etc. ► [haplotype](#), ► [association test](#), ► [Hardy-Weinberg equilibrium](#); Fallin D, Schork NJ 2000 Am J Hum Genet 67:947; Epstein MP, Satten GA. 2003 Am J Hum Genet 73:1316.

Expected Phenotypic Superiority: Expected phenotypic superiority is $i_p \sigma p_1$ where i is the selection intensity when fraction p is selected in a breeding program. ► [selection intensity](#)

Experiments: Experiments are conducted to test a hypothesis (deductive method) or to generalize from empirical data (inductive method). In either case the work has clearly defined objective(s). Genetics is basically an experimental science. The results of medical research are investigated by clinical trials. 28 Phase III trials conducted by the US National Institute of Health cost \$335 million. As a result the projected net gain to society during a period of 10 years was estimated to be \$15.2 billion. Six trials (21%) generated measurable improvement in health and four (14%) resulted in cost savings for society. In addition to saving, the trials adjusted 470,000 life years for the patients during a period of 10 years (Johnston S et al 2006 Lancet 367:1319). The experimental cost does include the annual investment of basic and applied health research in the USA. ► [science](#), ► [genetics](#), ► [clinical trial phases](#)

Explant: A cutout piece of (plant/animal) tissue, used for in vitro culture. ► [tissue culture](#)

Exponential Distribution: May represent the amount of time until the first of a series of events occurs and the distribution of time between occurrences of the subsequent events in case the events occur according to a Poisson process of independent events (see Fig. E64). ► [distributions](#), ► [Poisson distribution](#)

$$P(r \text{ occurrences in } T \text{ units} | \lambda = \frac{e^{-\lambda T} (\lambda T)^r}{r!} \text{ where } \lambda = \text{the intensity per time units } t \text{ and } T = \text{the number of units of } t; \lambda T = \text{intensity}/T \text{ units}$$

Figure E64. Exponential distribution

Exponential Growth: Takes place when nutrients and other factors required for growth are optimal. The multiplication of the cells is determined by the exponent of 2. For example, after 10 divisions of a cell the number of cells becomes $2^{10} = 1,024$ and if

the number of initial cells were 8, then after 10 divisions the number of cells becomes $2^{10} \times 8 = 8,192$. This type of growth is also called logarithmic growth because $\log_2[1024] = 10$. The conversion to \log_2 from \log_{10} is carried out as follows:

$$\begin{aligned}\log_2[1024] &= \log_{10}[1024](1/\log_{10}[2]) \\ &= 3.010299957 \times \log_{10}(1/0.301029995) \\ &= 3.010299957 \times 3.321928095 \approx 10\end{aligned}$$

►growth curve

Export Adaptor: Export adaptors are proteins which attach to proteins of RNAs and assist their export or import, respectively, between nucleus and cytoplasm. Leucine-rich nuclear export signals (NES) move, e.g., the 5S rRNA to the cytoplasm through the nuclear pore complex. The members of the hnRNP family (~20 proteins) are involved in the transport of mRNA. ►RRE, ►nuclear pore, ►nuclear localization sequence, ►Gle1, ►Mex67, ►RNA export, ►RNA transport, ►transportin, ►Ran, ►CBC, ►snRNA; Segref A et al 2001 RNA 7(3):351.

Export Signals: Export signals can be RNA-binding proteins specific for RNA classes (mRNA, tRNA, rRNA, etc.) and mediate the interaction with export receptor molecules. The recognition of U snRNAs depends on their monomethylguanosine caps, the cap and tail structures, the HIV-1 Rev-responsive element, and 5S RNA binding sites for TFIIIA. Or, they may bind to proteins with leucine-rich nuclear localization signals. ►U RNA, ►hnRNA, ►acquired immune deficiency syndrome, ►ribosomes, ►transcription factors, ►nuclear localization sequences, ►Cap, ►export adaptor; Rashevsky-Finkel A et al 2001 J Biol Chem 276:44963.

Exportin: ►chromosome maintenance region, ►nuclear pore

Expressed Protein Ligation: Links together natural or synthetic peptide blocks into a final, functional protein. The ends of the components are engineered to become sticky and peptides with several unnatural amino acids can be consolidated. This approach permits modification of only a single domain within a multidomain protein. ►semisynthesis of proteins; Muir TW 2003 Annu Rev Biochem 72:249.

Expressed-Sequence Tag (EST): A probe of short nucleotide sequences for genes that are expressed in a particular tissue, although no information may be provided regarding their function or role. The use of ESTs greatly facilitated the analysis of the functional fraction of the eukaryotic genomes. The use of ESTs was important for the progress of the genome projects by being usually single-pass tracts although they may involve various artifacts. Patents for them were

sought; the ethical justification for their patenting has been criticized. ►EST, ►physical mapping, ►gene discovery, ►UniGene, ►patent, ►ORESTES, ►dbEST, ►gene indexing; Adams MD et al 1991 Science 252:1651; Gemünd C et al 2001 Nucleic Acids Res 29:1272; UniGene, Genomic Survey, <http://www.ncbi.nlm.nih.gov/dbEST/index.html>; barley, pea, potato, wheat, tobacco EST: <http://pgrc.ipk-gatersleben.de/cr-est/index.php>; <http://www.ncbi.nlm.nih.gov/ncic-gap/>, human EST: <http://genecards.weizmann.ac.il/genetide>; Gene Indices: <http://www.tigr.org/tdb/tgi/>; human EST DNA segment sequences alignment tool: <http://egassembler.hgc.jp/>; new marker tool across legume and grass species: <http://cgi-www.daimi.au.dk/cgi-chili/GeMprospector/main>; EST of 49 diverse organisms: <http://tbestdb.bcm.umontreal.ca/>; EST characterization: <http://www.conifergdb.org/software/wtm1.2/>; EST annotation: <http://estexplorer.biolinfo.org>, cleansing and annotating EST: <http://estpass.kobic.re.kr/>.

Expression: In genetics means phenotype; the phenotype may be any morphological trait or a (protein) product of a gene. ►phenotype, ►genotype

Expression Cassette: Contains all the sequences required for the expression of a gene and can be inserted into various expression vectors for transcription. Also, the structural gene may be replaced by another structural gene. ►expression vector, ►structural gene

Expression Cloning (reverse biochemistry): Cloned cDNA is expressed in a cellular or cell-free translation system in order to study the pure product of a gene. ►molecular cloning, ►cDNA, ►FL-REX, ►rabbit reticulocyte in vitro translation system, ►wheat germ in vitro translation system

Expression Library: Includes cDNAs in expression vectors permitting their ready use for transformation and expression in several hosts. ►expression vector

Expression Matrix: An expression matrix may be used to study genetic data obtained by microarray hybridization. These are tables where rows designate genes, columns represent the various samples of tissues or conditions of expression, and within each cell of the grid the level of gene expression is shown. ►microarray hybridization; Brazma A, Vilo J 2000 FEBS Lett 480:17.

Expression Profile: The collection of mRNAs transcribed (expressed) from genomic DNA thus determining the cellular phenotype. It reveals developmental and extended, interacting metabolic pathways. It may represent, also, the expression pattern of a single gene over time or during development. ►transcriptome, ►microarray hybridization, ►DNA chips; Miki R et al 2001 Proc Natl Acad Sci USA 98:2199, tools for clustering,

gene expression, pattern discovery, gene ontology, regulatory sequences, protein interactions: <http://ep.ebi.ac.uk/EP/>.

Expression Trapping: The survey of embryonic stem cells containing gene-trap integrations in genes responding to specific agents. ▶trapping promoters, ▶stem cells

Expression Vector: An expression vector carries to the target cell by transformation the structural gene and all the regulatory signals required for expression. ▶vectors

Expression-Linked Copy: In the *Trypanosomes*, for the expression of a different type of antigen, gene transposition is required. ▶*Trypanosoma brucei*

Expression-Verified Genes (EVGs): Coregulated exons as detected by microarray hybridization. ▶microarray hybridization, ▶exon

Expressivity: The degree of expression of a gene. ▶penetrance, ▶microarray hybridization; Oleksiak MF et al 2002 Nature Genet 32:261.

EXProt: A database of proteins with experimentally verified function. (See <http://www.cmbi.kun.nl/EXProt/>; ▶metabolism).

Exstrophy: A rare congenital developmental anomaly of turning an organ inside out, involving the bladder or in the pubic area.

Extein: Flanking protein sequences remaining after the removal of inteins. ▶intein

Extensible Markup Language: The structural format for documents on the WEB. (See <http://www.w3.org/XML/>).

Extensins: Plant cell wall glycoproteins. (See Yoshida Y et al 2001 DNA Res 8:115).

External Guide Sequences (EGS): RNA oligonucleotides that can bind to specific RNA sites in an RNA molecule and guide to this location ribonuclease P that cleaves at specific sites. ▶Ribonuclease P, ▶antisense technology; McKinney J et al 2001 Proc Natl Acad Sci USA 98:6605).

External Transcribed Spacers: ▶ETS

Extinction: The loss of a genotype (phenotype) from a population; disappearance of a conditioned response; suppression of cell-type-specific function in fused somatic cells. During the Permian period (250–225 million years ago) atmospheric oxygen levels decreased and the warming climate caused extinction due to hypoxia of many species (fishes, amphibians, etc) that evolved in the preceding epochs before birds and mammals emerged (Huey RB et al 2005 Science 308:398). The causes of extinction are multiple, but

in larger mammals the increased body is a significant disadvantage for survival (Cardillo M et al 2005 Science 309:1239). (See ▶species extant, ▶equilibrium of mutations, ▶geological-evolutionary time periods) In spectrophotometry it means the intensity of the absorption (ϵ_{\max}) at the absorption peak (λ_{\max}). ▶O.D

Extirpation: The complete removal of an organ, a type of cell(s) or tissues. ▶ablation

Extracellular DNA: Extracellular DNA is cell-free, naked DNA that may be a waste of laboratory operations and may persist in the environment as a polymer and a potential hazard. In soil or other aqueous environments the polymer rapidly decays. Plasmid or other supercoiled DNA may be less prone to degradation. Antibiotic resistance DNA may not pose serious hazards unless selective conditions exist. (See Doblehoff-Dier O et al 2000 Trends Biotechnol 18:141).

Extracellular Matrix (ECM): A complex of polysaccharides and proteins, secreted by cells. Its role in the tissues is structural and physiological. ECM includes collagens, a variety of fibrous proteins of triple-helical coiled coil structure, glycoproteins (laminin, fibronectin), proteoglycans, etc. ECM is linked to the intracellular cytoskeleton by integrins. Without anchorage, most cells succumb to apoptosis. Matrix metalloproteinase modifies the extracellular matrix of cancer cells and allows changes in the shape of the cell and the cytoskeletal organization and thus facilitates the proliferation of cancer cells. Cell surface architecture and ECM organization attracted much interest recently because of the potentials of engineering natural and synthetic cell surfaces that can effect growth, tissue regeneration, cell migration, differentiation and novel application of medical implants (Stevens MM, George JH 2005 Science 310:1135). A FRET technique can be used to quantify the number of bonds formed between cellular receptors and synthetic adhesion oligopeptides coupled to an artificial extracellular matrix. Similar quantitative relations were found between bond number and the proliferation and differentiation of some preosteoblasts and myoblasts, although the relation was distinct for each cell type. This approach to understanding 3-dimensional cell-extracellular matrix interactions will allow one to both predict cell behaviors and to use bond numbers as a fundamental design criteria for synthetic extracellular matrices (Kong HJ et al 2006 Proc Natl Acad Sci USA 103:18534). ▶fibronectin, ▶collagen, ▶laminin, ▶proteoglycans, ▶basement membrane, ▶metalloproteinase, ▶integrin, ▶ICAM, ▶elastin, ▶fibronectin, ▶Kindler syndrome, ▶nanotechnology, ▶FRET

Extrachromosomal Inheritance: Extrachromosomal inheritance is determined by nonnuclear elements. ▶mtDNA, ▶mitochondrial genetics, ▶chloroplast genetics, ▶plasmids

Extragenic: The genetic factor is outside the boundary of the gene that it affects, e.g., suppressor tRNA. ▶suppressor tRNA, ▶suppressor gene

E

Extranuclear Genes: Extranuclear genes are in the cellular organelles (mitochondria, plastids), except the cell nucleus.

Extranuclear inheritance: Extranuclear inheritance is determined by genes in cellular organelles and not by those in the nucleus. ▶ctDNA, ▶mtDNA, ▶symbionts hereditary

Extrapolation: To calculate values beyond an interval on the basis of the knowledge of values known within the interval. This is usually done with the assistance of the linear regression equation, $Y = a + bx$. Extrapolation may involve some risks of error if the value of x is increasing beyond the range known and, even more seriously, if the linear regression equation (Y) values do not represent the values properly, but in effect may be a curved line beyond the interval. ▶correlation, ▶interpolation linear

Extrasensory Perception: Goes beyond the recognition of facts by rationally explainable means. ▶paranormal

Extraterrestrial Life: Living creatures outside the earth have been claimed on the basis of various observations but so far no unchallenged evidence has been available. (See Wilson TL 2001 Nature [Lond] 409:1110).

Extravasation: Passing cells from the blood into tissues. Such events occur during metastasis. ▶diapedesis, ▶metastasis, ▶intravasation

Extreme-Value Distribution Theory: If from a population many values are chosen but only the maximal values are reproduced repeatedly the distribution approaches the extreme-value condition. Also, the probability of an alignment score is caused by chance in the physical mapping of DNA. This principle is also applicable for search of microarray dataset-based gene selection (Li W et al 2004 J Comput Biol 11:215). ▶physical mapping, ▶microarray hybridization; Pagni M, Jongeneel CV 2001 Brief Bioinform 2(1):5; Dudbridge F, Koeleman BP 2004 Am J Hum Genet 75:424.

Extremities: Body appendages such as the limbs.

Extrinsic: Outside (factor); an adjective, defining that an effect is not intrinsic (essential feature) of the phenomenon. ▶intrinsic

Exudative, Vitreoretinopathy, Familial (11q13-q23): Dominant/recessive retinal detachment and vitreous hemorrhages. The symptoms are similar to vitelliform macular dystrophy. ▶macular dystrophy, ▶retinal dystrophy

Exules: Successive generations of insects (aphids).

Eye Color: Eye color in humans is a polygenically controlled trait. It is frequently assumed that one gene locus (BEY, 15q11-q15) is responsible for brown/blue color and another for green/blue (GEY, 19p13.1-q13.11) color. Genome-wide linkage scan for eye color suggested that 74% of variation in eye color in Europeans could be attributed to a QTL linked to the *OCA2* region of chromosome 15q (Duffy DL et al 2007 Am J Hum Genet 80:241). Brown (dark) tends to be dominant over blue, and green over blue. It is not too uncommon that blue-eyed parents have both blue-eyed and brown-eyed offspring. This is no basis for suspecting illegitimacy. Brown sectors in blue eyes (sometimes almost invisibly small) are attributed to somatic mutation. Such individuals are more likely to have brown-eyed children even if their spouses have blue eyes. Pigmentation of the retinal layer of the iris and the nature of the semi-opaque layers in front of the iris determine the eye color. A blue layer may be present in all individuals but it may be masked by another layer of melanin in the front part of the iris. Therefore, blue-eyed babies may develop brown eyes when melanin is accumulating in the front part of the iris at later stages. Green and hazel eyes indicate that melanin partially masks the reflections from the deeper layers of the iris. Gray eyes are variants of the blue color. Black eyes indicate very deep brown melanin layer. When all pigments are absent in albinos, the eyes appear pink or very pale blue because of the reflections of the blood vessels. Some eye diseases involving coloboma may change eye color. Phenylketonurics may display light eye color because of the defect in pigment synthesis. It is not too uncommon that the color of the two eyes of a person does not match (heterochromia iridis, Morrison DA et al 2000 Arch Ophthalmol 118:1590) due to a developmental anomaly. Heterochromia iridis may occur in individuals affected by Waardenburg syndrome II. It is also conceivable that somatic mutation to ocular albinism may result in white sectors in the otherwise normal eye (Hegde M et al 2002 Genet Test 6:7). In insects the bright red color is derived from pteridines and the brown from ommochromes. The intermediate shades develop from the presence of both pteridines and ommochromes. ▶albino, ▶Hermansky-Pudlak syndrome, ▶incontinentia pigmenti, ▶Waardenburg syndrome, ▶pigmentation in animals, ▶eye

diseases, ►coloboma, ►phenylketonuria, ►QTL; Sturm RR et al 2001 *Gene* 277:49; Frudakis T et al 2003 *Genetics* 165:2071.

Eye Diseases (ophthalmologic diseases): Eye diseases are concerned with anatomical and pathological conditions related to vision. More than 0.5% of the population of the USA is afflicted with some serious eye problems and almost 0.02% is legally blind. In other parts of the world, eye-related diseases may be even more prevalent. The genetic component of these ailments is variable and it is usually part of complex syndromes affecting anatomical and physiological disorders. Clouding of the cornea occurs in the Hurler, Marquio, Maroteaux-Lamy syndromes, and Fabry's disease. Cataracts may be present in Wilms tumors, Lowe syndrome, galactosemia, Werner syndrome, and myotonic dystrophy. A cherry-red spot may appear on the retina in sphingolipidoses, gangliosidoses, and mucopolidoses. Reduced vision occurs in neuroaminidase deficiency. Retinitis pigmentosa (most commonly clumped pigments and atrophy of the retina, contraction of the field of vision), Usher, Laurence-Moon, Bardet-Biedl syndromes, Refsum disease may involve eye pigment disorders. Amaurosis congenita, retinoschisis are malformations or deficiency of the retina. Loss of eye pigments and reduced vision in albinism, Blue sclera (the normally white outer surface of the eye) in osteogenesis imperfecta are characteristic. Variegation of the eye color (iris) is found in the Waardenburg syndrome. Retinal neoplasia is the most critical feature of Norrie disease. Hypoplasia of the iris occurs in Rieger syndrome and reduction in eye size is caused by microphthalmos. Myopia is common in the Stickler syndrome, Marfan syndrome, Kniest dysplasia. Tumors of the eye tissues develop in retinoblastoma and von Hippel-Lindau syndrome. Tumorous eyes are also found in the Crouzon syndrome. In human trisomy 21 (Down syndrome) slanted eyelids and white spots around the iris appear. Autoimmune eye disease may involve ocular cicatricial (scar-like) pemphigoid. Approximately 100 mapped genes are responsible for blindness. (See under separate entries the named conditions; ►mitochondrial diseases in humans, ►color blindness, ►night blindness, ►Oguchi disease, ►S-cone syndrome, ►ophthalmoplegia, ►oculodentodigital dysplasia, ►Michel syndrome, ►focal dermal hypoplasia, ►Hirschsprung disease, ►glaucoma, ►strabismus, ►Duane retraction syndrome, ►nystagmus, ►coloboma, ►aspartoacylase deficiency, ►cat eye syndrome, ►galactosemia, ►myopia, ►Rothmund-Thompson syndrome, ►Rieger syndrome, ►Cohen syndrome, ►Zellweger syndrome, ►cataracts, ►ferritin, ►foveal dystrophy, ►macular

dystrophy, ►macular degeneration, ►retinal dystrophy, ►Stargardt disease, ►cornea plana, ►anophthalmos, ►anophthalmia, ►microphthalmos, ►pemphigus, ►retinitis pigmentosa, ►choroidoretinal degeneration, ►choroidal osteoma, ►Aphakia, ►GDLD mitochondrial diseases of humans, ►Leber optical atrophy, ►choroideremia; <http://mutview.dmb.med.keio.ac.jp/>; www.eyepathologist.com; <http://eye.site.cryst.bbk.ac.uk/>.

Eyelashes, Long (trichomegaly): May be an autosomal dominant anomaly associated with cataract and spherocytosis and other ailments. An autosomal recessive form was also studied, and the latter involved mental retardation, retinal degeneration and a number of other symptoms with unclear relevance to the formation of the eyelashes. Multiple rows of eyelashes were also observed to apparently follow either recessive or dominant inheritance, or being only a nongenetic anomaly. ►spherocytosis, ►emphedema-distichiasis

eyeless: A *Drosophila* mutation controlling eye differentiation but not the ocelli. The *Small eye* (*Sey/Pax-6*) of mice and the human Aniridia genes are homologous. Several other genes also affect eye development in *Drosophila*. The gene *Eyes absent* encodes a transcription factor with a function of a protein tyrosine phosphatase (Rayapureddi JP et al 2003 *Nature [Lond]* 426:295; TootleTL et al *ibid* 299). ►aniridia, ►anophthalmia, ►microphthalmos

Eye piece: A microscope lens through which the eye directly views the object through the tube. The eye piece only enlarges the image but does not afford better resolution unlike the lens of the objective. ►microscopy, ►objective

Eyespot: A complex light-perception structure in algae involved also in the movement of the flagella (singular flagellum). By the light microscope in *Chlamydomonas reinhardtii* it appears as an orange spot in the chloroplast stroma. It is also involved with a Ca²⁺ channel. The eyespot is controlled by several genes. ►*Chlamydomonas*

Eyk: A receptor tyrosine kinase encoded by a chicken protooncogene. ►protooncogene, ►tyrosine kinase

Ezetimibe: A potent inhibitor of cholesterol and phytosterol uptake. It lowers circulating cholesterol levels by 15–20%, especially when it is administered with statins. It is a drug used for treatment of hypercholesterolemia (Knopp RH et al 2003 *Eur Heart J* 24:729). Ezetimibe targets the Neumann-Pick C1-like protein (see Fig. E65). ►cholesterol, ►phytosterol, ►familial hypercholesterolemia, ►Niemann-Pick disease; Garcia-Calvo M et al 2005 *Proc Natl Acad Sci USA* 102:8132.

Figure E65. Ezetimibe glucuronide

Ezrin: A cytoskeletal protein. ▶ICAM, ▶T cell receptor, ▶caveolae, ▶ERM, ▶*Listeria*; Ng T et al 2001 EMBO J 20:2723; Saotome I et al 2004 Dev Cell 6:855.

Historical vignette

Bacteriophages were discovered by FW Twort (1915, *Lancet* ††:1241). In 1925 F D'Herelle (then Directeur du Service Bacteriologique du Conseil Sanitaire, Maritime et Quarantenaire d'Egypte) wrote a remarkable book of 629 pages about this agent, which he named bacteriophage because it could eat bacteria. The preface of the book emphasizes the practical significance of bacteriophages:

“Although up to the present time but few authors have undertaken the study of the behavior of the bacteriophage within the organism there are a relatively large number who have carried out investigations on what might be termed the other side, that is to say, on the application of the bacteriophage to the therapy of various infectious diseases. Of particular interest are the contributions of Hauduroy, who has applied this mode of treatment in colon bacillus infections, of Gratia, who has conclusively demonstrated a therapeutic effect in staphylococcus infections, and of da Costa Cruz who, after having confirmed my first studies on the specific treatment of the bacillary dysenteries, has undertaken a large scale demonstration of this mode of therapy with such results that all other modes of treatment have today been abandoned in Brazil.”

Today bacteriophages are not used as therapeutic agents, but their application as a tool for biological research led to the development of molecular biology, which in turn is making a great impact on medicine.

At the 16th Cold Spring Harbor Symposium (p. 436) J Lederberg et al., discussing bacterial recombination, say: “The exposure of sensitive cells to suspensions of the free phage, which we named “λ,” by analogy to a killer factor in *Paramecium*, results in the lysis of a variable proportion of the cells. ... The speculation that λ might be involved in genetic recombination needs no further mention.”

F

F: The coefficient of inbreeding expresses the probability for homozygosity of alleles, identical by descent, at a locus. It can simply be determined from the pedigree of an individual in a family (see Fig. F1).

Figure F1. F

Each gamete has a 0.5 chance to transmit a particular allele through the paths available. Thus, in the progeny of a half-brother and half-sister mating, with three relevant ancestors involved, the coefficient of inbreeding, $F = 0.5^3$. Similarly, the value of F for the offspring of first cousins is $1/16$ because through two loops, represented by E-C-B-D-F and F-D-A-C-E, the same allele can be transmitted from the great grandparental gametes to the offspring I. F, therefore, is: $0.5^5 + 0.5^5 = 0.03225 + 0.03125 = 0.0625 = 1/16$. Note that the looping is done backwards from the I offspring. F_{IS} is the coefficient of inbreeding of an individual relative to the sub-population it lives in. Its value is determined by analysis of its descent (pedigree). F_{ST} is the index of fixation. F_{IT} is the coefficient of inbreeding of an individual (I) relative to the (T) total population. Employing F_{IS} , F_{ST} , and F_{IT} is called F-statistics. ▶ [coefficient of coancestry](#), ▶ [relatedness](#), ▶ [fixation index](#), ▶ [metapopulation](#); Wang J 1997 Genetics 146:1453, 1465.

F' (F prime): The fertility factor that carries regularly bacterial chromosomal gene(s). (See Clark AJ, Adelberg EA 1962 Annu Rev Microbiol 16:289).

F⁺: Bacterium carrying a sex element (F, fertility factor). ▶ [F plasmid](#)

F₁, F₂, F_n: Subsequent filial generations; the parents of the F₁ are homozygous for different alleles of the corresponding gene(s).

F Duction: In F duction, a gene is transferred to the F⁻ bacterial cell by an F plasmid, called F'; the process is the same as that of sexduction. ▶ [sexduction](#), ▶ [F plasmid](#)

F Element: The “dot-sized” smallest chromosomes, common to all *Drosophila* species.

F Elements: See non-viral retrotransposable elements. ▶ [hybrid dysgenesis](#), ▶ [I – R](#), ▶ [FB](#), ▶ [F factor](#)

F Factor: The bacterial fertility element (F plasmid, sex plasmid). ▶ [Hfr](#), ▶ [episome](#), ▶ [F plasmid](#); Bernstein HL 1958 Symp Soc Exp Biol 12:93.

F₂ Linkage Estimation: In some species where controlled mating or crossing is difficult, linkage intensities (recombination frequencies) can be estimated in the selfed progeny of F₁ or in the offspring of brother–sister matings. In testcrosses, the recombination frequencies can be determined in a straightforward manner by dividing the number of recombinants by the sums of the parental and recombinant individuals in the progeny. In F₂, the computations rely on indirect means, using statistical tables (see Table F1). The product ratio tables were constructed on the basis of the formula:

$\frac{ad}{bc} = \frac{T(2+T)}{(1-T)^2}$ where the meaning of a, b, c, d is given, and $T = (1 - p)^2$ for coupling, and $T = (p)^2$ for repulsion data; p is recombination frequency. The procedure can be best described by an example. Let us consider a hypothetical F₂ population with four phenotypic classes (a, b, c, d):

| AB (a) | Ab (b) | aB (c) | ab (d) | Total |
|--------|--------|--------|--------|-------|
| 660 | 38 | 40 | 183 | 921 |

Linkage is obvious, because the frequency of the double homozygous recessive class (ab or briefly d) exceeds that of the single heterozygotes (Ab and aB, classes b and c), the linkage phase is *coupling* in the two parents (AB and ab).

We can use the product ratio method (formula R for repulsion) and formula C in coupling:

$$\frac{a \times d}{b \times c} = R, \text{ and } \frac{b \times c}{a \times d} = C.$$

$(b \times c)/(a \times d) = (38 \times 40)/(660 \times 183) \cong 0.012584865 = C$. In the table, this exact fraction is not found; therefore, interpolation is necessary to find the right value (see Table F2). Interpolation is expected to provide a more accurate estimate than values in the product ratio table, where the recombination fraction is shown in increments of 0.005.

Table F1. F₂ Linkage Estimation. Recombination fractions determined by the product ratio method using F₂ data. Modified after F. R. Immer, *Genetics* 15:81. Recombination fraction = y , product ratio in repulsion: R , product ratio coupling: C factor to be divided by \sqrt{N} , to obtain standard error of y , for repulsion SeR and for coupling SeC . N = total number of individuals in F₂. When the value of the product ratio does not correspond to a close-enough value of y , interpolation is required. More precise estimates can be obtained by the table of W. L. Stevens (*J. Genetics* 39:171), using 5 decimals, rather than 3, as in this table. Since recombination fractions are generally variable, for most purposes this accuracy may be entirely satisfactory. For the method of use of this table, see text on preceding page and next page.

F

Corresponding to $y = 0.085$ and 0.090 in the C column, the table shows 0.01116 and 0.01262 . The procedure of **linear interpolation** is illustrated.

Table F2. F_2 Linkage Estimation

| | 1 | 2 | 3 |
|----------|---------|-------------|---------|
| C values | 0.01116 | 0.012584865 | 0.01262 |
| y values | 0.085 | ? | 0.090 |

Calculation: $\frac{C_2 - C_1}{C_3 - C_1} = \frac{0.012584865 - 0.01116}{0.01262 - 0.01116} = \frac{0.001424865}{0.00146} = 0.975934931 = \alpha$ and $1 - \alpha = 0.024065068$; **y2** (the recombination fraction sought) $= (y_1)(1 - \alpha) + (y_3)(\alpha) = 0.085(0.024065068) + 0.090(0.975934931) = 0.087834143$ or \approx **0.08783**

The interpolated SeC value is obtained as: $0.2339(0.024065068) + 0.3025(0.975934931) = 0.300849136$

The standard error of the y_2 is calculated by $0.300849136 / \sqrt{921} = 0.009913316$. Thus the interpolated recombination fraction, $(y_2) = \mathbf{0.08783 \pm 0.00991}$.

The efficiency of the product ratio method in F_2 coupling phase equals that of the testcrosses when the recombination frequency is low (below 8%) but approaching independent segregation the efficiency decreases. Maximally in F_2 , 2.5 times larger populations may be required to obtain equally dependable results. In repulsion, especially at close linkage, (below 8% recombination) the F_2 and product ratio procedures are very inefficient. The product ratio method is very useful when both recessive alleles reduce gametic or zygotic viability but not so when only one of the alleles is causing differential mortality. Generally, the product ratio method is equal in efficiency to the maximum likelihood procedure. The dependability of the results is determined primarily by the data collected and not by the statistical procedures. [►recombination](#), [►coupling](#), [►repulsion](#), [►maximum likelihood method applied to recombination frequencies](#), [►mapping functions](#), [►mapping genetic](#), [►table above](#), Table F1, Stevens WL 1939 J Genet 39:171.

F₃ Linkage Estimation: This process may be used both in repulsion and with coupling phases. In repulsion, the information is not very trustworthy unless the recombination frequency is about 0.1 or less. Recombination can be estimated by combining F_2 and F_3 data as follows: $x = \frac{a/aB/b}{n}$ = $\frac{\text{Number of segregating lines}}{\text{Number of } a/a \text{ lines}}$ then p (recombination fraction) =

$$\frac{x}{2-x} \text{ and the standard error of } p, s_p = \frac{2\sqrt{x(1-x)}}{[2-x]^2\sqrt{n}}$$

F⁻ Phenocopy: A bacterial cell that has no F pilus. Although it carries an F element, it is not in a conjugative state. [►bacterial conjugation](#), [►conjugation mapping](#)

F Plasmid: Also known as the F factor or fertility plasmid of *E. coli*; it is about 100 kb and has four major regions (see Fig. F2). The (1) *inc* and *rep* tracts control its vegetative replication. When only this is retained it is called a *miniplasmid*. The (2) *IS* sequences are insertion elements and *Tn1000* is a transposon (called also $\gamma\delta$) is similar to *Tn3*. In the (3) *silent region* few functions are known. The (4) *tra* sites control transmission of the plasmid, which originates at the *oriT* site. The *tra* region includes more than two-dozen genes. The *tra M* is regulated by the *traJ* gene, which in turn is negatively regulated by *fin* (fertility inhibition) gene products. The *tra* operon also includes genes for the formation of the sex pilus through which plasmid and/or chromosomal DNA is transferred to the recipient cells. The total number of genes in this plasmid is about 30. The plasmid may be present in one or two copies per F^+ bacterial cells. It is an episome and can integrate clockwise or counterclockwise at various sites into the bacterial chromosome. When excised it may become an F' plasmid. [►episome](#), [►conjugation](#), [►pilus](#), [►mapping](#), [►transposon](#), [►episome](#), [►F' plasmid](#), [►Hfr](#); Cavalli LL et al 1953 J Gen Microbiol 8:89.

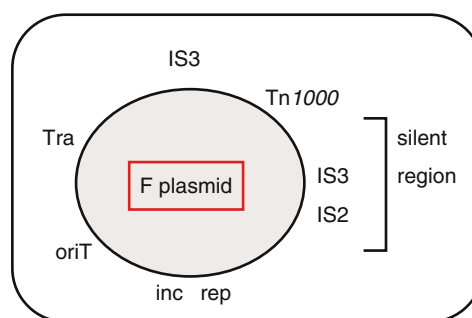

Figure F2. F plasmid

F Statistics: F statistics estimates the significance of the difference between means by the use of analysis of variance (ANOVA); it was named after R.A. Fisher who developed it. [►analysis of variance](#), [►F-distribution](#)

F₂ Segregation: [►Mendelian segregation](#)

φValue: A biophysical characteristic of a macromolecule. It is obtained by dividing the change in transition-state free energy accompanying a side-chain truncation by the change in native-state free energy. [►transition state](#)

FAA: A histological fixative containing formalin, acetic acid, ethanol. [►fixatives](#)

Fab Domain: The fab domain of the antibody includes a whole light chain and a part of the heavy chain (can be split off by digestion with papain), including the paratope (the antigen recognition site). ►antibody, ►epitope

FABPs: FABPs are fatty acid binding proteins facilitating lipid utilization and fat homeostasis. ►obesity; Maeda K et al 2005 Cell Metabolism 1:107.

Fabry Disease: An Xq22 chromosome disorder caused by a deficiency of α -glycosidase (α -galactosidase A) enzyme. Vascular NO dysregulation, increased nitrotyrosine staining, and accelerated atherosclerosis were confirmed in the murine model. The hemizygous males have skin lesions, opacity of the eye, periodic fevers, burning sensation in the extremities, and edema (fluid accumulation) due to kidney malfunction. The heterozygous females have much milder symptoms yet they also develop opacity of the eyes. The afflicted individuals survive to adulthood when death is caused by heart, kidney, and brain problems. The heterozygotes can be identified and the condition is detectable by amniocentesis; thus, genetic counseling is effective. Galactosylgalactosyl-glucosyl ceramide accumulates in the endothelium (the tissue lining the heart, blood and lymph vessels, and other cavities), in the nerve system, the epithelium (surface cell layers) of the kidney and cornea (the transparent outer coat in front of the eyes). Attempts have been made to correct the condition by retroviral vectors with α -glycosidase A (α -galactosidase A) expression. ►galactosidases, ►sphingolipidoses, ►sphingolipids, ►viral vectors, ►gene therapy, ►enzyme replacement therapy; Ioannou Y et al 2001 Am J Hum Genet 68:14; Blom D et al 2003 Am J Hum Genet 72:23.

FAC: ►Fanconi's anemia

Face/Heart Defects: ►Alagille syndrome, ►Williams syndrome, ►Noonan syndrome, ►Ellis-van Creveld syndrome, ►DiGeorge syndrome, ►velo-cardiofacial syndrome

Facet: The small flat surface on a structure or component of the insect eye. ►ommatidium, ►compound eye

Facilitation: In facilitation by repeated impulses to the nerve cells, the amount of neurotransmitter is increased but eventually this process may lead to exhaustion of the neurotransmitter supply.

Faciogenital Dysplasia (FGD1, Xp11.21): Faciogenital dysplasia involves hypertelorism (increased distance between parts of the face), cryptorchidism (hidden testes), bone deformation, cup-shape ear-lobes, etc., caused by defects in a guanine nucleotide exchange factor that activates Cdc42. ►Aarskog syndrome, ►guanine nucleotide exchange factor, ►CDC42, ►GEF; Estrada L et al 2001 Hum Mol Genet 10:485.

FACS (fluorescence-activated cell sorting): cell sorter, flow cytometry.

FACT (complex of p140 and p80): A histone chaperone, which in cooperation with other proteins, facilitates transcription through nucleosomes by chromatin remodeling and transcript elongation by RNA polymerase II. ►chromatin remodeling; Orphanides G et al 1998 Cell 92:105; Pavri R et al 2006 Cell 2006 125:703.

Factor: A genetic unit such as a gene.

Factor D: Synonymous with TIF-1B.

Factorial: $1 \times 2 \times 3 \dots \times (n - 1) \times n = n!$, the products of integers from 1 to n , the factorial of n numbers. Note: $0! = 1$.

Factorial Experiment: A factorial experiment analyzes simultaneously the effects of several factors, e.g., a_1b_1 , a_2b_1 , a_1b_2 , a_2b_2 . The comparison $a_2b_2 - a_1b_2$ assesses the "main effect" of A when B remains constant and $a_2b_1 - a_1b_1$ determines the B "main effect" when A is constant. Such experiments are very economical for testing simultaneously the consequences of several factors and their interactions (AB), and are frequently used to determine dose responses by using different levels of the individual elements such as a_1 and a_2 . ►Graeco-Latin square, ►principal component analysis; Fisher RA 1937 The design of experiments, Oliver & Boyd, Edinburgh, UK.

Facultative: A facultative has no absolute single determination; it may show alternative forms or functions.

Facultative Heterochromatin: Facultative heterochromatin behaves as a heterochromatin only under certain conditions, like in the mammalian X-chromosome when present in more than a single copy. ►heterochromatin

FAD: Flavin adenine dinucleotide, a riboflavin containing coenzyme in some oxidative-reductive processes; also an acronym of familial Alzheimer disease. ►Alzheimer disease

FADD/MORT-1 (FAS-associated death domain, 26-kDa): The FLIP proteins interact with FADD in the presence of FLICE and inhibit apoptosis. FADD interacting with Fas permits the recruitment of caspase-8 (FLICE/MACH) and that activates the protease cascade of apoptosis. FADD also signals to TNFR associated death domain (TRADD) and to developmental pathways. FADD also regulates the pre-T cell receptor and may act as a tumor suppressor. FADD^{-/-} cells are more susceptible to RNA virus infection (Balachandran S et al 2004 Nature [Lond] 432:401). ►FAS, ►FLICE, ►death domain, ►apoptosis, ►TNFR; Zhang J, Winoto A 1996 Mol Cell

Biol 16:2756; Gómez-Angelats M, Cidlowski JA 2001 J Biol Chem 276:44944; Werner MH 2006 Cell Cycle 5:2332; CD95 in apoptosis: Peter ME et al 2007 Cell 129:447.

FAHR Disease (14q): Idiopathic basal ganglia calcification, a neurobehavioral and cognitive disorder.

FAIRE (formaldehyde-assisted isolation of regulatory elements): A method to assay open chromatin using formaldehyde crosslinking followed by detection of the products using a genomic tiling array. It has utility as a positive selection for genomic regions associated with regulatory activity, including regions traditionally detected by nuclease hypersensitivity assays (Giresi PG et al 2007 Genome Res 17:877). ▶tiling, ▶nuclease-sensitive sites

FAK (focal adhesion tyrosine kinase): A protein tyrosine kinase occurring at high level in SRC transformed cells. Its role is in mediating cell adhesion and migration. FAK is localized at the cell membrane integrin receptors. Association of integrin with fibronectin results in binding of the Grb2 adaptor to SRC and FAK protein tyrosine kinases and in the activation of MAPK (mitogen-activated protein kinase) in the signal transduction pathway. FAK interacts with phospholipase C- γ -1. ▶CAM, ▶Grb, ▶SRC, ▶MAPK, ▶signal transduction, ▶PTEN, ▶integrin, ▶cell migration, ▶phospholipase, ▶FLT; Xie B et al 2001 J Biol Chem 276:19512; structural

and functional domains: Dixon RDS et al 2004 Structure 12:2161.

Fallopian Tube (uterine tube, oviduct): The fallopian tube connects the mammalian ovary to the uterus. Upon maturation, the egg is released into the Fallopian tube and fertilization may take place after the sperm injected into the vagina travels to the egg through the cervical canal. ▶fertilization, ▶gonads, ▶uterus, ▶ovary

Fallot's Tetralogy (TOF): Pulmonary stenosis, atrial septal defect, and right ventricular hypertrophy constitute the *trilogy*. The *tetralogy* = trilogy + the right shifting of the aorta overriding the interventricular septum and thus receiving both arterial and venous blood, the *pentalogy* = the tetralogy + open foramen oval or atrial septal defect. Mutations at JAG1 (20p12) ligand of NOTCH may cause TOF. Its prevalence is ~1/3,000 live birth. (See meaning of these terms under separate entries, ▶heart disease, ▶Alagille syndrome; Eldadah ZA et al 2001 Hum Mol Genet 10:163).

Fallout: The radiation emitted by isotopes released into the atmosphere by applying or testing nuclear weapons, by nuclear explosions and atomic power plants. ▶atomic radiations

False Allelism: A series of overlapping deficiencies may mimic an allelic series at a gene locus (see Fig. F3).

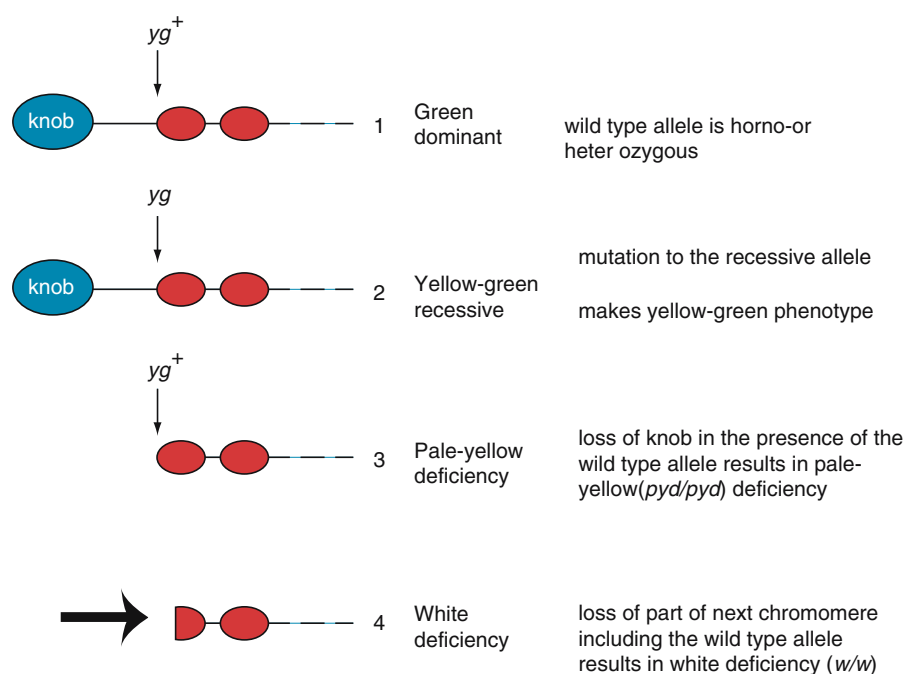

Figure F3. False allelism due to deficiencies

For an illustration, see the consequences of overlapping deficiencies observed at the tip of the short arm of chromosome 9 of maize. Note particularly that the *yg/pyd* heterozygotes are normal green demonstrating that in the *pyd* deficiency the wild type allele is present despite the phenotype of the homozygotes, and the allelism is only apparent. ► [allelism](#), ► [position effect](#)

False Discovery: Statistical procedures are available for the estimation of false negative and false positive information in scientific studies. (See Wakefield J 2007 *Amer J Hum Genet* 81:208).

F

False Negative: A result is a false negative when the test performed indicates the absence of a condition but in fact it is an incorrect observation. ► [false positive](#)

False Positive: A result is a false positive when it indicates the presence of a particular condition but the observation is incorrect. The determination of the rate depends on the prevalence of the condition. Example: on the basis of existing evidence the incidence of a disease in a particular population is 3/10,000 but the clinical test has an error rate of 6%. In this case, the probability that a person who is diagnosed positive actually has the condition is: $(3/10,000)/0.06 = 0.005$, i.e., 0.5% and that he/she represents a false positive case is $1 - 0.005 = 0.995$ or 99.5%. Hoffrage U et al 2000 (*Science* 290:2261) use the following illuminating example. Assume that 0.003 fraction (0.3%) of the population may be afflicted by colorectal cancer. The clinical laboratory test (blood in the feces) has a sensitivity of only 50% and the false positive rate is 3%. What then is the probability that a positive test is actually correct? According to the rate of incidence stated above (0.3%), out of 10,000 individuals 30 ($10,000 \times 0.003$) have colorectal cancer but because of the efficiency of the test (50% sensitivity) only 15 will be diagnosed as positive. Actually, of the 9970 ($10,000 - 30$), 300 individuals will test positive (3% of $10,000 = 300$). Thus the frequency of those actually afflicted among the positives is $15 / (15 + 300) \leq 0.047$. The correct estimation of the rate of false positives/negatives may be a question of life or death in medical or in forensic cases. ► [false negative](#), ► [sensitivity](#), ► [estimation of false positive](#), false negative and true discovery rates: Norris AW, Kahn CR et al 2006 *Proc Natl Acad Sci USA* 103:649.

Familial Adenomatous Polyposis: ► [FAP](#), ► [Gardner syndrome](#)

Familial Aggregation: A certain trait is more common in some families although the precise genetic control may not be known.

Familial Hypercholesterolemia (FHC, 19p13.2): FHC involves increase in low-density lipoprotein (LDL) bound cholesterol, as a consequence of which, at birth the homozygotes develop surface tumors filled with lipids (xanthomas) between the first two digits. Later on these plasias appear at the tendons, the cornea of the eye may also display gray lipid-containing little sacks, and by adulthood coronary heart disease is expected. The basic defect affects the cell membrane or its receptor of LDL. Under normal conditions, the LDL passes into the lysosomes where upon degradation, the liberated cholesterol feedback represses hydroxy-methylglutaryl Coenzyme A reductase (HMGR), an enzyme responsible for cholesterol biosynthesis. The fungal products lovastatin and compactin are inhibitors of this enzyme and may be considered for treatment of FHC. The LDL receptor with 18 exons codes for 13 polypeptides with homologies to different proteins of a large superfamily. The dominant gene located to human chromosome 19p13.2-p13.11 has various base substitutions, frameshift, and deletion mutations. Some of the deletions are apparently caused by unequal recombination in the Alu sequences of introns 4 and 5 or others and missplicing. The heterozygotes may show the same symptoms but less evidently. The serum cholesterol and low-density lipoprotein levels in the homozygotes may exceed up to twice or more than that of the normal (75–175 mg/100 mL). About 5% of the myocardial infarction patients are heterozygous for this condition. The prevalence of FHC homozygotes is in the 10^{-6} range and that of the heterozygotes is higher than 0.002. A cholesterol-lowering gene has been assigned to 13q. Animals transplanted with autologous but genetically engineered hepatocytes developed a persisting 30–50% decrease of serum cholesterol levels. FHC may be identified at birth. This condition may not result in obesity, high blood pressure, or some other common indicators of susceptibility to heart ailments. Using retroviral vectors carrying the LDL receptor gene, gene therapy has shown itself to be promising, although, improvement of the efficiency of the transformation technology is still desirable. FHC may involve haplo-insufficiency. Recessive mutations at 15q25-q26, 1p34-p32, and at 2p24 are also factors in FHC. An autosomal dominant hypercholesterolemia (HCHOLA3 or FH3) also at 1p34.1-p32 encodes also a subtilase family protein (PCSK9), which is related to the subtilisin kexin isoenzyme protease, controlling cholesterol homeostasis through sterol-regulatory element-binding proteins (Abifadel M et al 2003 *Nature Genet* 34:154). Other genetic factors may also contribute to the disease. ► [coronary heart disease](#), ► [lipoprotein](#), ► [LDL](#), ► [VLDL](#),

►HDL, ►lipids, ►cholesterols, ►statins, ►lovastatin, ►sphingolipidoses, ►unequal crossing over, ►Alu, ►genetic screening, ►missplicing, ►gene therapy, ►hypertension, ►haplo-insufficient, ►sitos-terolemia, ►Ezetimibe; Eden ER et al 2001 Am J Hum Genet 68:653.

Familial Hypertriglyceridemia: An autosomal dominant hyperlipoproteinemia leading to coronary heart disease. ►coronary heart disease, ►hyperlipoproteinemia

Familial Medullary Thyroid Carcinoma (FMTc): ►RET oncogene

Familial Trait: A familial trait appears in certain families; its cause may be hereditary or otherwise, e.g., deafness may result from about two dozen genetic conditions, but ear infection, diabetes of the mother, birth injury, or senescence may be responsible for it. ►congenital trait

Family: Offspring descended from a common mother (and father). In taxonomy it means a group of genera. ►nuclear family, ►gene family, ►protein families

Family Box: A group of RNA nucleotide triplets with identical nucleotides near the 5'-end but different at the 3'-end yet coding for the same amino acid. ►code genetic

Family History: The family history is an essential source for genetic counselors to determine recurrence risks. ►risk, ►genetic risk, ►recurrence risk, ►empirical risk, ►genetic counseling, ►pedigree analysis

Family of Genes: A similar set of genes (coding for basically similar polypeptides); they probably arose during evolution by successive duplications and modifications. ►duplication; detection of genes families arisen by duplication: <http://fgf.genomics.org.cn/>.

Family Planning: Family planning includes a variety of resources and considerations in determining family size, use of contraceptives, decisions regarding the genetic constitution, knowledge of genotypes, and family history. ►genetic counseling, ►ART, ►contraceptives, ►abortion medical

Family-Based Association Test (FBAT): A variation of the association mapping procedure, where case and control are selected within families rather than in the general population. ►association mapping, ►linkage disequilibrium; <http://www.biostat.harvard.edu/~fbat/default.html>.

FAN: A WD-repeat protein signaling to neutral sphingomyelinase activation. ►WD-40, ►sphingolipids

Fanconi Anemia (FA, aplastic anemia, Fanconi's syndrome, Fanconi's disease, Fanconi pancytopenia): A recessive genetic disorder assigned to nine complementation groups. The A complementation group (FANC-A/H) was localized to human chromosome 16q24.3, the FANC-C group to 9q22.3, the FANC-D to 3p25.3, FANCE (6p21-p22), FANCF (11p15), the FANC-G to 9p13, the same as XRCC9. The FANC-L complementation group (chromosome 2) encodes E3 ubiquitin ligase activity (PHF9) and it is essential for FANC-D2 (Meetei AR et al 2003 Nature Genet 35:165). FANCD1 is also called BRCA2. FANCF is a DNA helicase (BRIP1/BACH1) is a binding partner of the breast cancer suppressor gene BRCA1 (Levan O et al 2005 Nature Genet 37:931). The earlier assignment to chromosome 20q could not be confirmed by newer data. FA shows a wide range of symptoms: leukopenia (less than 5,000 leukocytes/mL blood), thrombocytopenia (reduced platelet count), pigmentation of the skin, and various malformations at different degrees of expression. The homozygous cells suffer high frequency chromosome defects. Both red and white blood cells appear normal. Generally, it is fatal by the teen years. The genetic basis is chromosomal instability and associated leukemia and other malignancies. FA is accompanied by genito-urinary anomalies, cystinuria, heart disease, dwarfism, skeletal problems, microcephaly (small head), deafness, etc. The genetic repair system appears to be defective in the complementation group C (FANC-C) protein (163-kDa), which seems to possess a nuclear localization signal. FancD2 after monoubiquitination—in association with other proteins—is involved in DNA repair (Matsushita N et al 2005 Mol Cell 19:841). Fanconi cells are hypersensitive to DNA cross-linking agents (mitomycin C, diepoxybutane) because of defects in DNA helicases involved in direct DNA repair or in bypassing the defect at replication (Niedemhofer LJ et al 2005 Cell 123:1191). The A complementation group-coded protein is cytoplasmic and its precise function is unclear, however, a general regulatory role is suspected. Because of apparent reverse mutations, there is evidence for somatic mosaicism. Gene therapy for the C protein appears promising, although does not remedy all the disease. The FANC-F (11p15) encodes a 347-amino acid protein, which is homologous to the prokaryotic RNA-binding protein, ROM. FA cells are very sensitive to bifunctional alkylating agents such as mitomycin C and diepoxybutane. FA involves a roughly three-fold increase in telomere defects and

a substantial increase in extra-telomeric and intra-chromosomal TTAGGG signals characteristic for telomeres.

PALB2 (partner and localizer of BRCA2) is a protein that interacts with BRCA2 and is important in determining the localization and stability of BRCA2 in the nucleus. If in HeLa cells RNAi reduces PALB2 expression, an increased sensitivity to mitomycin C (MMC) appears; FA is very sensitive to MMC (Xia B et al 2007 *Nature Genet* 39:159). Biallelic *PALB2* mutations cause a new subtype of Fanconi anemia, FA-N, and, similarly as biallelic *BRCA2* mutations, confer a high risk of childhood cancer (Reid S et al 2007 *Nature Genet* 39:162; Rahman N et al 2007 *Nature Genet* 39:165).
 ▶hemostasis, ▶platelet anomalies, ▶DNA repair, ▶stature in humans, ▶limb anomalies, ▶light-sensitivity diseases, ▶cancer, ▶Dubowitz syndrome, ▶Bloom syndrome, ▶breast cancer, ▶gene therapy, ▶XRCC, ▶ROM, ▶functionality of mutagens, ▶mitomycin C, ▶DEB, ▶PGD; de Winter JP et al 2000 *Am J Hum Genet* 67:1306; Medhurst AL et al 2001 *Hum Mol Genet* 10:423; Joenje H, Patel KJ 2001 *Nature Rev Genet* 2:446; Callén E et al 2002 *Hum Mol Genet* 11:439; D'Andrea AD, Grompe M 2003 *Nature Rev Cancer* 3:23; Meetei AR et al 2005 *Nature Genet* 37:958.

Fanconi-Bickel Syndrome: ▶glucose transporter (GLUT2)

Fanconi Renotubular Syndrome (15q15.3): An autosomal dominant, late onset kidney disease resulting in aminoaciduria and glycosuria; sometimes associated with bone problems. There are types with and without cystinosis. ▶aminoacidurias, ▶cystinosis, ▶glycosuria

FANCY (functional analysis by co-responses in yeast): An analytical method for the expression of genes with minimal effect, based on metabolite concentrations rather than metabolic flux. (See Raamsdonk L et al 2001 *Nature Biotechnol* 19:45).

FANTOM (functional annotation of microarrays): In 2005 the transcriptional landscape (control signals + transcripts) of the mouse genome included 181,047 transcriptional units (TU) with 1.32 start sites (5') for each 3' end. There were 7.3 TUs per transcriptional framework (TK) in the mouse genome. Overlapping transcription occurred on both strands of the DNA and separated by deserts without transcription. Since then, with FANTOM3, the coverage has increased. The mouse genome's ~22,000 genes seems to have more transcripts by an order of magnitude. The transcriptional forests include genomic regions transcribed by either strand without gaps. ▶microarray hybridization, ▶annotation, ▶gene expression,

▶interaction of gene products; FANTOM Consortium and RIKEN 2005 *Science* 309:1559; <http://fantom.gsc.riken.go.jp>.

FAO: Food and Agricultural Organization of the United Nations, Rome, Italy.

FAP: Familial adenomatous polyposis. The genetically controlled polyps in the colon may develop into colorectal cancer after additional somatic mutations.
 ▶polyp, ▶Gardner syndrome

FAP-1: A protein tyrosine phosphatase regulating the activity of the Fas cell surface receptor. ▶Fas

FAPY (formamidopyrimidine): A DNA base analog. It is removed from the DNA by the Fpg (a corresponding glycosylase). The lesion is repairable. ▶glycosylases; Ide H 2001 *Progr Nucleic Acid Res Mol Biol* 68:207.

FAR: A protein required for pheromone-induced cell cycle arrest at G1. ▶CKI, ▶cell cycle

Farber's Disease (8p22-p21.3): Farber's disease is concerned with a defect of the enzyme ceramidase. It manifests in early infancy as irritability, swelling of the joints, motor abnormalities, mental retardation, and early death. ▶sphingolipids, ▶ceramide

Farnesoid X Receptor (FXR): FXR is involved in the regulation of the bile acid metabolism. Chenodeoxycholic acid binds to FXR and subsequently, cholesterol 7 α -hydroxylase is down-regulated and bile acids are transported from the gut to the liver. Chenodeoxycholic acid indirectly regulates both its own proportion and that of bile acid. Other proteins playing key role in the synthesis of cholic acids from cholesterol are PPAR and LXR α . Oxysterol is the ligand for the latter in the liver. FXR and RXR (retinoid X receptor) jointly regulate cholesterol transport and bile acid synthesis. ▶PPAR, ▶cholesterol, ▶cholic acid, ▶sterol, ▶hepatocyte, ▶cholestasis; Kast HR et al 2001 *Mol Endocrinol* 15:1720; Zhang Y et al 2003 *J Biol Chem* 278:104.

Farnesyl Pyrophosphate: An intermediate in the synthesis of cholesterol. It plays a role in mediating binding of proteins to membranes. ▶prenylation

Farnesylation: ▶prenylation

Farsighted (hyperopia): In hyperopia, distant objects can be seen better than those nearer. ▶myopia

Far-Western Hybridization: A method for isolating genes, which encode interacting proteins. ▶Western blot, ▶two-hybrid method; Blanas MA, Rutter WJ 1992 *Science* 256:1014.

FAS (fatty acid synthase): A homodimeric enzyme with seven catalytic domains. This explains its multifunctional nature in fatty acid synthesis. FAS activity is

indispensable for embryo development and FAS^{+/-} progeny has reduced embryo viability. ▶ [fatty acids](#); Chirala SS et al 2003 Proc Natl Acad Sci USA 100:6358; mammalian fatty acid synthase structure: Maier T et al 2006 Science 311:1258; fungal fatty acid synthase structure: Jenni S et al 2006 Science 311:1263; yeast FAS crystal structure: Lomakin IB et al 2007 Cell 129:319.

Fas (fibroblast associated surface antigen, CD95, APO-1, 10q24.1): A member of the tumor necrosis factor and nerve growth factor receptor protein family that also includes Cd40, CD27, CD30, OX40, and SFV-2. FasL or the Fas ligand is encoded in human chromosome 1q23. FasL expression is induced by PMA. Fas plays a key role also in apoptosis and autoimmune disease by binding the FasL, a TNF protein. PMA and protein tyrosine kinase inhibitors (herbimycin, genistein) can rapidly induce FasL and cyclosporin inhibits its induction. The antibody to FasL is an immunoglobulin M (IgM), whereas the antibody to APO-1 is IgG3. Human Fas is a trans-membrane protein containing 325 amino acids. Fas is up-regulated by interferon- γ and tumor necrosis factor- α in human B and T cells. Fas signaling leads to apoptosis and it is triggered by cross-linking of Fas with Fas antibodies, and by cells expressing FasL. Fas-induced apoptosis is faster than that induced by TNF-receptor. Fas and TNF induce apoptosis in the cells of the immune system. Therefore, in cancer gene immunotherapy the Fas-L may be considered an appropriate target. Fas mediates two apoptotic pathways; one involves the FADD adaptor protein and pro-caspase-8. The other path is mediated by Daxx (death associated protein, human chromosome 6q21.3) and the activation of the JNK - MAPKKK through ASK1 (apoptosis signal-regulating kinase 1). FAS-FasL expression, however, does not lead to apoptosis under all circumstances. The DcR3 (decoy receptor, human chromosome 20q) may associate with the FasL and inactivate the apoptotic pathway in lung and colon cancer cells. Apo-3 is a CD120A homologous TNF/NGF receptor encoded at 1p36.3. ▶ [apoptosis](#), ▶ [caspase](#), ▶ [TNF](#), ▶ [autoimmune disease](#), ▶ [FADD](#), ▶ [FAP-1](#), ▶ [PMA](#), ▶ [cyclosporin](#), ▶ [immune system](#), ▶ [signal transduction](#), ▶ [JNK](#), ▶ [Lyell syndrome](#), ▶ [CD120](#), ▶ [NGF](#), ▶ [Canal-Smith syndrome](#), ▶ [survival factors](#), ▶ [TACE](#); Nagata S 1999 Annu Rev Genet 33:29.

Fasciation: An abnormal development resulting in a flat stem and club-shaped fruit with four rows of seeds rather than two in *Arabidopsis*. In zoology, it designates sheets of tissues. ▶ [CAF](#); Kaya H et al 2001 Cell 104:131, see Fig. F4.

Figure F4. Fasciation

Fascicle (fasciculus): A bundle of (nerve, muscle, etc.) fibers.

Fasciclins: Cell adhesion molecules of the immunoglobulin superfamily that are expressed in motor neurons. It acts with semaphorin and connectin/titin. ▶ [titin](#), ▶ [semaphorin](#); Cheng Y et al 2001 Cell 105:757; Wright JW, Copenhaver PF 2001 Dev Biol 234:24.

FasL: ▶ [FAS](#)

FAST (fiber-optic array scanning technology): FAT cytometry combined with laser-printing optics can excite 300,000 cells per sec and the emission collected on a wide field of view is 500 times faster than ADM with comparable sensitivity and specificity for the early detection of rare metastatic cells in blood. ▶ [ADM](#), ▶ [metastasis](#); Krivacic RT et al 2004 Proc Natl Acad Sci USA 101:10501.

Fast Blue: A fluorescent (neuronal) tracer dye.

Fast Component: The fast component of the nucleic acid reassociation reaction represents the repetitive sequences. ▶ [c₀t curve](#), ▶ [c₀t value](#)

Fast Green: A histochemical stain for basic proteins; it is generally used in combination with other stains, e.g., safranin or pyronin.

Fastlink: A computer program for genetic linkage analysis.

Fast Neutrons: Fast neutrons are particulate, ionizing radiations released at atomic nuclear fission. They are highly effective mutagens. ▶ [radiation](#), ▶ [physical mutagens](#); Hacker-Klom UB et al 2000 Radiat Res 154:667.

FASTA: A program used for sequence comparisons in DNA, RNA and proteins (Pearson WR 1991 Genomics 11:635). E-mail address ►fasta@ebi.ac.uk. (See BLAST; BLOSUM; FASTA programs: <http://www.ebi.ac.uk/fasta/>).

Fat: Fatty acid–glycerol ester. Its caloric value (9.3 kcal/g) is approximately 2.3 times that of carbohydrates and proteins. Oxidation of fats (rancidity) may result in the formation of mutagenic compounds in natural products. ►[fatty acids](#), ►[cholesterol](#), ►[triacylglycerols](#), ►[atherosclerosis](#)

F

Fat Body: An insect organ comparable to the liver of higher animals. It secretes antimicrobial peptides and its role is similar to that of the immune system of higher animals. Fat cells in the *Drosophila* head are the sites of expression of several male and female-specific genes (Fujii S, Amrein H 2002 EMBO J 21:53). These genes appear to modulate sex-specific neuronal activity in the brain. ►[sex determination](#), ►[oenocyte](#); Khush RS, Lemaitre B 2000 Trends Genet 16:442.

Fatal Familial Insomnia (insomnia-dysautonomia thalamic syndrome, FFI): An autosomal dominant degenerative disease of the thalamic nuclei (the basal; part of the brain involved in transmission of sensory impulses). It is a progressive insomnia that involves defects in the autonomous nervous system, speech defect, tremors, and seizures, and may eventually lead to death. The pathological symptoms may resemble those of the Creutzfeldt-Jakob disease (CJD) with the difference that the spongy transformation of the cells here is limited to the thalamus. In CJD, the mutation at amino acid position 129 results in a valine replacement, whereas in FFI there is a methionine at 129. In mice devoid of prion protein (PrP^C) because of mutation, the circadian activity rhythm, including the sleeping pattern is altered. Sporadic fatal insomnia also occurs because of somatic mutation. ►[prion](#), ►[encephalopathies](#), ►[Creutzfeldt-Jakob syndrome](#); Collins S et al 2001 J Clin Neurosci 8(5):387; Montagna P 2005 Sleep Med Rev 9:339.

Fate Map, Morphogenetic: The morphogenetic fate map indicates the positions in the blastoderm from which adult structures (legs, eyes, nerves, etc.) develop. In terms of basic principles, it has some resemblance to the genetic mapping of genes to chromosomes (both ideas were developed by A. Sturtevant). The procedure is generally as follows. The investigator constructs a diploid individual with an unstable chromosome with the wild type allele and the homologous chromosome carries the recessive gene whose expression is to be traced to developmental origin or control center. When the unstable chromosome is

lost, the critical recessive allele can display pseudodominance in the sector, which no longer carries the wild type allele. Most commonly the defective chromosome in *Drosophila* is an X-chromosome. Thus its loss generates a gynandromorphic sector as well. The association between the gynander sector and critical gene expression can be classified and the developmental origin of the function determined. The developmental distances calculated from fate mapping are expressed in *sturt* units; 1 *sturt* is the fate mapping quotient multiplied by 100. In other words, 1 *sturt* means that two cell clusters are different in 1% of the mosaics.

The results of a fate mapping experiment using an unstable ring X-chromosome and the *drop dead* mutation of *Drosophila* are shown here (see Table F3).

Table F3. Fate map morphogenetic

| Behavior ↓ | Number of individuals with the constitution indicated in the head cuticle and in the abdominal cuticle | | | |
|------------------|--|----|---------|----|
| | Head | | Abdomen | |
| | XX | XO | XX | XO |
| Normal | 91 | 8 | 54 | 28 |
| <i>drop-dead</i> | 6 | 72 | 23 | 51 |
| Total | 97 | 80 | 77 | 79 |

The homo- and hemizygous individuals walk in an uncoordinated manner and suddenly die about ten days after eclosion. (Abridged from Hotta Y, Benzer S Nature [Lond] 240:527).

The frequency of *drop-dead* gynander and non-gynander (normal) heads and abdomens can be calculated similarly to recombination frequencies.

Thus,

| HEAD | ABDOMEN |
|---------------------------------|-----------------------------------|
| $\frac{6 + 8}{97 + 80} = 0.079$ | $\frac{23 + 28}{77 + 79} = 0.327$ |

The fractions above indicate that the *drop-dead* phenotype is more closely associated with the head cuticle gynandromorphy than with that of the abdomen. It shows that this behavior is determined by the development of the head. Anatomical studies have shown perforations in the brain of the flies, confirming the conclusions of the fate-mapping experiments. Fate maps can be constructed also on the basis of the distribution of molecules in the developing embryo. According to the suggestion of

Sydney Brenner, the fate of individual cells may follow the “European plan,” i.e., the ancestry of a cell determines its developmental fate or according to the “American plan,” when interaction with neighboring cells is the most critical for its fate. The distinction between these alternatives may not always be possible. In a more complex organisms such as mice, fate mapping may be possible by injecting cells equipped with a site-directed recombination or mutation system. ►[gynandromorphs](#), ►[deletion mapping](#), ►[mapping](#), ►[physical mapping](#), ►[cell lineages](#), ►[site-directed mutation](#), ►[site-directed recombination](#); Inoue T et al 2000 Dev Biol 219:373.

Fatty Acids: Aliphatic carboxylic acids of long chain structure, parts of the membrane phospho- and glycolipids, cholesterol, and fats and oils (see Fig. F5). Saturated fatty acids are formic (1:0), acetic (2:0), propionic (3:0), butyric (4:0), lauric (12:0), myristic (14:0), palmitic (16:0), stearic (18:0), arachidic (20:0), behenic (22:0), and lignoseric (24:0) acids (Indicated within the parenthesis is the number of carbon atoms in the chain and after the colon the number of double bonds.). Unsaturated fatty acids are crotonic acid (4:12), palmitoleic (16:1), oleic (18:1), vaccenic (18:1), linoleic (18:2), linolenic (13:3), and arachidonic (20:4) acids. Triacylglycerides (glycerol esters with three fatty acids) are one of the major sources of energy in mammals, particularly during hibernation (when nearly all the energy comes from these compounds). Linoleate and linolenate are essential fatty acids for mammals. Lipids are complexes of fatty acids with phosphates, sterols, or sugars and have indispensable functions in the cellular membranes. Lipids associated with proteins have the role of transporting fatty acids.

Figure F5. General nomenclature of fatty acids

When fatty acid nodules are deposited on the inner walls of the blood vessels, it results in atherosclerosis, a major cause of heart disease. Fatty acid biosynthesis is important, not just from the viewpoint of human disease, but its knowledge may help in developing plant varieties for human consumption and also for the production of special raw material for industrial

purposes. FAS (fatty acid synthase) is a primary enzyme in fatty acid synthesis (see Fig. F6). Inhibition of FAS has antitumor effect. Fatty acids regulate in a positive and negative way the transcription of some genes (Duplus E et al 2000 J Biol Chem 275:30749). ►apolipoproteins, ►fat, ►triaglycerols, ►lipids, ►lipidoses, ►sphingolipids, ►sphingolipidoses, ►glucose, ►atherosclerosis, ►omega-3-fatty acids, ►FAS, ►acetyl-coenzyme A carboxylase; Black PN, DiRusso CC 2003 Microbiol Mol Biol Rev 67:454; White SW et al 2005 Annu Rev Biochem 74:791.

Favism: A hemolytic anemia caused by eating even extremely small quantities of *Vicia faba* (broad bean) or by inhaling its pollen. The initial reaction (headache, dizziness, nausea, chills, etc.) may occur within seconds and may be followed within a day by jaundice and blood in the urine. People who are deficient in glucose-6-phosphate dehydrogenase are susceptible to this condition. The light sensitivity of the skin after eating the seeds of *Fagopyrum vulgare* (buckwheat) is different; a photodynamic substance causes the latter. ►glucose-6-phosphate dehydrogenase deficiency, ►broad bean, ►buckwheat, ►vicine; Burbano C et al 1995 Plant Foods Hum Nutr 47 (3):265.

FB: ► hybrid dysgenesis

FBI Site (fold back inhibition): The transcript of *Tn10* transposase folds back a region (UGGUC) complementary to the modified Shine-Dalgarno sequence (AUCAG) and prevents ribosome binding and thus reduces transposition. ▶ *Tn10*

F-BOX: A cyclin F interacting protein domain recruiting various proteins for proteolytic degradation (ubiquitination). F-box proteins are involved with the cell cycle, developmental processes, the immune reactions, etc. ►SCF, ►ubiquitin, ►cyclin F, ►IκB, ►proteasome, ►glucose induction, ►dominance reversal, ►protein degradation; Strohmaier H et al 2001 Nature [Lond] 413:316.

FBS: Fetal bovine serum.

Fc: A crystallizable fragment of immunoglobulin containing the C end of the heavy chains. The Fc receptors are expressed in monocytes and macrophages and some other cells of the immune system.
▶antibody, ▶immune system, ▶FcRn

Figure F6. Oleate

FcγR: Receptors (I, II, III) of the immunoglobulin G antibody crystalline fragments. ►antibody, ►ITIM

FcεRI: Immunoglobulin IgE (Igε) crystallizable fragment high-affinity receptor on lymphocytes. It controls IgE-mediated antigen presentation and participates in several signaling pathways of the allergic responses. ►immunoglobulins, ►antibody, ►antigen presentation, ►allergy, ►asthma

FCP: ►transcription complex

F

FcRn: The crystallizable fragment receptor of the neonatal antibody. It transfers antibodies from the placenta to the fetus and secures the newborns' immunity right after birth. ►antibody, ►Fc

FCS (fluorescence correlation spectroscopy): FCS facilitates measuring diffusion constants of various proteins, the ratios of free and bound proteins, and protein-protein connections within the cell by microscopic examinations. ►FRAP, ►FRET

F-Distribution: This process is used for testing the significance of the difference between variances. The *F-test* is based on $F = (s_1)^2/(s_2)^2$ [s = standard deviation] that are computed from two different populations or samples. In this procedure, the null hypothesis is that the two samples are identical. However, if the variance ratio exceeds the values at the appropriate degrees of freedom, in the body of the table the differences are significant. (The name *F* is in honor of R.A. Fisher). (See Table F4).

fdNA (fossil DNA): DNA extracted from ancient bones or other relics. ►ancient DNA

F-Duction: Transfer of genes from donor to the recipient bacteria with the aid of an *F'* plasmid. (See Hanson RL, Rose C 1979 J Bacteriol 138:783).

Fear (Cdc fourteen, early anaphase release): FEAR regulates the mitotic exit network (MEN) with the joint action of the polo kinase Cdc5, the separase Esp1, kinetochore-associated protein Slk19, and Spo. ►Cdc14, ►MEN, ►polo, ►separins, ►kinetochore, ►SPO; Stegmeier F et al. 2002 Cell 108:207.

Feature: DNA chips.

Fechtner Syndrome: ►May-Hegglin anomaly, ►Alport disease

Fecundity: Reproductive ability determined by the quantity of gametes produced per time units. ►fertility, ►parity

Feedback Control: A late metabolite of a synthetic pathway regulates synthesis at earlier step(s). It can be negative or positive. Two specific sites on an early enzyme in the biosynthetic pathway mediate the

feedback control. One site serves for recognition of the substrate, the other site recognizes a later product in the biosynthetic path. When this late product (end product) accumulates because it is not utilized in proportion to its synthesis, it may combine with the early enzyme's feedback recognition site, resulting in a reversible conformational change and cessation or lowering the activity of this enzyme.

The feedback is an economy device of the cell; the production of a metabolite is slowed down in the absence of a need. Feedback systems may operate in a number of self-explanatory ways (see Fig. F7); for the compensating feedback a note is needed. E inhibits the path between C and D, but product F may alleviate the inhibition by reducing the activity of enzyme A. Thus, E never accumulates excessively.

If feedback-sensitivity is eliminated through mutation, the system may be overproducing the end product and this, in industrial or agronomic organisms, may be beneficial from the economic point of view.

These are the most common regulatory mechanisms in eukaryotes. In living cells, feedback systems of metabolic processes are interlinked (Brandsman O et al 2005 Science 310:496). ►regulation of enzyme activity, ►inhibition, ►repression, ►attenuation negative control, ►positive control, ►genetic networks; Savageau MA 1972 Curr Top Cell Reg 6:6.

Feeder Cell Layer: The feeder cell layer provides soluble nutrients to the cells layered above in animal and plant cell cultures.

Feed-Forward: A mechanism of interacting networks. Such a system operates in the brain where the effect of individual inputs is much increased by activation of additional neurons (see Fig. F8). From very simple processing units, extremely complex tasks can be performed. The essential requirement is that the first signal received must exceed a certain threshold level. Similar networking occurs in other biological systems too. ►genetic networks, ►feedback control, ►cascade; Penn BH et al 2004 Genes and Development 18:2348.

Feingold Syndrome (OED, MOED, MMT, 2p23-p24): A complex dominant anomaly including defects of the esophagus (food tube leading from the throat to stomach), eyes, digits, duodenum (small intestine), microcephaly, mental retardation, etc.). The basic defect is in the MYCN protooncogene, and most commonly is the truncation of the 3rd exon. ►MYC; van Bokhoven H et al 2005 Nature Genet 37:465.

Feline: Pertaining to cat or cats.

Table F4. F-Distribution at 5% and 1% probability levels. At significance the F value computed must exceed the numbers in the table at the intersection of the degrees of freedom (df_1 and df_2). (Condensed by permission from S. Koller, *Biochemisches Taschenbuck*, H. M. Rauen, ed. Springer-Verlag, Berlin.)

Figure F7. Feedback Control. The dashed lines indicate feedback loops. The solid lines stand for biosynthetic pathways. Redrawn after Savageau MA 1972 Curr. Top. Cell. Reg. 6:63

Figure F8. Feed forward

Female: The individual producing the larger usually non-motile gamete (egg). Its symbol is the “Venus mirror” or in pedigree charts, a circle (see Fig. F9). This is the most ancient symbol of genetics, used as far back as three thousand years ago on stone tablets in Asia Minor. ▶pedigree analysis, ▶Mars shield

Female Gametophyte: ▶gametophyte; <http://biocomp.cnb.uam.es/FEMME/>: database storing topological and geometrical features of medium resolution data solved by three-dimensional electronmicroscopy or high-resolution data simulated from atomic coordinates regardless of the resolution.

Femto-: 10^{-15} , e.g., femtomole.

FEN: ▶Rad27

Fenton Reaction: The Fenton reaction in the presence of (Fe^{2+}) iron and copper (Cu^{2+}) catalyzes the formation of $\text{OH}^\bullet + \text{H}_2\text{O}$ from H_2O_2 . ▶OH $^\bullet$, ▶ROS; Dikalova AE et al 2001 Proc Natl Acad Sci USA 98:13549.

FEO (familial expansile osteolysis): ▶Paget disease

Feral Population: Feral animals inhabit natural surroundings rather than living under laboratory or domesticated conditions (e.g., feral mice, feral *Drosophila*, feral pigs, etc.).

Fermentation: The energy-producing anaerobic degradation of carbohydrates to lactate or ethanol. Engineered mutations in the transcription factor TFIID, affecting TATA-binding protein of yeast (SPT15), and the TATA-binding protein associated factor (TAF25) substantially increase the fermentation capability and improve the efficiency of ethanol production (Alper H et al 2006 Science 314:1565).
▶transcription factors, ▶TAF

Fermentors: Precisely controlled mass culture vessels that may be used for industrial manufacturing of biological products (such as alcohol, antibiotics, proteins, etc.) by bacterial, fungal, animal or plant cells.

Ferns: Lower plants of the *Pterophyta* taxonomic group. They exist in two generations: sporophyte and gametophyte. The sporophytes develop roots, rhizomes, and leaves (see Fig. F10). These diploid plants form generally one type of sporangium on the lower surface of the leaves in aggregates called sori. Meiosis takes place within the sporangia and the released haploid products develop into generally heart-shaped gametophytes that (unlike in higher plants) form an independent organism on soil (thallus). When mature, on the lower surface of the gametophyte, eggs develop within the female archegonia and sperms in the male antheridia (6–10 cells). After a swimming spore fertilizes an egg, the diploid zygote grows on the gametophyte until the young sporophyte becomes ready (rooted) for independent existence. The gametophytes then die and the life cycles are repeated through the sporophytes. Ferns have a wide range of chromosome numbers of relatively large sizes, and many species are well suited for cytological analyses also because of the long haploid phase.

Figure F9. Female. Probably the earliest (~5000 years old) pedigree chart excavated in East Ur of Mesopotamia (From Amschler W 1935 J Hered 26:223)

Figure F10. Fern

F

Ferredoxin: An iron-containing protein involved in electron transport.

Ferritin: An ubiquitous, iron-storing cellular protein, and thus protects the cells from the toxic effects of this heavy metal. Also, it transports iron to the sites of need. Ferritin consists of 24 subunits around an iron core that are encoded in human chromosomes at 11q13 and 19q13.1. An intronless 242 precursor of a ferritin-like protein, encoded at 5q23.1, is targeted to the mitochondria. An iron-regulatory protein (IRP) and an iron-responsive element (IRE) CAGUGU determine the synthesis. Small molecules such as yohimbine, which blocks oxidation in the three-dimensional loop of guanines in the IRE in the mRNA, selectively inhibit the binding of the iron-regulatory protein (IRP) and increase ferritin synthesis in a cell-free system by ~40% (Tibodeau JD et al 2006 Proc Natl Acad Sci USA 103:253). Mutation in IRE results in dominant hyperferritinemia that may cause cataracts. Neuroferritinopathy (19q13.3) is a dominant disease of the basal ganglia caused by mutation in the gene encoding the light polypeptide of ferritin. In Alzheimer disease and Parkinson disease, ferritin increases as iron accumulates in the brain. ▶aconitase, ▶apoferritin, ▶eye diseases, ▶hyperferritinemia, ▶MYC, ▶ganglion, ▶Alzheimer disease, ▶Parkinson disease, ▶Hallervorden-Spatz syndrome, ▶yohimbine; Levi S et al 2001 J Biol Chem 276:24437; Curtis ARJ et al 2001 Nature Genet 28:350.

Ferroportin: An iron exporting protein regulated by hepcidin, a liver-secreted hormone (see Fig. F11). Decreased hepcidin causes iron overload in the tissues. Hepcidin overproduction causes hypoferrremia and anemia. Ferroportin-deficient mouse accumulates iron in macrophages, enterocytes, and hepatocytes. Human hemochromatosis may be

related to ferroportin malfunction (Donovan A et al 2005 Cell Metabolism 1:191). ▶ferritin, ▶ferroportin, ▶hemochromatosis, ▶IRE, ▶transferrin; Nemeth E et al 2004 Science 306:2090.

Figure F11. Mouse intestinal cells. Left: normal, Right: accumulated iron at periphery. (Redrawn after Donovan, A. et al.)

Fertilin: A sperm cell surface protein mediating membrane adhesion and sperm-egg fusion, migration from the uterus to the oviduct and binding to the zona pellucida. Fertilins belong to the ADAM family of proteins. The disintegrin domain binds to an integrin receptor of the egg plasma membrane during fertilization. ▶fertilization, ▶acrosomal process, ▶ADAM, ▶integrin, ▶CD9; Evans JP 2001 Bioessays 23:628.

Fertility: The production of viable offspring (gamete) per individual during the reproductive period. *Effective fertility* denotes the reproductive rate of individuals afflicted by a disease compared to that of normal, healthy individuals. The ability to form fertile hybrids has been generally used to define species. Different species are not expected to produce fertile hybrid progeny. This distinction has some problems because, e.g., the female hybrids of *Drosophila melanogaster* female and *D. simulans* male are viable and fertile, whereas the males of the same cross die at the larval/pupal stage of development. In the reciprocal crosses, *D. simulans* female x *D. melanogaster* male, most of the females also die as embryos, and only a few escape death. Human susceptibility to conception is about six days prior and including the day of ovulation. The raise in hormone level, particularly by the raised level of luteinizing hormone (LH), can clinically monitor ovulation. ▶fecundity, ▶fitness, ▶ovulation, ▶reproductive isolation, ▶species, ▶speciation, ▶infertility, ▶spermiogenesis, ▶transmission, ▶animal hormones, ▶parity

Fertility Factor: ▶F factor, ▶F plasmid

Fertility Inhibition: In fertility inhibition, the conjugal function of the bacterial cell is prevented by an inhibitory plasmid. ▶bacterial conjugation

Fertility Restorer Genes: Fertility restorer genes may assist to overcome cytoplasmically determined male sterility. Their ability to function also depends on the nature of the cytoplasm. In the S cytoplasm of maize, the restoration of fertility by *Rf3* is gametophytic, i.e., only 50% of the pollen is fertile in the heterozygous plants. In the T cytoplasm, the restoration of fertility is under sporophytic control and the heterozygotes for the two complementary fertility genes *Rf1* and *Rf2* produce nearly 100% viable pollen. The *Rf4* gene is a sporophytically expressed restorer in the C cytoplasm. Fertility restoration may also involve some additional minor factors. The cytoplasmic male sterility in these cytoplasms is controlled by mitochondrial plasmid genes. The fertility restorer genes have applied significance in the commercial production of hybrids. T (Texas) cytoplasmic male sterility is associated with susceptibility to *Helminthosporium* blight. However, the fertility restorer genes do not alleviate the symptoms of the disease, indicating that the latter is controlled by other means than the fertility. Cytoplasmic male sterility occurs in several plant species. ▶cytoplasmic male sterility, ▶pollen sterility, ▶mtDNA; Duvick DN 1965 *Advances Genet* 13:1; Liu F et al 2001 *Plant Cell* 13:1063; When L, Chase CD 1999 *Curr Genet* 35:521.

Fertilization: Fertilization involves the fusion of gametes of opposite sexuality (see Fig. F12). It may take place in different forms in hermaphroditic organisms such as the majority of plants and some of the animals: self-fertilization (autogamy), cross-fertilization (allogamy) or a mixture of the two. Only cross-fertilization can take place in the dioecious species of the majority of animals and a few plants. Fertilization results in the formation of zygotes and the restoration of the chromosome number to the 2n level. In many plant species, double fertilization takes place: the generative sperm fertilizes the egg and the vegetative sperm unites with the fused polar nuclei and as a result the triploid endosperm mother cell is generated. In some plant species, the sperm egg

nuclei fail to fuse and each contributes independently to the development of the embryo: *semigamy*. In some plants, the generative sperm and the vegetative sperm may come from a different pollen grain and thus *heterofertilization* results. If the genetic constitution of these two sperms is not identical, there is discordance (non-correspondence) between the genetic constitution of the embryo and the endosperm. Embryo development without fertilization is called *apomixis* in plants, and *parthenogenesis* in animals. In the majority of plants and animals, only the nucleus of the sperm enters the embryosac and egg, respectively, and the cytoplasmic genes are transmitted only through the female in these cases. Some plants also transmit cytoplasmic elements via the sperm during fertilization, resulting in complete biparental inheritance. In plants, only a limited number of pollen tubes grow down the pistil. In animals, more than a thousand sperms may attach to the surface of the egg but only one succeeds in fertilization, although normal ejaculates may contain 20 million sperms. In autogamous plants, the pollen count is much more limited than in the allogamous species. A large quantity of sperm is essential for normal fertilization of plants and animals. Human males with spermatozoa counts per ejaculate below 20,000 are generally sterile. The number of eggs per ovule in plants or number of ova released during ovulation in animals may also be only one or a few. *Drosophila* females can, for a prolonged period, store about 700 sperms (spermatozoa) from a single injection by the males and fertilization may take place gradually. After a second mating within a period of two weeks, the leftover sperms may be destroyed. Usually, fertilization takes place within the female body, in other cases fertilization is an external process or the eggs may be deposited in a pouch of the female where fertilization and further development follow. Even in cases of internal fertilization, a variable amount of time may elapse between pollination or copulation and the actual penetration and fusion of the sperm and egg nuclei.

During spermatogenesis the paternal genome is condensed about 6-fold and (98% in the mouse and ~85% in humans) histones are replaced by protamines. After penetration in the male pronucleus, the protamines are replaced by histones. In humans, it takes about an hour for the spermatozoa (~250/24 million) to travel the 6–7 inch route to the ovum. Within 24–48 hours after copulation, generally a single spermatozoon fertilizes the human ovum. In mammalian fertilization, the first step after the sperm reaches the follicular cells is the binding to the egg membrane. The sperm is “capacitated” to this task by changes in the sperm plasma membrane through the secreted products of the female (Wu C et al 2001 *J Biol Chem* 276:26962). The sperm then

Figure F12. Fertilization. The paternal and maternal pronuclei within an ascaris egg (left), The pronuclei have fused into a zygote nucleus, Ready for mitosis (right)

binds to the zona pellucida membrane. This membrane is made up of cross-linked network of glycoproteins ZP1, ZP2, ZP3. The latter are *sperm-receptors*. In mouse, the sp56 spermatid-specific protein recognizes ZP3. After this step, the protease and hyaluronidase content of the acrosome is released (*acrosomal reaction*), facilitating the penetration and passing through the zona pellucida. On the egg membrane, CD9 was essential and on the sperm Izumo globulin was required even after the penetration of the zona pellucida for fusion with the egg (Inoue N et al 2005 Nature [Lond] 434:235). After one sperm has fused with the egg plasma membrane, the so-called cortical reaction blocks the entry of other sperms as the zona hardens. For the prevention of polyspermy, the fertilized sea urchin egg releases hydrogen peroxide through the action of a protein encoded by gene *Udx1*. This peroxidase has a dual function, it converts oxygen into peroxide and later it breaks down the peroxide so the toxic substance would not hurt the zygote (Wong JL et al 2004 Dev Cell 7:801). The mitochondria of the fertilizing sperm are generally destroyed by ubiquitination and other components, not required for the following events, are also degraded.

The *cortical reaction* is mediated by an increase in cytosolic calcium through an inositol-phospholipid signaling pathway. On the surface of the egg coat, microvilli develop in such a manner that they firmly hold the sperm. After fertilization, the egg becomes a zygote and the process is completed when the male and female pronuclei fuse into a *zygote nucleus*. The sperm donates to the egg not just the male pronucleus, containing a complete haploid set of chromosomes, but also the *centriole* that is not available in the egg. The centrioles are then associated with the female *centrosome* and a *mitotic organizing center* is initiated. Transcription factors such as STAT4, perinuclear theca protein (PT32), and phospholipase C ζ are released. Paternally derived proteins, mRNAs, and microRNAs also seem to be transferred to the ovum. Mitotic divisions and embryogenesis follow these events. The mammalian zygote is formed through the fusion of the highly compacted nucleoprotamine-containing sperm chromatin, and the metaphase II-arrested chromosomes of the oocyte. Remodeling of the chromatin of the two gametic chromosome sets into a diploid genome takes place following fertilization. The sperm genome is much more highly methylated than that of the egg. Within 7–8 hours after fertilization, the paternal genome is significantly de-methylated. Demethylation of the maternal genome follows after the second division of the zygote. The global demethylation however, exempts the imprinted genes. ▶*apomixis*, ▶*androgenesis*, ▶*gametogenesis*, ▶*embryogenesis*, ▶*selective*

FES: Feline fibrosarcoma viral oncogene (*fes*). It is in the long arm of human chromosome 15, and in most cancer cells it is translocated to chromosome 17, causing leukemia. Its protein product is a protein tyrosine kinase. ▶*ABL*, ▶*ERBA*, ▶*PTK*

FET: Genes involved in iron uptake and metabolism

Fetal Alcohol Syndrome: ▶*alcoholism*

Fetal Hydantoin Syndrome: ▶*epoxide hydrolase 1*

Fetal Tissue Research: ▶*embryo research*, ▶*stem cells*

Fetoprotein- α (AFP): AFP is expressed in the embryonic yolk and liver of mammals. Serum albumin and α -fetoprotein genes are linked at about 15 kb apart, and each encodes approximately 580 amino acids. The two proteins are immunologically cross-reactive and display about 35% homology. The rate of transcription of AFP drops four orders of magnitude after birth in the majority of mouse strains. BALB/cJ is an exception because in these animals the adult serum contains 5–20-fold higher levels of AFP. This anomaly was caused by a recessive transcription factor mutation, *Afr1^b*, unlinked to the AFP coding gene. *Afr1^a*, the wild type allele, is a suppressor of *Afp* and its 1st intron encodes—in chromosome 15—a putative zinc finger homeobox protein (ZHX), derived from a murine endogenous retrovirus. This repressor affects also gene *H19* involved in imprinting (Perincheri S et al 2005 Proc Natl Acad Sci USA 102:396).

Regulatory sequences are positioned within 150 bp 5' and there are also enhancers 6.5, 5, and 2.5 kbp upstream from the transcription initiation site. The gene (human chromosome 4q11-q22) is a classical example for tissue-specific and developmental regulation. ▶*MSAFP*, ▶*imprinting*; Mizejewski GJ 2001 Exp Biol Med 226:377.

Fetoscopy: The viewing (or possibly sampling of tissues) of the fetus within the womb to detect probable developmental or biochemical anomalies in case there is a good indication for them. Fetoscopy may involve up to 10% risk to the fetus, and if other less invasive (e.g., sonography) methods are available, it should be avoided. It is also used for the

detection of fetal heartbeat. ►[prenatal diagnosis](#), ►[amniocentesis](#), ►[sonography](#), ►[echocardiography](#)

Fetus (foetus): The unborn child of viviparous animals at the stages following the embryonal state after substantial differentiation has been completed. In humans, the fetal period is from nine weeks after conception to birth. ►[vivipary](#), ►[embryo](#), ►[embryo research](#)

Feulgen: A microtechnical staining method detecting deoxyribose and thus, DNA, in warm acid-hydrolyzed tissue followed by staining with leucobasic fuchsin. ►[stains](#)

FeV (feline leukemia virus): A retrovirus causing immunodeficiency in cats. Its receptor is CD134 (in contrast to HIV, which requires CD4). Productive infection also requires CXCR4. ►[acquired immunodeficiency syndrome](#), ►[CD4](#), ►[CD134](#), ►[CXCR](#); Shimojima M et al 2004 Science 303:1192.

Fever, Periodic: A periodic fever is observed in different diseases. The familial Mediterranean fever appears recessive (16p13) and may be associated with amyloidosis. The dominant form (12p13.2) is based on a defect in the tumor necrosis factor receptor. The recessive Dutch type (12q24) is a mevalonate kinase deficiency. ►[Fabry disease](#), ►[hyperimmunoglobulinemia D](#), ►[amyloidosis](#), ►[fibroblast growth factor](#); Aksentijevich I et al 2001 Am J Hum Genet 69:301.

Feverfew (*Chrysanthemum parthenium*/*Tenacetum parthenium*): An old herbal medicinal plant used against headache (see Fig. [F13](#)). It contains a sesquiterpene lactone parthenolide (C₁₅H₂₀O₃),

Figure F13. Feverfew

which effectively and selectively induces apoptosis in myelogenous and chronic leukemia stem cells. The molecular basis of action is the inhibition of NF-κB, the pro-apoptotic activation of p53 tumor suppressor, and the increase in reactive oxygen species (ROS). It inhibits thromboxanes and leukotrienes. ►[leukemia](#), ►[NF-κB](#), ►[p53](#), ►[ROS](#), ►[leukotrienes](#), ►[thromboxanes](#); Guzman ML, Jordan CT 2005 Expert Opin Biol Ther 5:1147.

FFA (focus forming activity): A 170-kDa protein (a RecQ helicase) is required for the association of replication protein A (RPA) with the focus forming units of replication (the 100 to 1000 DNA loops [replication bubbles], centers of replication along the euchromatic chromosome). (See Chen C-Y et al 2001 J Cell Biol 152:985; ►[replication bubble](#), ►[replication protein A](#), ►[Werner syndrome](#))

Ffh: A GTPase of the signal recognition particle of bacteria. ►[FtsY](#), ►[SRP](#)

FGENE: A program based on linear discriminant function for the identification of splice sites, 5'[-coding, internal exons, and 3'-coding sequences with high accuracy. ►[GENESCAN](#), ►[Genie](#), ►[MZEF](#); Solovyev VV et al 1995 Proc Int Conf Intell Syst Mol Biol 3:367.

FGF (fibroblast growth factor, 22 human genes): FGF is also an FGF-related oncogene (see Fig. [F14](#)). FGF-B (the bovine form, FGF2) was assigned to human chromosome 4q25. FGF-6 and FGF-4 (human chromosome 2q13) bear similarity to the NT2 oncogene. FGF may also have a critical role in organ differentiation. The fibroblast growth factor receptor (FGFR) has a cytoplasmic tyrosine kinase domain. Mutations in FGFR1 and FGFR2 have been associated with the Crouzon, Jackson-Weiss, Pfeiffer, and Beare-Stevenson syndromes. FGFR3 is involved in hypochondroplasia. Defects in FGFR1c may lead to diabetes type II. FGF1 (in human chromosome 5q31) is implicated in angiogenesis. FGF3 (11q13) is homologous to a mouse mammary carcinoma gene, FGF5 (4q21). FGF7 is a keratocyte growth factor. FGF8 is an androgen-induced growth factor and it mediates heart development (Ilagan R et al 2006 Development 133:2435). FGF9 is the glia-activating factor. FGF10 is essential for limb and lung development in mice. The activation of FGF requires appropriate transmembrane receptors that are activated by oligomerization in the presence of heparin-like molecules. The human genome contains 30, and *Drosophila* and *Caenorhabditis*, each show two FGFs. ►[growth factors](#), ►[signal transduction](#), ►[HST oncogene](#), ►[INT oncogene](#), ►[organizer](#), ►[tyrosine kinase](#), ►[achondroplasia](#), ►[hypochondroplasia](#), ►[thanatophoric dysplasia](#), ►[Jackson-Weiss](#)

Figure F14. FGF. In *Drosophila*, the *stumps* gene is required for the FGF-dependent migration of the tracheal and mesodermal migration in the embryo. The tracheal phenotype of the wild type (Left) and the *sms* mutant (Right) is shown at stage 15/16. (Courtesy M. A. Krasnow, see Genetics 152:307)

syndrome, ▶Pfeiffer syndrome, ▶Apert syndrome, ▶Crouzon syndrome, ▶Beare-Stevenson syndrome, ▶hypochondroplasia, ▶craniosynostosis, ▶angiogenesis, ▶glial cell, ▶keratosis, ▶heparin, ▶embryogenesis, ▶diabetes, ▶sex reversal, ▶LADD syndrome; Dubrulle J et al 2001 Cell 106:219; Vasiliauskas D, Stern CD 2001 Cell 106:133; Ahmad SM, Baker BS 2002 Cell 109:651; Sun X et al 2002 Nature [Lond] 418:801.

FGFR (fibroblast growth factor receptor): ▶FGF

FGR Oncogene: The FGR oncogene located to human chromosome 1p36.2-p36.1 encodes an actin-like sequence and a tyrosine kinase sequence that is homologous to the viral gene *fgr*. Mouse involved with reduced FGR1c receptor is prone to inflammatory response upon aging (Aoshiba K, Nagai A 2007 FEBS Lett 581:3512).

FHA (forkhead-associated domain): FHA interacts with phosphorylated molecules. It has a role in DNA damage signaling and CHK2-dependent tumor suppression and various developmental processes. ▶CHK2; Durocher D et al 2000 Mol Cell 6:1169.

FHIT: ▶renal cell carcinoma

fi Plasmid: The fi plasmid inhibits the fertility factor of bacteria. ▶F element, ▶F plasmid

Fialouridine (FIAU, [1-(2-deoxy-2-fluoro-D-arabinofuranosyl)-5-iodouracil]): An inhibitor of DNA polymerase γ , responsible for the synthesis of mtDNA. ▶DNA polymerases, ▶mtDNA

Fibonacci Series: In the Fibonacci series, the denominator doubles in each subsequent term while the numerator becomes the sum of its two preceding numerators, e.g., 1, 1/2, 2/4, 3/8, 5/16, 8/32, 13/64, and so on. This has applications in predicting the proportion of heterozygotes in an interbreeding population at each loci that were heterozygous initially ($H = 0.5$). Thus six generations of sib mating leave 13/64, i.e., ~20.31% heterozygous for each

originally heterozygous loci, and its complement ($100 - 20.31$) 79.69% will be expected to become homozygous. The phyllotaxis of plant leaves may follow Fibonacci series. Various developmental patterns may represent Fibonacci patterns. ▶phyllotaxis; Li C et al 2005 Science 309:909.

Fibrillarin: A fibrillar protein present in many snRNPs within the nucleolus; it is also an autoantigen. ▶snRNP, ▶autoantigen, ▶snoRNA; Snaar S et al 2000 J Cell Biol 151:653.

Fibrillin: A large cystein-rich glycoprotein molecule involved in the formation of microfibrils along with elastin. The fibrillin microfibrils are encoded by two genes in human chromosomes 15q-21.1 (FBN1) and 5q23-q31 (FBN2), respectively. Mutation of *Fbn-2* in mouse may cause syndactyly. ▶Marfan syndrome, ▶Marfanoid syndrome, ▶aneurysm aortic, ▶arachnodactyly, ▶syndactyly; Chaudhry SS et al 2001 Hum Mol Genet 10:835.

Fibrin: An insoluble protein formed during blood clotting from fibrinogen (4q28) by the action of thrombin. ▶thrombin, ▶fibrinogen, ▶fibrin-stabilizing factor deficiency

Fibrin-Stabilizing Factor Deficiency: The fibrin-stabilizing factor deficiency is controlled by X-chromosomal recessive factors causing a deficiency of blood coagulation factor XIII that normally stabilizes clot formation by cross-linking fibrin. Wounds heal more slowly, the umbilicus bleeds days after birth, bleeding may occur inside the joints (hemarthrosis), in the genito-urinary tract (hematuria), abortion with bleeding, intracranial bleeding (generally lethal) may occur. Apparently, the condition is caused not by the lack of factor XIII, but rather by the formation of defective molecules. ▶afibrinogenemia, ▶defibrinogenemia, ▶antihemophilic factors, ▶hemophilia, ▶von Willebrand disease

Fibrinogen: ▶fibrin

Fibrinolysin: A serine endopeptidase. ▶plasmin

Fibroblast: The elongated connective tissue cells (give rise to tendons and other supportive structures), which may produce collagen; they are relatively easy to culture in vitro (see Fig. F15). ►collagen

Figure F15. A fibroblast cell. They may occur in many shapes

Fibroblast Growth Factors (FGF): Stimulates blood vessel growth. Genes were located in several human chromosomes: FGF1 at 5q31, FGF2, 4q25-q27, FGF3 at 11q13, FGF4 at 11q13, FGF6 at 12p13, FGF7 at 15q15-q21.1, FGF9 at 13q11-q12, FGF10 at 5p13-p12, FGF11 at 17q21, FGF12 at 3q28, FGF13 at Xq26.3, FGF14 at 13q34, and FGF23 at 12p13.3. The *FGF receptors* (FGFR) proteins have an extracellular immunoglobulin-like domain and the cytoplasmic domains are tyrosine kinases. FGFR1 in chromosome 8p112-p11.1 co-segregates with the Pfeiffer syndrome. FGFR2 in chromosome 10q26 seems to be associated with the Crouzon syndrome (identical with the Jackson-Weiss syndrome). FGFR3 (4p16.3) deficiency accounts for achondroplasia, hypochondroplasia, and thanatophoric dysplasia. ►signal transduction, ►angiogenesis, ►achondroplasia, ►Crouzon syndrome, ►Pfeiffer syndrome, ►achondroplasia, ►hypochondroplasia, ►thanatophoric dysplasia, ►RTK, ►craniosynostosis

Fibrochondrogenesis: A rare autosomal lethal recessive malformation of the hip cartilage (rhizomelic chondrodysplasia).

Fibrodysplasia Ossificans Progressiva (FOP): A rare autosomal (4q27-q31) dominant progressive ectopic (malplaced) bone formation. The basic defect appears to be the inappropriate production of bone morphogenetic protein (BMP-4) by the lymphocytes. Sometimes FOP is accompanied by short fingers, anomalous vertebrae, deafness, baldness, and mental retardation. The activin A type I receptor of the bone morphogenetic protein, which causes FOP, has been mapped to 2q23-q24 (Shore EM et al 2006 *Nature Genet* 38:525). ►exostosis, ►metachondromatosis, ►bone morphogenetic protein, ►activin

Fibromatosis, Juvenile Hyaline (JHF, 4q21): and infantile systemic hyalinosis (ISH) are apparently allelic recessive conditions caused mutations in the capillary morphogenesis protein 2. The basic defect appears in the assembly of the basement membrane. Subcutaneous skin nodules, gingival hypertrophy, joint contractures, and hyaline deposition appear during the first few years of life. The symptoms in ISH appear usually at birth and the condition may

improve later. ►hyaline, ►basement membrane; Hanks S et al 2003 *Am J Hum Genet* 73:791.

Fibromyalgia: An apparently non-hereditary, non-progressive, not life-threatening condition of general tiredness and pain in muscles, tendons, and ligaments. Its cause of it is not entirely clear and no sure medication is available. Improving sleeping habits and exercise may help.

Fibroin: Silk protein. ►silk fibroin, ►silk worm; Hayashi CY, Lewis RV 2001 *Bioessays* 23:750.

Fibronectin: Dimeric (~220-kDa monomers, 2q24) extracellular matrix glycoprotein involved in development, morphogenesis, wound healing, anti-tumorigenesis (anti-metastasis), and suppressing angiogenesis. Fibronectin is required, however, for the metastasis of melanoma. Fibronectin binds to the Fc fragment of immunoglobulins, particularly to IgG. It may play a role in autoimmune diseases, pulmonary fibrosis (formation of fibrous tissues), and glomerulonephritis. Fibronectin deficiency is characteristic for type X Ehlers-Danlos syndrome. ►integrin, ►L1, ►RGD, ►immunoglobulins, ►autoimmune disease, ►glomerulonephritis, ►CAM, ►metastasis, ►angiogenesis, ►melanoma, ►Ehlers-Danlos syndrome; Yi M, Ruoslahti E 2001 *Proc Natl Acad Sci USA* 98:620; Sakai T et al 2003 *Nature [Lond]* 423:866.

Fibulin-5 (DANCE): An integrin ligand required for tissue elasticity. Fibulin-1, component of the extracellular matrix, rescues gonad morphogenesis in *Caenorhabditis* in the absence of two secreted metalloproteases (Hesselson D et al 2004 *Current Biol* 14:2005). ►integrin; Nakamura T et al 2002 *Nature [Lond]* 415:171.

Ficoll: A synthetic polymer of sucrose. It is used in the Denhardt reagent and in gel-loading buffers to increase the density of the sample applied to the wells in the agarose gel. ►gel electrophoresis, ►Denhardt reagent

Fidelity in Gene Conversion: The converted allele is identical to the converter. ►gene conversion

Fidelity of Replication: ►error in replication

Fidelity of Transcription: The fidelity of transcription may be mediated by the very low level 3'→5' ribonuclease activity of eukaryotic RNA polymerase II. ►RNA polymerase, ►error in transcription

Fidelity of translation: In the fidelity of translation, errors occur approximately in the 10⁻⁴ range. ►ambiguity in translation

Fidelity Paradox: *E. coli* DNA polymerase II makes 3–5-fold more incorporation errors at the AT-rich sequences than at the GC-rich sequences. The

polymerization activity of the same enzyme is 2–6-fold higher at the AT sequences. Normally, one would expect higher proof-reading by the 3'-exonuclease function in the less stable AT-rich tracts. It seems that the increased polymerization activity prevents proof-reading efficiency. ►[proofreading](#); Wang Z et al 2002 J Biol Chem 277:4446.

Fiducial Limits: Synonymous with confidence limits and confidence intervals. ►[confidence intervals](#)

F

Field-Flow Fractionation (FFF): A size-based fractionation of large molecules through thin channels. From its retention time hydrodynamic properties are estimated.

Field-Inversion Gel Electrophoresis: ►[FIGE](#)

FIG (*Ficus carica*): The genus includes about 2,000 species with $x = 13$, and the majority of them are diploid ($2n = 26$), although triploid and tetraploid forms are also known. It is a freeze-sensitive fruit tree with the amount of Ca^{2+} in the fruits about three times higher than those in fruits in other plant species.

FIGE: Field-inversion (10–0.02 Hertz) gel electrophoresis; it has been used to separate DNAs in the range of 15–700 kb, similar in size to the genetic material in the chromosomes of lower eukaryotes. Its advantage over pulsed-field gels is that the runs are straight. ►[pulsed field electrophoresis](#), ►[Hertz](#)

Filaggrin: A protein controlling terminal differentiation of the epidermis. ►[eczema](#), ►[ichthyosis](#)

Filament: Myosin and actin fibers in animal tissue. The microfilaments (6 nanometers in diameter), the intermediate filaments (10 nm), and the microtubules (23 nm) form the structural mesh of the cytoplasm. The intermediate filaments (IF) carry out a variety of functions, depending on the ca. 50 genes that encode them in human cells. Defects or deficiency of the IF may lead to genetic lesions of the epidermal keratin and thus, blistering. Defects in the neurofilaments may account for some cases of amyotrophic lateral sclerosis, muscular atrophy, and sensory neuropathy. ►[intermediate filaments](#), ►[cytoskeleton](#), ►[keratosis](#), ►[epidermolysis](#), ►[amyotrophic lateral sclerosis](#), ►[neuropathy](#), ►[corneal dystrophy](#), ►[monilethrix](#), ►[desmosome](#), ►[plakin](#), ►[pachyonychia](#), ►[stamen](#)

Filamentation: Bacteria may grow as long filaments during SOS repair. ►[SOS repair](#)

Filamentous Growth: ►[pseudohypha](#)

Filamentous Phages: Filamentous phages frequently used as cloning vectors in genetic engineering are M13 (6408 b), f1 and fd (6408 b) single-stranded DNA phages. The f1 phage is $8,500 \text{ \AA} \times 60\text{--}70 \text{ \AA}$ in size. They have many advantages; among others they are easy to purify, have little constraint on packaging, and accept relatively large inserts (up 5 times their original DNA). M13 and its derivatives are generally used in DNA sequencing by the Sanger method. They contain multiple cloning sites within a truncated *E. coli lacZ gene*. The vectors containing a successful insertion produce white plaques, whereas the plaques of the phage without the insertion are blue on X-gal medium because *LacZ* is not interrupted and thus expressed. The f1 phage—unlike the lytic ones—does not destroy the host bacterium in order to exit. The phage encodes and excretes protein pIV that is used to create a tightly gated channel in the bacterial cell membrane. Through this gate, the single-stranded phage genome emerges dressed in the coat protein and fully formed without disruption of the bacterial host. ►[bacteriophages](#), ►[phagemids](#), ►[DNA sequencing Sanger](#), ►[cloning vector](#), ►[cloning site](#), ►[Xgal](#), ►[lysis](#), ►[pUC vectors](#), ►[phage display](#); Horiuchi K 1997 Genes Cells 2(7):425; Marvin DA 1998 Curr Opin Struct Biol 8(2):150; Cabilly S 1998 Methods Mol Biol 87:129; Larocca D et al 1999 FASEB J 13 [6]:727.

Filamins: Diverse extended dimeric proteins that cross-link actins involved in membrane receptors and signaling molecules. Filamin-A is a 280-kDa protein encoded at Xq28 and its defect is responsible for heterotopia. Filamin-B (encoded at 3p14.3) is similar in size to Filamin-A and it is bound to it. Filamin-C is encoded at 7q32-q35. The filamin defects may be the cause of several human maladies such as Alzheimer disease, Graves disease, platelet abnormalities, von Willebrand disease, epilepsy, malformations, etc. (See terms at separate entries; Stossel TP et al 2001 Nature Rev Mol Cell Biol 2:138; Robertson SP et al 2003 Nature Genet 33:487).

File: A unit of related records in the computer.

File Server: A file server permits additional users to share files and application programs on a computer.

Filial: Filial refers to offspring (generation). ►[F₁](#)

Filler DNA: Nucleotides inserted at the junctions and excision sites of transposable elements and genetic vector-carried sequences or at sites of non-homologous end-joining. ►[transposable elements](#), ►[insertion elements](#), ►[NHEJ](#)

Filopodium: A slender amoeba-like cell structure involved in movement and/or growth. Also, the spikes on the growth cones or on cell surface (see Figs. F17 and F18). Myo10 myosin motor protein, localized to the tip of cell-surface filopodia, appears to be responsible for their formation (Bohil AB et al 2006 Proc Natl Acad Sci USA 103:12411). ▶[growth cone](#), ▶[lamellipodium](#); Wood W, Martin P 2002 Int J Biochem & Cell Biol 34:726.

Filter Enrichment: ▶[filtration enrichment](#)

Filter Hybridization: In this process, one of the nucleic acid components is immobilized on a (nitrocellulose) filter and the other labeled, liquid component is allowed to anneal with it. ▶[DNA hybridization](#)

Filter Mating: In filter mating, the bacterial cells at high density conjugate on the surface of a filter.

Filter Sterilization: The removal of microbes from liquids without heating by the use of 0.45 or 0.2 μm pore size membranes. ▶[sterilization](#), ▶[autoclaving](#)

Filterable Agent: Filterable agent was the name of tobacco mosaic virus, and other viruses, before their nature was revealed. The name comes from the fact that they passed through bacterial filters and retained their biological activity. ▶[TMV](#)

Filtering Data: Filtering data extracts subgraphs of representative links in a complex dataset such as encountered in protein networks, metabolic correlations, etc.

Filtering Nucleotide and Protein Sequences: The removal of low-complexity (repetitive) sequences

that might inflate the homology between/among macromolecules and would introduce errors in conclusions concerning common ancestry. Some of the BLAST search programs automatically filter the data. ▶[BLAST](#)

Filtration Enrichment: A method of selective isolation of all types of nutritional mutants used primarily in fungi. The wild type mycelia grow on minimal media but cells that have any type of special nutritional requirement most likely will not. A filter will retain the wild type mycelia while the non-growing spores pass through and are thus separated from the bulk. This mutant-enriched filtrate can then be analyzed for the specific nutritional requirement. ▶[mutant isolation](#), ▶[mutation detection](#); Fries N 1947 Nature [Lond]:159:199; Woodward VW et al 1954 Proc Natl Acad Sci USA 55:872.

Fimbriae: Flagellum-like appendages in the surface of bacteria that help, e.g., *Salmonella* in adhering to and infecting intestinal epithelia. ▶[pilus](#), ▶[E. coli](#); Shembri MA, Klemm P 2001 EMBO J 20:3074; Vetsch M et al 2004 Nature [Lond] 431:329.

Fimbrin: An actin filament bundling protein, encoded by gene *SAC6* in yeast. Its overproduction may be lethal. ▶[actin](#), ▶[ankyrin](#), ▶[spectrin](#); Klein MG et al 2004 Structure 12:999.

Finches (Galapagos finches, Darwin's finches): 14 species of small birds of South America, showing substantial variations primarily in the shape and size of the beak depending on their terrestrial or tree habitat and life style, yet Darwin correctly recognized their common descent (see Fig. F19). A calmodulin-dependent pathway regulates the elongated beak morphology (Abzhanov A et al 2006 Nature [Lond] 442:563), whereas bone morphogenetic protein has major role in the development of sturdy beaks. ▶[calmodulin](#); more about Darwin's finches: Grant PR, Grant R 2005 Current Biol 15(16):R614.

Figure F19. Finches

Fine Structure Mapping: Genetic mapping of the position of mutations (alleles) within a gene locus.

►allele, ►locus

Fine Structure of Genes: Initially, the fine structure of genes meant recombinational analysis at high resolution in large populations, frequently based on selective identification of the recombinants that permitted mapping of the sites of different alleles within the locus. The ultimate fine structure analysis uses DNA (RNA) sequencing of cloned genes.

►mapping genetic, ►physical mapping, ►deletion mapping

F

Finger: ►Zinc finger, ►Ring finger

Fingerprint Clone Contig: Clones are arranged in contigs on the basis of fingerprints generated by restriction enzyme-digests. (See Barillot E et al 1991 Proc Natl Acad Sci USA 88:3917).

Fingerprinting of Macromolecules: Two-dimensional separation (by chromatography and/or electrophoresis) of digests of proteins or electrophoretic separation pattern of restriction enzyme digests of DNA for the purpose of characterization. ►chromatography, ►electrophoresis, ►RNA fingerprinting, ►DNA fingerprinting, ►motifs; Ingram VM 1956 Nature [Lond] 178:792; Baglioni C 1961 Biochim Biophys Acta 48:392; Tao Q et al 2001 Genetics 158:1711, <http://www.bioinf.man.ac.uk/dbbrowser/PRINTS/printsman.html>.

Fingerprints: Fingerprints are analyzed by forensic and police investigations to determine personal identity through dactyloscopy, a branch of dermatoglyphics. Ink is applied to the fingertips and impressions are made on paper. There may be a slight difference between the fingerprint pattern of the corresponding left and right hand fingers yet the overall pattern is characteristic for an individual. Fingerprints are determined by a relatively small number of genes, yet each person has a unique fingerprint pattern. There is about 0.43 correlation between paternal and offspring fingerprints. The pattern is determined by the end of the third month of the fetus. The forensic value of fingerprints depends on quality of the prints collected.

Environmental effects have very little influence upon fingerprints. Even if the epidermis is destroyed, regrowth reestablishes the original pattern. Toe and palm prints may provide additional confirmatory evidence for identity. There are three major types of fingerprint *loops*, *whorls*, and *arches* with 65, 30, and 5% of the fingerprints falling into these broad categories (see Figs. F20 and F21). Autosomal dominant genes are known that either eliminate the

dermal ridges or alter their pattern. There are elaborate systems for their classification into up to a million subgroups within which, individual differences are still detectable. The uniqueness of the fingerprints became known by the second half of the sixteenth century at about the same time as the anatomist, Nehemiah Grew, identified sexuality of plants. Francis Galton, the founder of quantitative genetics, had already used it for forensic purposes in the nineteenth century. The forensic value of fingerprints may not be always perfect because the analysis may be subject to personal errors.

Figure F20. Fingerprints and palmprint patterns. The main types of the fingerprints are “loop”, “whorl” and “arch” as shown but the additional dermal ridges within and outside are omitted here. The average number of ridges for women is about 127 and for men about 144. The far-left palmprint illustrates the main angles of the palmar triradial ridges. These are separate from the palmar creases affected in certain hereditary anomalies. (See Down’s syndrome)

Figure F21. Whorl type fingerprint.

Fingerprinting is used also in visa applications of foreigners (some countries are exempt) and at entry points to the USA for screening undesirable individuals. Prints are generally taken of both index fingers. The pattern is checked against a watchlist maintained in a database by the National Institute of Standards and Technology. The currently used system has a detection probability of 0.526 to 0.733 (using 10 fingers the probability increases to 0.949) and the probability of false positives is 3.1×10^{-3} in a list of

6 million people. In case the quality of the fingerprints is low because of surgery or deliberate erasure of the dermal ridges by sand paper or by other means, the identification probability is lower (Wein LM, Baveja M 2005 Proc Natl Acad Sci USA 102:7772).

Although lip prints have not been used for the same purpose as fingerprints, they also may permit individual identification. ▶ectodermal dysplasia, ▶dyskeratosis, ▶DNA fingerprinting, ▶iris pattern, ▶lip-prints, ▶forensic genetics; Alter M 1966 Medicine 46:35; Williams G et al 2001 J Forensic Sci 46:1085.

Finishing: A DNA sequencing step that eliminates most of the errors and gaps in the genomic sequence and leads to a nearly complete sequence from the first draft. The finished DNA sequence originally was not expected to have a higher error rate than 1×10^{-4} ; the 2004 finished euchromatic sequence of the human genome has an error rate of only 1×10^{-5} . ▶first-draft sequence, ▶gaps; Deloukas P et al 2001 Nature [Lond] 414:865; Nature [Lond] 431:931 (2004).

Finlay-Marks Syndrome: Autosomal dominant scalp lesions, anomalous ears, reduced or absent nipples in females, and syndactily.

FIR (*Abies* spp.): Timber trees, $2n = 24$.

Fire: The intragenic (negative) regulatory element in the c-fos proto-oncogene and it must be relieved before Fos can be expressed. ▶FOS

Firmicutes: A phylum of low GC content Gram-positive bacteria.

First Division Segregation: ▶tetrad analysis

First-Male Sperm Precedence: A method of sperm competition in case of multiple mating during a period of receptivity of the same female. In the newt, the process is controlled by the female in contrast to other animals, and last-male precedence may occur. ▶certation; Jones AG et al 2002 Proc Natl Acad Sci USA 99:2078.

First Messenger: Peptide hormones. ▶animal hormones

First Strand DNA: The immediate product of reverse transcription. ▶reverse transcription, ▶cDNA

First-Draft Sequence: Before entirely completing a genome project, a nearly contiguous sequence may still have an error rate of 10^{-3} . ▶high-quality sequence, ▶genome projects

FirstEF: A computational program based on discriminant function that detects promoters and first exons with over 80% accuracy. ▶discriminant function; Davuluri RV et al 2001 Nature Genet 29:412.

FIS (factor for inversion stimulation): A protein involved in the movement of inversion and transposable elements. This element (11.2-kDa) may activate rRNA transcription (7x) after binding upstream promoter sites at -71, -102, and -143. In *E. coli* and *Salmonella typhimurium*, Fis affects also recombination, replication and other functions. ▶invertases, ▶insertion elements, ▶transposable elements, ▶promoter, ▶rm; Pan CQ et al 1996 J Mol Biol 264:675.

Fish: ▶zebrafish, ▶medaka, ▶pufferfish, ▶salmon, <http://www.fishbase.org/search.cfm>, fish biology: <http://www.larvalbase.org>.

FISH (fluorescence in situ hybridization): FISH detects eukaryotic chromosomal sites by the use of non-radioactive, fluorescence-labeled probes (see Fig. F22). In human chromosomes it permits the resolution of about 0.05–10 million base pairs as a band. The multiplex FISH technique using several fluorochromes simultaneously permits the identification of rather complex chromosomal rearrangements in amazing colors. Using DNA fibers, cloned probes can be mapped with a resolution down to 1 kb. The effectiveness of the FISH approach has been greatly increased by the use of epifluorescent filters and computer evaluation, permitting the simultaneous identification of 27 different DNA probes. This *multiplex FISH* (M-FISH) has been described by Speicher R et al 1996 Nature Genet 12:368; Henegariu O et al 1999 Nature Genet 23:263. In recent years, special probes for different chromosomal locations (centromere, telomere and various insertions) have become available (▶ENCODE; <http://genome.cse.ucsc.edu/>). *Fibre FISH* deals with chromosome fibers that were subjected to histone removal and it has a resolution of 1–500 kb. *RNA FISH* uses a fluorescently labeled nucleic acid probe to detect cellular transcripts in situ. Probes that are complementary to intronic sequences will hybridize at the site of nuclear transcription. ▶chromosome painting, ▶spectral karyotyping, ▶non-radioactive labels, ▶fluorochromes, ▶GISH, ▶in situ hybridization, ▶probe, ▶WCPP, ▶telomeric probes, ▶stretching chromosomes, ▶Chip, ▶FRET, ▶DIRVISH, ▶MFISH, ▶COBRA, ▶combinatorial labeling, ▶ratio labeling, ▶IRS-PCR, ▶chromosome territories; Azofeifa J et al 2000 Am J Hum Genet 66:1684; Lee C et al 2001 Am J Hum Genet 68:1043; Speicher MR, Carter NP 2005 Nature Rev Genet 6:782.

FISH: low sequence homology search: <http://babel.ucmp.umu.se/fish/>.

Fish Orthologous Genes: <http://www.evolutionsbiologie.uni-konstanz.de/Wanda>.

Figure F22. Fish. Human male metaphase chromosomes. In situ multiplex-fluorescence hybridization identified each chromosome pair in different color. (Courtesy of Dr. Michael Speicher, Institut für Anthropologie und Human Genetik, LMU, München, Germany)

Fisher's Exact Test: is an exact probability test for independence that can be used similarly to a goodness of fit and contingency tests. The probabilities are determined with the aid of hypergeometric distribution tables and if the populations are large the binomial distribution may satisfactorily approximate the hypergeometric distribution. (See for details Sokal RR, Rohlf FJ Biometry, Freeman, Everitt, B.S., ed. 2002 Cambridge Dictionary of Statistics. Cambridge University Press, Cambridge, UK, also ►association test, ►chi square, ►G test, ►hypergeometric distribution)

Fisher-Muller Hypothesis: As per the Fisher-Muller hypothesis, the advantage of sex is that beneficial mutations occurring in two different individuals can be combined in one.

Fish-Eye Disease: Cholesterol acyltransferase deficiency. ►lecithine

Fission: A mode of asexual reproduction involving the division of a single cells or organelles by cleaving into two (generally) equal progeny (daughter) cells or organelles (see Fig. F23). ►alternation of generations, ►life cycles, ►contractile ring

Figure F23. Fission

Fission Yeast: ►*Schizosaccharomyces*

FITC: A fluorochrome, a conjugate of fluorescein with isothiocyanate, used for cellular, chromosomal labeling. ►chromosome morphology, ►fluorochromes, ►chromosome painting, ►FISH

Fitch-Margoliash Method for TD: In the Fitch-Margoliash method, using n number of species, an evolutionary distance is computed by minimization of the branches of the evolutionary tree:

$$S_{\text{Fitch-Margoliash}} = \left[\frac{2 \sum_{i < j} \{ (d_{ij} - e_{ij}) / d_{ij} \}^2 }{n(n-1)} \right]^{1/2} \times 100 \quad \text{where}$$

d_{ij} is the observed distance between species i and j and e_{ij} is the patristic distance. ►evolutionary tree, ►evolutionary distance, ►patristic distance, ►transformed distance

Fitness: The reproductive value in a population under specified conditions, determined by a genotype (see Table F5). High fecundity and fertility do not necessarily increase fitness of a population if the offspring does not reach or proceed beyond reproductive age. In monogamous societies, primarily the females determine the reproductive success. For the method of calculation of fitness see table. In natural populations when hybrids have superior fitness, it can be estimated by the following equation: $w_{F1} = [(1 - p_1)p_3]/[p_1(1 - p_3)]$ where p_1 and p_3 are the frequencies of hybrids at the beginning and at the end of the study (Ebert D et al 2002 Science 295:485).

In pre-industrial American populations, increasing number of offspring and rates of reproduction were associated with reduced parental survivorship, especially more for mothers than fathers. Parental mortality resulted in reduced survival and reproduction of offspring, and the mothers' mortality was more detrimental to offspring than the fathers'. Increasing family size was associated with lower offspring survival, primarily for later-born children, indicating a tradeoff between offspring quantity versus quality. Thus maximal reproduction imposed fitness costs (Penn DJ, Smith KR 2007 Proc Natl Acad Sci USA 1004:553).

►selection coefficient, ►hybrid vigor, ►mutation rate in fitness, ►inclusive fitness, ►fecundity, ►fertility, ►parity, ►cultural transmission of fitness; Loeske EB et al 2000 Proc Natl Acad Sci USA 97:698; Wloch DM et al 2001 Genetics 159:441; Rozen DE et al 2002 Current Biol 12:1040.

Fitness-Associated Recombination: Breaking linkage with deleterious genes or generating new linkage relations in a changing environment may increase the fitness of an evolving population. ►genetic load,

►recombinational load, ►fitness; Hadany L, Beker T 2003 Genetics 165:2167.

Fitness Density: The proportion of amino acids in a protein that affect fitness during evolution.

Fitness, Standardized: ►selection coefficient

Fitness Valley: In graphical representation of fitness, individual mutations reduce fitness whereas joint effects of mutations increase fitness.

fix: ►nitrogen fixation

Fixation: The allele becomes homozygous in every individual of the population.

Fixation Index: The fixation index is the average coefficient of inbreeding in a population. In case of random mating, the probability that an offspring would have exactly the same two ancestral alleles at a locus is $(1/2)N$, where N is the number of diploid individuals in the population. The probability of having two different alleles at the same locus is $1 - (1/2)N$. The coefficient of inbreeding of the first generation of this population is also $(1/2)N$ by definition of inbreeding. In each succeeding generation, the non-inbred part of the population will have a chance to produce offspring with an allele pair identical by descent. Therefore, the coefficient of inbreeding in the next generations will be $(1/2)N + [(1 - (1/2)N) \times F]$, where F is the inbreeding coefficient of the preceding generation. After the g th generation the coefficient of inbreeding of this population will be: $F_g = (1/2)N + [1 - (1/2)N]F_{g-1}$ and this is called the *index of fixation*. Its complement is the *panmictic index* (P_g) that represents the average non-inbred fraction of the population:

$$P_g = 1 - F_g$$

Table F5. Estimation of fitness and equilibrium frequencies of the alleles at heterozygote advantage in a hypothetical population

| | | | |
|---|---|-----------------------------------|---|
| Observed (N = 2000): | AA = 900, | Aa = 1000, | aa = 100 |
| Representation of alleles ($\Sigma = 4000$): | A: $(2 \times 900) + 1000 = 2800$, | a: $(2 \times 100) + 1000 = 1200$ | |
| Allelic frequencies: | A: $2800/4000 = 0.7 = p$, | a: $1200/4000 = 0.3 = q$ | |
| Expected no. of genotypes N | AA: 0.49×2000 , | Aa: 0.42×2000 , | aa: 0.9×2000 |
| ($p^2 + 2pq + q^2$) | AA: 980 | Aa: 840 | aa: 180 |
| Fitness <small>$\frac{\text{observed number of genotypes}}{\text{expected number of genotypes}}$</small> | AA: $\frac{900}{980} = 0.92$ | Aa: $\frac{1000}{840} = 1.19$ | aa: $\frac{1000}{180} = 0.56$ |
| Standardized fitness (rel. to w_2) | AA: $\frac{0.92}{1.19} = 0.77$ | Aa: $\frac{1.19}{1.19} = 1.00$ | aa: $\frac{0.56}{1.19} = 0.47$ |
| Selection coefficients | $s = 1 - 0.77 = 0.23$ | | $t = 1 - 0.47 = 0.53$ |
| Allelic frequencies at equilibrium | A: $\frac{t}{s+t} = \frac{0.53}{0.23+0.53} = 0.7$, | | a: $\frac{s}{s+t} = \frac{0.23}{0.23+0.53} = 0.3$ |

The probability for the offspring to have two identical *A* or *a* alleles is $F_{p_{AA}}$ and $F_{q_{aa}}$, respectively. Also, the probability of two alleles of a locus being non-identical by descent is $1-F$, and the proportions of *AA*, *Aa*, and *aa* are p^2 , $2pq$, and q^2 (according to the Hardy-Weinberg theorem). Because the population will have both inbred and non-inbred components, its genetic structure will be:

$$(p_{AA} + q_{aa}) \text{ and } (1-F)(p^2AA + 2pqAa + q^2aa)$$

F

When a population is completely inbred, only homozygotes are found. There may be a change in genotypes but may not be a change in allelic frequencies if both alleles have equal fitness. The change may actually be from $AA + 2Aa + aa \rightarrow AA + AA + aa + aa$, i.e., mathematically it is the same. The ultimate probability of fixation $P_f = \frac{1-e^{-N_e s p}}{1-e^{-N_e s}}$ may be estimated also on the basis of the *initial frequency of the gene* ($= p$), the *selection advantage* ($= s$) and the *effective population size* (N_e). [The base of the natural logarithm $= e \approx 2.718$]. ▶inbreeding, ▶panmixis, ▶inbreeding rate, ▶Hardy-Weinberg theorem, ▶mutation neutral, ▶mutation beneficial, ▶hybrid vigor; Whitlock MC 2003 Genetics 164:767.

Fixative: An agent(s) required to treat biological materials before a stain is applied for microscopic examination (see Table F6). The fixative rapidly kills the cells, immobilizes the structures, and assures better staining. Many different types of fixatives have been developed since the introduction of microscopic techniques. Some of the most widely used (especially for cytology) with composition in parts (volume) are given.

Newer fixatives may contain formalin 5%, glacial acetic acid 5%, 90% or 70% ethanol, glutaraldehyde (4% in 0.025 M phosphate buffer pH 6.8), etc. Detergents (Tween 20) may be added for facilitating penetration or aspiration is applied for a few minutes. Fixation time is a day or two. The fixed material can be stored for months in 70% ethanol in a refrigerator. For electron microscopy, different fixatives are required. The fixatives used in photographic processing are completely different. ▶light microscopy, ▶electron microscopy, ▶stains

FixL: *Rhizobium* kinase regulating N₂ fixation by FixJ. ▶nitrogen fixation

FFU (focus forming unit): The measure of focus formation in transformed (cancer) cells.

FK506 (Tacrolimus): An immunosuppressive protein, in combination with rapamycin, binds to cellular proteins FKB12/FKBP13. FK506 intercepts the signal of the T lymphocyte receptor while rapamycin interferes with the signal of cytokines and growth factors. The FKBP12 - FK506 complex inhibits the serine-threonine phosphatase, calcineurin. The FK506 family protein FPR3 helps to maintain meiotic checkpoint to facilitate recombination through controlling protein phosphatase 1. Thus the chromatid breakpoints remain open until strand exchange is completed by delaying the premature progression of meiosis (Hochwagen A et al 2005 Cell 122:861). The rapamycin-FKBP12 complex binds to FRAP and regulates p70 ribosomal protein S6 kinase that is required for the progression from G₁ phase of the cell cycle. Fkbp6 is essential for normal chromosome pairing in male mouse meiosis and fertility (Crackower MA et al 2003 Science 300:12191). Mutant Fkbp does not seem to affect female meiosis and fertility. (Also called TOR, RAFT, FRAP. Members of this protein family are common in animals (FKBP25, FKBP12, FKBP51, etc.) and occur also in fungi (Npi46) and plants (FKBP73). ▶immunosuppression, ▶cell cycle, ▶calcineurin, ▶immunophilins, ▶ataxia telangiectasia, ▶signaling to translation, ▶checkpoint, ▶cell cycle, ▶meiosis, ▶PPI, ▶NF-AT, ▶FkpA, ▶peptidyl-prolyl isomerases, ▶recombination molecular mechanism of, ▶checkpoint, ▶cardiomyopathy hypertrophic familial, ▶cyclosporine, ▶immunophilins, ▶plasmacytoma, ▶amyloids, ▶histone tails; Glynne R et al 2000 Nature [Lond] 403:672; Aghdasi B et al 2001 Proc Natl Acad Sci USA 98:2425.

FK1012: A lipid-soluble ligand; a dimeric form of FK506. It directs the interaction between proteins linked to the FKBP12 receptor. ▶FK506

FKB12/FKBP13: The enzyme complex involved in the catalysis of peptidyl-prolyl cis-trans isomerization of

proteins. The FKBP12 molecules may be complexed with hormones or other proteins and facilitate the export of molecules from the endoplasmic reticulum. ►FK506, ►COP, ►Ire; Marx SO et al 2000 Cell 101:365; Gaburjakova M et al 2001 J Biol Chem 276:16931.

FKH (forkhead): The embryonic lethal *Drosophila* gene at 3–95. A human homologue (13q14) is a DNA-binding protein; the human gene (FKHL7) at 6p25 encodes a transcription factor responsible for a dominant glaucoma. It seems that that FKH1 and FKH2 of yeast are general transcription factors regulating the elongation of the RNA polymerase II transcripts (Morillon A et al 2003 Science 300:492). Translocations to 2q35 (PAX) may result in rhabdomyosarcoma (epithelial tumor). The forkhead homolog of *Caenorhabditis* (DAF-16) controls longevity of the worms and in humans it indirectly mediates apoptosis and the cell cycle. The protein Chfr (checkpoint with FHA and ring finger) seems to control in the cell cycle the entry into metaphase. The human homolog, FoC1 at 6p25 is a glaucoma gene. FOXC2 defect involves lymphedema distichiasis. FOXC1 and FOXL2 genes are also involved in several other human diseases. Foxa2 regulates lipid metabolism and ketogenesis in liver during fasting and in insulin-deficient diabetes (Wolfrum C et al 2004 Nature [Lond] 432:1027). FOXP3 deficiency leads to autoimmune disease (IPEX). FOXP3 controls ~700 genes that are key modulators of T_R cell activation (Marson A et al 2007 Nature [Lond] 445:931; Zheng Y et al Nature [Lond] 445:936). ►PAX, ►glaucoma, ►lymphedema distichiasis, ►Axenfeld-Rieger anomaly, ►blepharophthalmosis, ►Akt, ►checkpoint, ►FHA, ►ketogenesis, ►diabetes, ►dyspraxia, ►hepatocyte, ►T cell regulatory; mitotic program: Alvarez B et al 2001 Nature [Lond] 413:744; Tran H et al 2002 Science 296:530; fox gene classifications for various organisms: <http://www.biology.pomona.edu/foxbyclass.html>.

FkpA: A periplasmic FK506-binding protein. ►FK506, ►periplasma

Flag: The eukaryotic translation initiation factor (eIF-4G2, encoded in humans at 11p15) and provides support for the capping protein eIF-4F by binding to eIF-4A. FLAGGED proteins are usually repressed. ►eIF-4G, ►eIF-4A, ►eIF-4F, ►cap, ►capping enzymes

Flag Tag: An 8-amino acid (Asp-Lys-Tyr-Lys-Asp-Asp-Lys) fusion tag is used for immunoaffinity chromatographic purification of proteins (Einhauer A, Jungbauer A 2001 J Biochem Biophys Methods 49:455).

Flagellar Antigen: Flagellar antigen of *Salmonella* is encoded by the *H1* and *H2* genes. At a particular time, only one of the two flagellins is expressed. The expression is controlled by “phase variation”, i.e., a transposition (inversion) of the 970 bp long DNA segment. In one of the positions, the *rh1* regulatory element represses the *H1*, and after the inversion of the other, *H2* is expressed. ►phase variation, ►flagellin, ►Trypanosoma, ►mating type determination in yeast; Masten BJ, Joys TM 1993 J Bacteriol 175:5359.

Flagellin: The protein material of the (bacterial) flagellum. Perception of flagellin is an early step of bacterial resistance in *Arabidopsis* (Zipfel C et al 2004 Nature [Lond] 428:764). Flagellin induces non-host innate immunity against bacteria, but *Pseudomonas syringae* suppresses the effector in *Arabidopsis* (Li X et al 2005 Proc Natl Acad Sci USA 102:12990). ►flagellum, ►phase variation, ►host-pathogen relation, ►EF-Tu; Samatey FA et al 2001 Nature [Lond] 410:331.

Flagellum (plural flagella): A cell appendage used for back and forth movement of microbial cells; in bacteria it is controlled by about 50 genes (see Fig. F24). The core components of the bacterial flagellum originated through the successive duplication and modifications of a few, or perhaps even a single, precursor gene (Liu R, Ochman H 2007 Proc Natl Acad Sci USA 104:7116). ►flagellin, ►cilia; Yonekura K et al 2003 Nature [Lond] 424:643; molecular structure: Samatey FA et al 2004 Nature [Lond] 431:1062.

Figure F24. Flagellum

Flame: ►FLICE, ►apoptosis

Flanking DNA (flanking gene): Nucleotide sequences adjacent to a gene, or adjacent genes.

Flap: A binding or attaching/overlapping site of an enzyme/protein.

Flap Nuclease: The flap nuclease has both endo- and exonuclease activity. ►RAD27/FEN1; Debrauwere H et al 2001 Proc Natl Acad Sci USA 98:8263; Dervan JJ et al 2002 ibid. 99:8542.

Flash (FLICE-associated huge protein): A caspase-regulatory protein in apoptosis, it interacts with FAS/CD95. ►apoptosis, ►Fas, ►caspase, ►FLICE, ►DISC; Choi Y-H et al 2001 J Biol Chem 276:25073.

Flat File: A non-machine-readable, non-standardized file that can be used for information exchange in databases. ▶[databases](#)

Flatworm (*Planaria torva*): $2n = 16$ (see Fig. F25).
▶[Planarians](#)

Figure F25. Planaria

Flax (*Linum usitatissimum* ($2n = 30, 32$)): Flax includes the fiber crop and the seed crop, linseed, altogether with about 200 species. In the highly variable *Linum* genus, the basic chromosome numbers vary: $x = 8, 9, 12, 14, 15, 16$ but the most common $2n$ numbers are 18 and 30. Some strains also show non-nuclear inheritance.

Flavin Nucleotides: Riboflavin-containing coenzymes.
▶[FMN](#) and ▶[FAD](#)

Flavone: Along with, flavonones, flavonols are plant pigments derived from chalcones. ▶[anthocyanidins](#) and ▶[chalcone](#)

Flavonoids: Pigments with trimeric heterocyclic nucleus, and are frequently glycosylated. The synthetic enzymes may assemble as macromolecular complexes. Flavonoids may act as antioxidants and their presence in dark chocolate or red wine may be advantageous for the cardiovascular system. ▶[flavone](#); Serafini M et al 2003 Nature [Lond] 424:1013.

Flavoproteins: Flavoproteins are tightly bound with a flavin nucleotide prosthetic group. ▶[flavin nucleotides](#)

flea: ▶[copia](#)

FL-cDNA (full-length cDNA): Genuine fl-cDNAs include the 5' ATG initiating codon, which is frequently missing in cDNA libraries. ▶[cDNA](#); Draper MP et al 2002 Genomics 79:603.

Flora: A description of higher plant communities growing in a particular area or the vegetation present in an area.

Floral Dip: A simple method of transformation of *Arabidopsis* plants by agrobacterial vectors. The inflorescence is dipped into a bacterial suspension containing 5 g sucrose and 500 μ L Silwet L-77 surfactant. No in vitro tissue culture is required. ►[transformation genetic/plants](#); Clough SJ, Bent AF 1998 Plant J 16:735.

Floral Evocation: The process of commitment to flower differentiation of plants. ►[commitment](#), ►[determination](#); Nelson DC et al 2000 Cell 101:331.

Floral Induction: The internal and external factors bringing about floral evocation. Induction of flowering is a complex process and may require low temperature (vernalization), long- or short-day photoperiodic regimes, respectively (see Fig. F26). Recessive mutations of single genes of *Arabidopsis* at several unlinked loci may dramatically affect the flowering response. The flowering response is under the negative control of *FLC* (*FLOWERING LOCUS C*), which is regulated by vernalization and methylation (Sheldon CC et al 1999 Plant Cell 11:949).

Figure F26. Floral induction. Segregation of the *gr²* Mutant with wild type sibs (From Rédei GP 1962 Genetics 47:443)

Two small RNAs (30 and 24 nucleotides) corresponding to the reverse strand 3' to the canonical poly(A) site of *FLC*, an *Arabidopsis* gene encode a repressor of flowering. These RNAs originate from a genomic region of *FLC* lacking repeats. The 24-nt small RNA, which is most abundant in developing fruits, is absent in mutants defective in RNA polymerase IVa, RNA-dependent RNA polymerase 2, and DICER-LIKE 3, components required for RNAi-mediated chromatin silencing. The corresponding genomic region shows histone 3 lysine 9 dimethylation (Swiezewski S et al 2007 Proc Natl Acad Sci USA 104:3633).

It seems that siRNAs control methylation of specific loci involved in the onset of flowering (Chan SW-L et al 2004 Science 303:1336). *FLC* is apparently repressed by FVE, a retinoblastoma-associated protein that deacetylates histones (Ausin I et al 2004 Nature Genet 36:162). The role of negative regulators of flowering in mutants of *Arabidopsis* has been shown as early as 1966 (Rédei GP et al 1974 Stadler Symp 6:135). Nitric oxide (NO) appears to be a repressor of floral initiation of the *co* and *gi* mutants but was found to enhance the expression of *FLC* (He Y et al 2004 Science 305:1968). ►[flower differentiation](#), ►[florigen](#), ►[photoperiodism](#), ►[vernalization](#), ►[shade-avoidance syndrome](#), ►[RNAi](#), ►[histones](#), ►[RNA polymerases](#); Rédei GP 1962 Genetics 47:443; Suárez-Lopez P et al 2001 Nature [Lond] 410:1116; Simpson GG, Dean C 2002 Science 296:285; Mouradov A et al 2002 Plant Cell 14:S111; Blázquez MA et al 2003 Nature Genet 33:168; He Y et al 2003 Science 302:1751.

Floret: An individual small flower that is a part of an inflorescence.

Florigen: A term coined in the mid 1930s by Mikhail Chailakhyan, a Russian plant physiologist, for a hypothetical mobile flowering hormone under the control of photoperiodism. During the decades, its chemical definition has defied all efforts of description. Although gibberellins have been attributed with its property, this suggestion has been incorrect. Research in 2005 credited the *Arabidopsis FT* mRNA or the encoded protein with florigen properties, i.e., synthesized in the leaves and moving to the shoot apex and promoting flower evocation (Huang T et al 2005 Science 309:1694; this paper has been retracted: Böhlenius H et al 2007 Science 316:367). More recently, the mRNA nature of the flowering substance has been questioned and evidence has supported its protein-like nature (Corbesier L et al 2007 Science 316:1030). The rice homolog of FT, Hd3a has been identified also as a florigen protein (Tamaki S et al 2007 Science 316:1033). ►[photoperiodism](#), ►[flower differentiation](#), ►[flower induction](#), ►[gibberellins](#)

F

Flor's Model: The Flor's model developed by the plant pathologist, H.H. Flor in the 1950s, claims that for each virulence gene of the pathogen, a gene exists in the host and thus, corresponding gene pairs (GCP) exist. These can be expressed in four different categories. Actually, the models were further elaborated and only pathogenicity and host reaction alleles were recognized, while the terms virulence and resistance were deemed unnecessary. Thus, the expression of the disease symptoms (aegricorpus), dependent also on environmental factors, required an inter-organismal genetic system. This rather complicated, interacting system was considered a great idea to explain the genetic control of host–pathogen relationships by many plant pathologists. But many geneticists dismissed it as commonplace. They argued that in all organisms, all functions are genetically controlled and it is the interaction of gene products that determines the phenotypes within organisms and also between organisms, and disease is no exception. Thus, the model—they argued—in the absence of biochemical or molecular facts, is not helpful. Since several plant genes have now been cloned, there will be new opportunities to study host–pathogen relationships in physico-chemical terms. The resistance of maize against *Cochliobolus carbonum* (*Helminthosporium*) seems to support the latter argument inasmuch as a plant enzyme degrades the fungal toxin. The discoveries that some resistance genes encode elicitors of the signal transduction pathways in one way or another still do not invalidate the simplest interpretation. Recent experiments using the yeast two-hybrid system with the *Lac* reporter indicate that the *AvrPto* bacterial virulence gene interacts with the tomato resistance gene *Pto*. This reaction was evident only in this genic combination. Analysis of the *Pto* protein also revealed that a 95 amino acid stretch (129 to 224) of the protein was alone responsible for the specific interaction between the pathogen and the host. The plant resistance proteins (R) contain nucleotide-binding sites (NBS) and leucine-rich repeat (LRR) domains for the recognition of pathogens. The pathogens generally contain avirulence (*Avr*) proteins that are effectors of infection. These two groups of proteins co-evolved competitively to assure infection by the pathogen and resistance in the host, respectively. The plant *Arabidopsis* synthesizes RPM1, RPS2, and RPS5 nucleotide-recognition and leucine-rich repeat proteins. These proteins are modified by the effector function of the pathogenic *Pseudomonas syringae* *Avr* proteins made by virulent strains. During evolution, a balance must have evolved between these two sets of genes in order to maintain the status quo despite mutations. In flax plants, there is a polymorphic L locus, which encodes NBS-LRR

proteins that recognize different variants of *Avr* of the fungus *Melampsora lini*. The *AvrL567* rust locus encodes 150 amino acid proteins, which are presumably cleaved and release a 127 amino acid polypeptide. The flax proteins L5, L6 and L7 R recognize the signals of the pathogen. During evolution, the many variants existing in the different strains fungi and plants are apparently in a continuous arms race (Dodds PN et al 2006 Proc Natl Acad Sci USA 103:8888). ▶aegricorpus, ▶host-pathogen relations, ▶immune response, ▶quadratic check, ▶two-hybrid system; Flor HH 1971 Annu Rev Phytopath 2:131; Ellis J et al 2000 Curr Opin Plant Biol 3:278; Bergelson J et al 2001 Science 292:2281.

Flotillin: A protein of the caveolae. ▶caveolae; Garin J et al 2001 J Cell Biol 152:165.

floury (fl-2): The *fl-2* gene of the maize improves the nutritional value of the kernels by reducing the contents of prolamine and zein, resulting in an increase in lysine, tryptophan, and methionine. ▶opaque, ▶kwashiorkor

Flow Cytogenetics (flow karyotyping): The analysis of chromosomes by flow cytometry. (See Davies DC et al 2000 Flow Cytometry, see below).

Flow Cytometry: In the flow cytometer, suspended particles (cells, chromosome, etc.) are stained with fluorochromes and a laser beam excites the dyes. The particles are then sorted with the aid of a computer according to their special properties. The procedure directly estimates cell (rather than population) characteristics such as nucleic acid content, enzyme activity, membrane potential, calcium flux, cell surface receptors, cytoplasmic constituents, etc. It requires sophisticated instrumentation. ▶bivariate flow cytometry; Ormerod MG ed. 2000 Flow Cytometry, Oxford University Press, Oxford, UK; Gygi MP et al 2002 Nucleic Acids Res 30:2790.

Flowchart: The graphical display of procedures of analyses for the solution of a particular problem or subset of that problem or an experimental protocol.

Flower Differentiation: Flower differentiation is under very strict genetic control. Numerous genes have been identified which change the basic pattern of the morphogenesis. An idealized wild type dicot flower and the most common three types of homeotic conversions are indicated in the diagram. The homeotic transformations may not be complete and thus, e.g., carpelloid sepals, stamoid petals, or petaloid stamens, etc. were identified. Usually, an entire whorl of the flowers ([1] sepals, [2] petals, [3] stamens, [4] and carpels) is affected. The conversions generally involve adjacent whorls and simultaneously more than two whorls may be affected. On the basis of mutational evidence, it has been

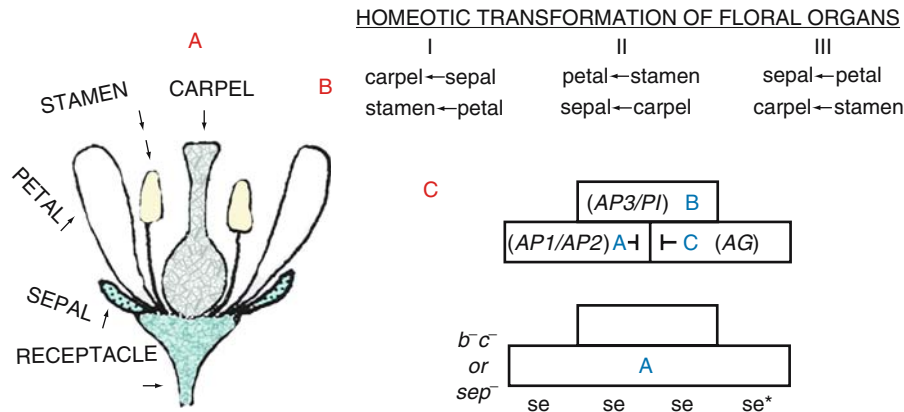

Figure F27. Homeotic transformation of floral organs. Genetic determination of flower organs (shown at A). Homeotic transformation affects neighboring whorls (B). The Meyerowitz-Coen-Yanofsky model of flower organ identity (C). This is also called the ABC model represented by the blue letters in the three boxes (at top) and including the symbols of the genes (in italics) responsible for the control of differentiation of these organs. Box **A** Alone specifies sepals, **C** Alone controls carpels and **A** and **B** are responsible for petals whereas **B** and **C** for stamens. **A** counteracts the activity of **C** and **C** is antagonistic to **A**. If **c** is not active an indeterminate number of floral whorls appear. The lower two boxes illustrate the floral development in double mutants when both **B** and **C** genes mutate ($b^- c^-$) or when mutation occurs at the *sepallata* (formerly denoted as *agamous-like* AGL) sites. When all three (*sep1*, *sep2*, *sep3*) are mutant only **A** activity is displayed, i.e., in all three whorls sepals appear

suggested that the four whorls belong to A (1 + 2), B (2 + 3), and C (3 + 4) identity groups in the floral meristem (see Fig. F27, Fig. F28).

The identity groups affected by the mutation(s) determine the actual phenotype of the mutants. e.g., a type II change is the result of interaction between domain A (*Apetala 1* [*AP1*] and 2 [*AP2*] genes) and domain B (*Apetala 3* [*AP3*] and *Pistillata* [*PI*] genes). Mutations in the C and B domains result in the *agamous* (*AG*) in *Arabidopsis* and in the *plena*, *pleniforma* or *petaloida* alterations in *Antirrhinum*. *AP1*, *AP3*, *PI*, and *AG* proteins all contain a MADS box, but *AP2* represents another DNA binding protein. microRNA 177 appears to be a translational suppressor of *AP2* (Chen X 2004 Science 303:2022). In *Antirrhinum*, phenotypically similar mutations *blind* (*bl*) and *fistula* (*fis*) control microRNA genes located in the center of the flower although they are expressed also during early floral development (Cartolano M et al 2007 Nature Genet 39:901; for *fis* phenotype ► [mutation spectrum](#)).

The plant MADS box proteins contain another conserved element, the K box that may form amphipathic α helices. *AG* binds also to another consensus ([CC(A/T)₆GG], the CA₂G-box).

These proteins interact with each other and may form *AP1/AP1*, *AP3/PI*, and *AG/AG* dimers including the truncated *AG/PI* heterodimer. The association of these proteins is mediated to a large degree by the so called L (linker) region that involves amino acids 31–35 situated between the MADS box and the K (keratin homology) box:

Figure F28. Some mutants of *Arabidopsis* violate the normal path of development of the flower whorls. Here we see 7 petals and 12 stamens and a somewhat complex stigma and carpels but the sepals are absent. (G.P. Rédei, unpublished)

N — terminus < MADS DOMAIN >
< L REGION > < K BOX > C terminus

The MADS box appears to represent a large family of genes with critical functions in plant development.

Flower differentiation seems to be controlled at the level of transcription and the specific RNA transcripts

appear in regions of the flower primordia, which are affected by the specific genes (see Fig. F29). These genes are studied under the control of different promoters introduced by transformation. Recent studies also indicate that at least some of the genes are regulated post-transcriptionally.

Cell fate signaling in the apex of *Arabidopsis* is mediated by a receptor encoded by the *CLAVATA1* trans-membrane protein kinase gene and it is activated by the ligand encoded by *CLAVATA3*, regulating the balance between growth and differentiation. The *WUSCHEL* gene interferes with the activity of *CLAVATA* and maintains the undifferentiated status of the meristem. In *Arabidopsis*, the *LEAFY* and *SPLAYED* genes appear to be activators of the floral homeotic genes such as *APETALA1* and *AGAMOUS*. The quartet theory of floral differentiation has been proposed by Honma T, Goto K 2001 (Nature 409:525). According to this model, four MADS box proteins in four different combinations determine primarily the identity of floral parts in *Arabidopsis*. Petals are under the control of genes *API*, *AP3*, *PI* and *SEP*, carpels under (*AG*, *SEP*)₂, stamens under *PI*, *SEP*, *AP3*, and *AG* and sepals under *API* and two as yet unidentified proteins.

Constans (*CO*) mutants of *Arabidopsis* mediate photoperiodic induction. *FLOWERING LOCUS T* (*FT*), expressed in the vasculature of the cotyledons and in the shoot apex, is a promoter of flowering and regulates *CO*. *FD*, a basic leucine zipper transcription factor expressed in the shoot apex, supports *FT* and they cooperatively mediate initiation of flower development through transcriptional activation of *APETALA 1*, which a floral meristem identity gene

(Abe M et al 2005 Science 309:1052; Wigge PA et al 2005 Science 309:1056).

LEAFY and *APETALA1* promote the establishment of floral identity by positive regulation of other flowering genes. *AGAMOUS-LIKE24* is a central regulator of the floral meristem, and *LEAFY* and *APETALA1* negatively control *AGL24*. Without their activity the floral primordium develops inflorescence characteristics (Yu H et al 2004 Nature Genet. 36:157; this paper summarizes the intricate control of flower differentiation up to 2004).

Normally, *Arabidopsis* develops flowers following the development of a whorl of leaves in the vegetative rosette. The *EMBRYONIC FLOWER* (*EMF*) eliminates the rosette stage and promotes the development of a flower at the apical meristem of each shoot. Other MADS box genes (*SHP1*, *SHP2* and *STK*) mediate the development of the carpels and the ovules.

Flower Pigments: ► [anthocyanin](#), ► [flavone](#), ► [chalcones](#)

Floxing: ► [targeting genes](#)

FLP/FRT: A *Saccharomyces* recombinase system that can be expressed also in *Drosophila*. FLP is a recombinase and FRT defines target sites of transposable elements (see Fig. F30). The system is very similar to the Cre-loxP of bacteriophage P1. The 43-kDa “flip” (FLP) is encoded by the 2μ circular yeast plasmid. Recombination (X) takes place within the core sequence and between FLP binding sites.

Figure F30. FLP/FRT

This, as well as the *Cre/loxP* system, can be used for site-specific integration of transgenes and also for engineering chromosomal rearrangements in higher eukaryotes. ► [recombinase](#), ► [Cre/loxP](#), ► [targeting genes](#), ► [transposable elements](#), ► [chromosomal rearrangements](#), ► [homing endonuclease](#); Buchholz F et al 1998 Nat Biotechnol 16:857.

Flpter: The fractional length from the hybridization signal to the terminus of the short arm of the chromosome. It is used for the localization of FISH labels on the chromosome. ► [FISH](#)

FL-Rex (fluorescence localization based retrovirus-mediated expression cloning): In FL-Rex cloning, mRNA is isolated and reverse-transcribed into cDNA. Then the cDNA (about 1000 bp) is inserted into a multiple cloning site of a green fluorescent protein (GFP) gene within a retroviral vector (see Fig. F31). With the aid of the vector, packaging cells are transfected and the isolated retroviruses used to infect cultured mammalian cells. The GFP fusion permits the screening of the infected cells and subcloning individual cell lineages for a variety of different proteins with subcellular expression. Also the different DNAs can be amplified by PCR and sequenced. In a similar manner, GFP fusion proteins can be localized within the cytoplasm of plants with the aid of agrobacterial vectors. ► [expression cloning](#), ► [subcellular](#), ► [subcloning](#), ► [aequorin](#), ► [reverse transcription](#), ► [polymerase chain reaction](#), ► [DNA sequencing](#), ► [lipofection](#), ► [packaging cell lines](#), ► [ψ](#); Misawa K et al 2000 Proc Natl Acad Sci USA 97:3062.

FLT Oncogene: FLT oncogene is located in human chromosome 13q12 and it encodes a protein tyrosine kinase. It shows homology to FMS and ROS. Flt-1 is essential for animal embryonal vasculature but not for endothelial differentiation. The FLT3/FLK2 receptor tyrosine kinase is closely related to KIT and FMS. Flt-4 is a receptor of VEGF-C and promotes angiogenesis and their activity correlates with cancer metastasis (Su J-L et al 2006 Cancer Cell 9:209). ► [vascular endothelial growth factor](#), ► [Flk-1](#), ► [KIT](#), ► [FAK](#), ► [oncogenes](#), ► [Tie-1](#), ► [Tie-2](#), ► [receptor tyrosine kinase](#), ► [FMS](#), ► [ROS](#), ► [eclampsia](#), ► [VEGF](#); Maru Y et al 2001 Biochim Biophys Acta 1540:147.

Fluctuation Test: The fluctuation test was designed originally to determine whether the mutations observed were induced by a particular treatment or the treatment merely was a means of screening for that particular class of mutations that preexisted in the cultures. The design of the fluctuation test by Luria and Delbrück in 1943 initiated experimental bacterial genetics. It can be used also in other microorganisms and in animal and plant cell cultures; and the principles can be adapted to most types of mutation experiments. The principle is as follows: from the same original culture two series are generated. In series I the culture

F

is continued until a particular cell density is reached. In series II, small inocula are placed in say 10 (or more) vessels and the culture is continued until the same cell density is reached in all vessels of series I and II. Then plating is made in say 10 Petri plates from the single vessel culture I, and one Petri plate from each of the 10 test tubes of series II. After incubation for a period the number of mutations are scored separately on each of the 20 Petri plates. The abridged data of an experiment by M. Demerec (J Bacteriol 56:63) are tabulated. The averages (\bar{x}) and the variances ($(\sum x^2 - n\bar{x}^2)/n - 1$) are determined. If it appears that the average number of mutational events in both series I and II are practically the same but the variance in series II significantly exceeds that of series I, the conclusion is that the treatment was not the cause of the mutations. A fluctuation test of bacterial mutation for streptomycin resistance series I showed an average of 127.6 mutations, and the variance was 145.4. In series II, the average was almost the same at 123.3, but the variance was 4,392.0. Thus, streptomycin only revealed the presence of preexisting mutations for streptomycin resistance. The logic of this argument is that in the single vessel #I the preexisting mutants were distributed uniformly and therefore upon plating the variance was low. In the 10 vessels of series #II, mutations occurred or did not before plating. If mutations occurred early, many mutants appeared on that Petri plate, if mutation occurred late in the test tube,

few mutations were detectable after plating and if no mutations occurred in a particular test tube, the Petri plate failed to display any. The propagation of the pre-existing mutations caused the presence of a large number of the mutant colonies on some plates and when there were no mutations prior to the treatment, no such colonies appeared after plating in series II. In series I in the single batch the pre-existing mutations were uniformly dispersed without fluctuation in the variation. Thus the different fluctuations on the identical series of Petri plates presented the critical argument for the conclusion that the treatment was ineffective (see Table F7). Interestingly the classical publication of Luria & Delbrück contains computational error yet the basic principle contributed significantly to the development of bacterial and cell genetics. ►mean, ►variance, ►statistics; Luria SE, Delbrück M 1943 Genetics 28:491.

Fluid genome Paradigm: ►constant genome paradigm

Fluidity: Lipids can move within membranes. ►cell membranes

Fluorescein: A fluorochrome with excitation at 490-nm wavelength of light and emission at 525-nm (see Fig. F32). Generally used in conjugates with avidin, isothiocyanate or antibodies.

Table F7. Fluctuation test

Figure F32. Fluorescein → R = radix of different types

Fluorescein Diacetate: A vital stain for protoplasts.

Fluorescence: The property of chemical compounds to emit radiation (light) upon absorption of radiation from another source. Fluorescent radiation generally has longer wavelength than the wavelength absorbed, e.g., nucleotides irradiated by 260 nm UV light display a visible purple color. The fluorescence lasts only as long as the exposure to the irradiation. ▶UV

Fluorescence Microscopy: This technique uses a microscope with an illuminator equipped with a light filter that assures that the stage receives only that narrow spectral band of light that is required for the excitation of the fluorochrome used for staining the specimen. In front of the ocular, there is another filter that transmits only the fluorescence emitted but shuts out the exciting wavelength light. By staining with more than one dye and changing filters, in the same specimen different structures (molecules) may be distinguished by different bright colors. Some of the fluorochromes permit viewing also living cells. ▶fluorochromes, ▶chromosome painting, ▶FISH, ▶microscopy; Lippincott-Schwartz J, Patterson GH 2003 Science 300:87; Hadjantonakis A-K et al 2003 Nature Rev Genet 4:613.

Fluorescent Dyes: ▶fluorochromes

Fluorescent in Situ Hybridization: ▶FISH

Fluorescent-Focus Assay: The fluorescent-focus assay is used to determine titers of non-killer viruses. Permeabilized (by acetone, methanol) cells are incubated with antibody against the virus. Then another antibody that recognizes the first, and is conjugated with a fluorescent dye is added. The fluorescing cells are counted by UV light microscopy. (See Yang DP et al 1998 Clin Diagn Lab Immunol 5:790).

Fluorescent Speckle Microscopy (FSM): FSM permits the analysis of the dynamics of the cytoskeleton in living cells. ▶cytoskeleton; Waterman-Storer CM, Danuser G 2002 Current Biol 12:R633.

Fluorochromes: Non-radioactive labels such as DAPI, fluorescein, rhodamine B, FITC, Texas Red, R-Phycoerythrin, RED613, RED670, allophycocyanin, isothiocyanate, aequorin, Cy3 (green), Cy5 (red), etc. The dipyrrometheneboron difluoride dyes may have special advantages for automatic sequencing of DNA. The fluorescent amino acid 2-amino-3-[5-(dimethylamino)naphthalene-1-sulfonamide]propanoic acid (dansylalanine) can be genetically encoded in *Saccharomyces cerevisiae* by using the amber codon (UAG) and the appropriate tRNA/aminoacyl-tRNA synthetase pair (see Fig. F33). This procedure thus forgoes the use of fluorochrome complexes for the study of protein structure, folding and localization (Summerer D et al 2006 Proc Natl Acad Sci USA 103:9785). See under individual names, ▶fluorescent microscopy, ▶biotinylation, ▶FRET, ▶FISH, ▶aequorin, ▶unnatural amino acids; Han M et al 2001 Nature Biotechnol 19:631; Giepmans BNB et al 2006 Science 312:216.

Figure F33. Dansylalanine

Fluorography: A method used to enhance the sensitivity of autoradiographic detection by adding to the sample scintillants such as 2,5-diphenyloxazole (PPO) or sodium salicylate. ▶autoradiography, ▶scintillation counters

Fluorophore: A pigment that upon activation brings forth color. Numerous different fluorophores are used for labeling of macromolecules. ▶fluorochrome

Fluoroscope: A medical apparatus for X-ray examination of deep-seated tissues. The image is seen on a fluorescent screen coated with calcium tungstate or zinc cadmium sulfide and other materials. It was favored in the past because it could also detect motions. It has become of lesser significance with introduction of television cameras. It uses about ten fold higher doses of radiation than diagnostic X-ray machines, because of which it poses radiation hazards to both operator and patient. ▶X-rays, ▶tomography, ▶sonography

5' Fluorouracil (FU): A uracil analog that is incorporated into RNA. It is metabolized into deoxyfluorouridine monophosphate and triphosphate, and can get incorporated into the DNA (see Fig. F34). It is a potent antineoplastic agent, although resistance can develop. ▶neoplasia

Figure F34. FU

Flush-Crash Cycles: In flush-crash cycles, the size of a natural population fluctuates greatly.

Flush End: ▶blunt end (of DNA)

Flux: The spread of a label from a metabolic precursor to other molecules in the cell.

Flux, Genetic: Alterations in the cell in response to internal and external stimuli.

Flux, Metabolic: The production or decrease of metabolite(s) in an organ or individual within a period of time; it may be expressed as mole/kg/hr.

Fluxome: The complete set of metabolic fluxes within a cell. (See Almaas E et al 2004 Nature [Lond] 427:839).

FlyAtlas: Provides information on gene of interest expressed/enriched in the adult *Drosophila*. mRNA signal is provided for each gene and tissue. The homologs of many human genetic disease loci show selective expression in the *Drosophila* tissues analogous to the affected human tissues, providing a useful filter for potential candidate genes (Chintapalli VR et al 2007 Nature Genet 39:715) (<http://flyatlas.org>).

Flybase: *Drosophila* database (<http://flybase.bio.indiana.edu>).

fMet: Formylmethionine is generally the first (modified) amino acid in the translation on the ribosome of prokaryotes mediated by tRNA^{fMet-i} (i for initiator). At internal peptide sites even at prokaryotes, the tRNA^{Met-e} (e for elongation) is functional. The formylation is the duty of the methionyl-tRNA^{Met} formyltransferase. This enzyme recognizes the tRNA as the initiator by a CA mismatch at position 1–72. The eukaryotic (and Archea) initiator carries the A1–T72 base pair at the comparable site. In the mitochondria, there may be only a single type of tRNA^{Met} and that resembles the initiator type or it

may have the C1–A72 mismatch. Trypanosomal mitochondria lost their tRNA genes and imports from the cytosol all the tRNAs. Further, the mitochondria formylate some of the imported elongation tRNAs with the aid of an enzyme that is similar to formyltransferases, but has twice the mass of that of the prokaryotic enzyme. ▶formylmethionine; ▶protein synthesis; Tan THP et al 2002 Proc Natl Acad Sci USA 99:1152.

FMN: Flavin mononucleotide composed of flavin (riboflavin) phosphate and dimethylisoalloxazine base (yellow enzyme); it is a coenzyme for oxidation-reduction mediating proteins.

FMR (fragile X mental retardation): ▶fragile X chromosome

FMR1: ▶trinucleotide repeats, ▶fragile, ▶sites, ▶KH module

FMRI (functional magnetic resonance imaging): ▶MRI

FMR1 Mutation: FMR1 mutation involves the expansion of the CGG trinucleotides, which are frequently methylated on C and thus silenced. Hypermethylation of FMR1 is called *full mutation*, whereas the *premutation* is an intermediate range of expansion (50–200) of these repeats. ▶fragile sites, ▶trinucleotide repeats, ▶human intelligence, ▶KH module; Crawford DC et al 2001 Genet Med 3(5):359.

FMRFamides: Neuropeptides. (See Parker SL, Parker MS 2000 Can J Physiol Pharmacol 78[2]:150).

FMS: Feline sarcoma virus protooncogene is a receptor of colony-stimulating factor-1 [CSF] and macrophage colony stimulating factor. This gene is located in human chromosome 5q33.2–q33.3. It is involved in different types of leukemias. Its sequence is homologous to oncogene FLT, a tyrosine kinase. ▶leukemias, ▶colony stimulating factor, ▶FGR, ▶FLT, ▶protooncogene

FNR: A ferrous/ferric binding bacterial aerobic/anaerobic regulator protein with some similarity to the catabolite repressor protein. ▶catabolite repression; Moore LJ, Kiley PJ 2001 J Biol Chem 276:45744.

Foam Cells (xanthoma cells): Lipid streaks develop into foam cells, which can develop into atherosclerotic plaques and restrict the lumen of arteries, and can lead to thrombosis and myocardial infarction. ▶atherosclerosis, ▶thrombosis, ▶myocardial infarction, ▶angina pectoris

Foamy Viral Vectors: Foamy viral vectors are derived from Spuma retroviruses that may not be pathogenic for humans, although they infect many cell types in several hosts. Their carrying capacity is ~12 kb, somewhat larger than that of the murine leukemia

virus (MLV) which accepts 9–10 kb. In addition, they transduce non-dividing cells somewhat more efficiently than the MLV vectors. ►retroviral vectors; Vassilopoulos G et al 2001 Blood 98:604.

Focal Contact: An adhesion plaque on the surface of a cell that is attached to the extracellular matrix by transmembrane proteins (integrin).

Focal Dermal Hypoplasia (Goltz syndrome, FDOF): X-linked dominant lethal in males, involving atrophy, skin pigmentation in a linear pattern, papillomas (epithelial neo-plasms), polydactyly, underdevelopment of teeth, small defective eyes, mental retardation, etc. Apparently, deficiency of a putative O-acetyltransferase, regulator of Wnt signaling, is involved (Grezschik K-H et al 2007 Nature Genet 38:833; Wang X et al 2007 *ibid.* 38:836). ►skin diseases, ►cancer, ►pigmentation defects, ►polydactyly, ►eye diseases, ►mental retardation

Focus Formation: In focus formation, neoplastic (cancerous) cells grow up in dense clusters. ►cancer

Focus Forming Unit: ►FFU

Fodrin (spectrin): α -fodrin is a non-erythroid α -spectrin (a cytoskeletal protein) with the critical amino terminus of RQKLEDSY RFQFFQRDAEEL. β II-spectrins (2p21, 11q13, 15q21) are schwannomin- and other membrane-binding proteins. ►spectrin, ►Sjögren syndrome, ►schwannoma, ►neurofibromatosis; Takahashi K et al 2001 Eur J Pediatr 160:520.

Foetus: ►fetus

FOG (Friend of GATA): A multitype zinc finger protein cofactor of the GATA transcription factors. FOG facilitates the access of GATA to the transcription site. ►GATA; Tsang AP et al 1997 Cell 90:109; Pal S et al 2004 Proc Natl Acad Sci USA 101:980.

FokI: The FokI endonuclease recognizes the 5'-GGATG-3' sequence and cleaves away DNA 9 and 13 bases.

Folate: Salt of folic acid. ►folic acid

Folate Malabsorption: A defect in the transport of folate through the blood-brain barrier, resulting in anemia, movement problems, mental defects, seizures, etc.

Folate-Sensitive Fragile Site: In cultured cells in folate or thymine deficiency, the chromatin fails to condense normally.

Fold Recognition (prediction): A program that detects tertiary structure of proteins from the primary structure. ►folding, <http://bioinf.cs.ucl.ac.uk/psipred/index.html>.

Fold-Back DNA: Palindromic (inverted repeat sequences) sequences in a single strand of polynucleotides pair within the same strand (see Fig. F35).

Figure F35. DNA fold-back

Fold-Back Inhibition Site: ►FBI site

Fold-Back Transposon (FB): FBs transpose through DNA-intermediate carrying imperfect inverted repeats ranging from 300-bp to several kbp. They may or may not contain open reading frames. ►transposon, ►repeat, ►inverted, ►open, ►reading, ►frame

Folded Leaf: Protein α -helices wrapped around a hydrophobic core. ►hydrophobic, ► α -helix

Folding: A thermodynamically reversible process involving macromolecules (proteins), resulting in a functional conformational state. The folding may follow different pathways from simple two-state to sequential complex ones. Thiol (SH) \rightleftharpoons disulfide (-S-S-) conversions are generally involved. During the process of folding, the foldons assemble in a step-wise manner (Maity H et al 2005 Proc Natl Acad Sci USA 102:4741). Duplications followed by truncation and rearrangements may lead to new proteins with sufficient fitness (Peisajovich SG et al 2006 Nature Genet 38:168). ►conformation, ►chaperone, ►protein folding, ►ITCHY; Thomas PJ et al 1995 Trends Biochem Sci 20:456; Baker D, Agard DA 1994 Biochemistry 33:7505; Frydman J 2001 Annu Rev Biochem 70:603; Mirny L, Shakhnovich E 2001 Annu Rev Biophys Biomol Struct 30:361, <http://www.ebi.ac.uk/dali/>.

Foldon: The protein domain involved in folding.

Folic Acid (pteroyl glutamic acid): A water-soluble vitamin; it is required for *de novo* nucleotide synthesis and amino acid conversions. As a derivative of pteridines, it is involved in many oxidation reactions, in mediating animal coloring, and in various light reactions (see Fig. F36). Tetrahydrofolic acid is an important coenzyme. Folic acid deficiency during pregnancy may lead to congenital malformations. Experimental data indicate that the folic acid-binding FOLR1 receptor may be insufficient. Folic acid deficiency may increase single-strand and double-strand chromosome breakage (~4 million/cell) because of uracil incorporation into the DNA in place of thymine. Leukemia (ALL but not AML) and colon cancer risk may also increase, especially when at site 677 of methylenetetrahydrofolate, reductase C is replaced by T. The same genetic alteration may increase the risks of Down syndrome and various types of cancer. Diets high in fruits and vegetables

(and thus folic acid) and micronutrients such as vitamins B12, B6, niacin, C, E, and iron and zinc may be beneficial. ►fragile sites FMR1, ►methotrexate, ►aminopterin, ►phosphoribosylglycineamide formyltransferase, ►formiminotransferase deficiency, ►5,10-methylenetetra-hydrofolate dehydrogenase, ►formyltetrahydrofolate synthetase, ►homocystinuria, ►nondisjunction, ►spina bifida, ►vitamins; Ames BN 1999 Proc Natl Acad Sci USA 96:12216; Hobbs CA et al 2000 Am J Hum Genet 67:623.

F

Figure F36. Folic acid

Folksonomy: A communication system (a language) for Internet-based information retrieval by collaboratively generated labels (tags) that identify web pages and other web links. ►WEB, ►collaborative tagging. See <http://del.icio.us/>; for references: <http://www.conno-tea.org/>; find photos: <http://www.flickr.com/>.

Follicle: A small secretory sac or gland. Examples are the cell layer covering the ovary, and in botany a simple dry fruit, dehiscing along one suture and formed of a single carpel. ►ovary, ►carpel

Follicle Stimulating Hormone: ►FSH

Fölling Disease: ►phenylketonuria

Follistatin: A maternally expressed protein that by binding activin may interfere with activin-induced mesoderm formation. Follistatin-deficient mice die within hours after birth because of multiple defects indicating its requirement for several proteins of the transforming growth factor family. Follistatin regulates tooth enamel formation in balance with bone morphogenetic protein (Wang X-P et al 2004 7:719). ►activin, ►mesoderm, ►organizer, ►bone morphogenetic protein; Michel U et al 1993 Mol Cell Endocrinol 91:1; DePaolo LV 1997 Proc Soc Exp Biol Med 214:328.

Fomivirsen (Isis 2922): An antisense DNA phosphorothioate (5'-dGCGTTGCTCTTCTTC TTGCG-3') "drug" against the 55-kDa protein of the cytomegalovirus, causing RNase H degradation of the mRNA, and inhibition of human CMV replication. In addition, it may interfere with viral adsorption.

►cytomegalovirus, ►antisense technologies; Perry CM, Balfour JA 1999 Drugs 57(3):375.

Fonts: The various styles of characters and scripts that the computer can use.

Footprinting: In footprinting, fragments of 5'-labeled double-stranded DNA are partially degraded by a DNase in the presence and also in the absence of a protein that is expected to bind to certain sequences in the DNA. Subsequently, both samples (with and without the binding protein) are sequenced (Maxam and Gilbert method) and a comparison reveals the nucleotide sequences protected from DNase by the binding protein. Thus, from the path (footprints) of the DNase, the position of the binding protein is revealed. These sites may have importance for transcription initiation. In vitro *footprinting* is basically very similar to the methylation interference technique but it is performed in living cells and is followed by DNA extraction and electrophoresis. Footprinting may be used, with the aid of PCR, to identify the position of transposable elements in the genome when the PCRs are compared with the transposon-free and transposon-containing genomic tracts. ►regulation of gene activity, ►methylation interference assay, ►PCR; Fox KR, Waring MJ 2001 Methods Enzymol 340:412; Metzger W, Heumann H 2001 Methods Mol Biol 148:39; phylogenetic footprinting of prokaryotes: <http://bio.cs.washington.edu/software.html>; footprinting across phylogeny server: <http://genome.cs.mcgill.ca/cgi-bin/FootPrinter3.0/FootPrinterInput2.pl>.

Footprinting, Genetic: The role of sequenced genes without known function can be determined by inserting transposable elements (Ty) in a sequential manner and then determining the genetic consequences of the disruption. This process can screen yeast cell populations in 10^{11} range and detects a wide range of mutations of variable severity or fitness. ►Ty, ►transposon footprint, ►mutation detection

Footprinting, Evolutionary: The analysis of cis- and trans-acting regulatory elements in different species (Gumucio D et al 1996 Mol Phylogenet Evol 8:18). ►footprinting

Footprints, Transposable Element: After a mobile genetic element (insertion- or transposable element) moves, it usually leaves behind some nucleotides (as a footprint) at the original target site. ►insertional mutation, ►transposon mutagenesis, ►transposon footprint; van Houwelingen A et al 1999 Plant Cell 11:1319.

Foramen: A natural, anatomical opening or passageway.

Forbes Disease: A defect or deficiency of amylo-1,6-glucosidase and/or oligo-1,4-1,4-glucantransferase. (See under alternative name of glycogen storage disease III).

Forbidden Knowledge: A controversial concept regarding areas that we ought not to know, and research in which should be restricted. The problem lies generally not in the scientific goals but rather in the means of the inquiries. Human experimentation should be forbidden to avoid torture, exposing people to unnecessary risks, and violating human dignity or religious beliefs. In these instances, alternative but not offensive means must be adopted to arrive at the same goals. Medical procedures can be tested on animal models or in cell cultures or by in vitro molecular means. Some concepts of forbidden inquiry also have cultural or historical context, such as studies of evolution, the physical nature and origin of the universe, sexuality, and genetic engineering. Knowledge itself is not unethical or immoral, but some of the methods used or their applications in obtaining knowledge may be contrary to enlightened human standards. (See discussion in Science 308:1549 2005, ethics).

Fore Tribe: The fore tribe of New Guinea is most affected by the kuru disease because of the behavioral tradition of cannibalizing dead relatives. ► [kuru](#)

Forelock, White: A dominant autosomal human trait (a lock of white hairs in the front part of the scalp) (see Fig. F37). ► [Waardenburg syndrome](#)

Figure F37. White forelock

Forensic Genetics: Genetic studies used for legal purposes or in the judiciary courts, relying on fingerprints, blood groups, other antigens, isozymes, VNTR (variable number tandem repeats of DNA), by employing RFLP (restriction fragment length polymorphism), PCR, mitochondrial DNA, or other heritable criteria to identify biological relationship, paternity, or criminals, etc. Admitting or compelling genetic tests to the court is somewhat controversial in cases of diseases such as schizophrenia or other mental conditions, but fragile X syndrome or complex genetic traits and environmental impacts on the condition are generally more acceptable to judges (Hoffmann DE, Rothenberg KH 2005 Science 310:241). Evidence from nuclear DNA is the most

reliable. Mitochondrial DNA is important when nuclear samples are not available because of decay of soft tissues, but bone mitochondria can be extracted. The usefulness of mtDNA is more limited yet by proper analysis the information obtained may be very critical. Most of the chemical analyses require small samples of blood (60 μ L), semen (5 μ L), hair roots, saliva, or teeth. For some of the tests, dried blood or semen spots may be useful even if they are weeks, months, or years old. On the basis of polymorphic proteins, identity can be defined to higher than 99% probability and the exclusion of an individual requires much less effort. Generally, the spectrum of the protein components (separated by electrophoresis) in the sample obtained from the person to be identified is compared with the spectrum of the same protein components within the same (ethnic) population. The product of the frequencies expected by chance is compared with the actually observed data. The first test is generally for the ABO blood group but this alone rarely suffices because of the limited variations and its failure to identify all heterozygotes. Other proteins assayed for polymorphism are adenylate kinase (AK), adenylate deaminase (ADA, must be examined within six months), carbonic anhydrase (CA-II, within a week), erythrocyte acid phosphatase (EAP, within six months), esterase (EsD, within one month), glyoxylase (GLO), hemoglobin (Hb), peptidase A (pepA), phosphoglucomutase (PGM, within six months), gammaglobulin (Gm, displays about a dozen antigens determined by very closely linked genes and the clusters have different frequencies in different ethnic groups), Lewis antigens (Lea, Leb), and the rhesus antigens (47 Rh determinants, within six months). In semen samples, generally ABO, GLO, Pep A, PGM, and Le are used. If in a case of rape, the semen sample is obtained by vaginal swabs it may be contaminated by vaginal fluids (may obscure semen fluids), proteolytic enzymes (that may degrade the proteins), or the presence of bacteria may interfere with blood typing. Actually, female cells may be separated from sperm by digestion with sodium dodecylsulfate/proteinase K that does not destroy sperm. Later the sperm can also be digested in the same reaction mixture with (dithiothreitol) DTT added. The greatest specificity of identification can be obtained by analysis of the DNA in body fluids or skin or other tissue samples. The interpretation of the evidence must be carefully weighted as Bruce Weir pointed out. When it seems, on the basis of DNA evidence, that there is only one chance in a million that someone else than the defendant left the critical evidence at the scene of the crime, it should rather be said that if the defendant did not leave behind a sample there is only 1/1,000,000 chance that the observed match would be

with his DNA. The DNA profile also depends on the population concerned.

By June 1998, the Forensic Science Service in the United Kingdom had collected 320,000 DNA samples and removed from the databank 51,000 of them after the suspects were exonerated. The establishment and maintenance of such national databases—although very useful—may be quite demanding because about 30% of the male population under age 30 may have at least one felony conviction. Forensic technologies are all loaded with some degrees of error, inherent in the methods or due to the experience of the technicians. DNA evidence is the most reliable and in dermal fingerprints there may be an average of 4–6% examiner's errors. The old types of forensic technologies generally involved higher errors (Saks MJ, Koehler JJ 2005 Science 309:892). DNA fingerprints may facilitate personal identification also by comparing the databases of relatives if law permits (Bieber FR et al 2006 Science 312:1315). ►fingerprinting, ►lip-print, ►DNA fingerprinting, ►mitochondrial DNA, ►VNTR, ►RFLP, ►SNIPs, ►blood groups, ►ADA, ►PGM, ►hemoglobin, ►gammaglobulin, ►sodium dodecyl sulfate, ►Frye test, ►forensic index, ►CODIS, ►phylogenetic analysis, ►admissibility criteria; National Research Council Technology in Forensic Science by Natl Acad Sci USA, Washington, DC; Budowle B et al 2000 DNA Typing Protocols: Molecular Biology and Forensic Analysis. BioTechniques Press/Eaton Publishing Co., Westborough, Massachusetts; Masters JR et al 2001 Proc Natl Acad Sci USA 98:8012; Benecke M 2002 EMBO Rep 3:498; mt DNA: Wilson MR et al 1995 Int J Legal Med 108(2):68; population specificities: Budowle B et al 1995 J Forensic Sci 40:45; Lee HC, Tirnady F 2003 blood evidence: How DNA is Revolutionizing the Way We Solve Crime. Basic Books, New York; Budowle B et al 2003 Annu Rev Genomics Hum Genet 4:119; ethical issues in population identification: Shriver M et al 2005 Nature Genet 37:449; Cho MK, Sankar P 2005 Nature Genet 37:450; genetic identification: <http://www.fbi.gov/hq/lab/fsc/backissu/oct2002/index.htm>; <http://www.merck.com/mrkshared/mmanual/section21/chapter286/286i.jsp>.

Forensic Index: The forensic index provides statistical information regarding the probability that the evidence (E) collected at a crime scene or from other potentially incriminating object would belong to the perpetrator (P) or to a suspect (S). Let us assume that the perpetrator and the suspect have DNA (VNTR or STR) or protein profile (blood group or enzymes) A and we must find the probability for the suspect being liable for that event or fact (C). Or, we can assume the suspect and the perpetrator are different individuals

(event C'). These conditional probabilities are called L (forensic index) $\rightarrow L = \frac{\Pr(E|C)}{\Pr(E|C')} = \frac{\Pr(S=A|P=A,C)}{\Pr(S=A|P=A,C')}$

S = A indicates that the profile of S is A, i.e., the match is L times more probable if S and P are the same persons. Actually, the decisions are more complex because in the match, the relatedness within the population (population structure) must be considered. ►inbreeding coefficient, ►inbreeding and population size, ►fixation index, ►Bayes theorem, ►conditional probability, ►DNA fingerprinting, ►VNTR, ►STR, ►paternity index

Forespore: In the division of some bacteria two unequal-size products are generated: the larger mother cell and the smaller forespore. The mother cell eventually engulfs the forespore and the endospore results. After a process of maturation controlled by factors in these two components, the mother cell releases the endospore and undergoes apoptosis, whereas the endospore becomes the vegetative cell and assures its continuity by the process outlined here. ►endospore; Stragier P, Losick R 1996 Annu Rev Genet 30:297; forespore engulfment: Broder DH, Pogliano K 2006 Cell 126:917.

Forest Trees: <http://foresttree.org/fldb>.

Forestomach: The forestomach is found in mice, rats, and hamsters between the esophagus (the channel of food from the throat to the stomach) and the glandular stomach. Humans do not have it. The forestomach is a common target of chemical carcinogens.

FORKED (*f*, 1–56.7): *Drosophila* gene affecting the ends of micro-, macrochaete, and trichomes. This phenotype may be suppressed by *suppressor of forked*, *su(f)* (1–65.9) and *suppressor of Hairy wing*, *su(Hw)* (3–54.8) in an allele-specific manner. ►chaeta, ►trichome, ►cleavage stimulation factor

Forked Tongue: The forked tongue enables snakes to assess different signals (pheromones) simultaneously.

Forkhead: A family of transcription factors. ►FKH

Forma specialis: A genetically distinguishable 'race' of a pathogen that can infect primarily a particular host or a host of a defined genotype/phenotype.

Formal Genetics: ►classical genetics

Formiminotransferase Deficiency: An autosomal recessive physical retardation without mental retardation, anemia, etc., caused by oversupply of folate. ►folic acid

Formin: A large family of morphoregulatory proteins involved in the polymerization of actin cables controlling cytokinesis, cell (oocyte) polarization, limb development, etc. Formins have basically

similar features in different organisms. Profilins accelerate filament elongation by formin without the requirement of ATP hydrolysis for processivity (Kovar DR et al 2006 Cell 124:423). ▶[actin](#), ▶[profilin](#), ▶[cytokinesis](#); Leader B et al 2002 Nature Cell Biol 4:92; Kobiela A et al 2004 Nature Cell Biol 6:211; Goode BL, Eck MJ 2007 Annu Rev Biochem 76:593.

Formylmethionine: The translation initiation amino acid in prokaryotes and cytoplasmic organelles (plastids and mitochondria) of eukaryotes, but not used in the cytosol of eukaryotes. It is carried to the 70S ribosomes by a formylmethionine tRNA (tRNA^{fMet} or tRNA^{fMet}) that is distinct from the regular tRNA^{Met}. ▶[protein synthesis](#); Takeuchi N et al 2001 J Biol Chem 276:20064.

10-Formyltetrahydrofolate Synthetase: A key enzyme of folic acid metabolism. ▶[folic acid](#)

Forskolin: A diterpene isolated from the plant *Coleus forskohlii*. It is an activator of adenylate cyclase and some other mechanisms that depend on cAMP. ▶[signal transduction](#), ▶[adenylate cyclase](#), ▶[cAMP](#)

Forssman Antigen: A glycopospholipid, a ceramide pentasaccharide; it is frequently used for the identification of anti-sheep hemolysin in various animals. It has been used also to react with stage-specific and mouse embryonal carcinoma cells. ▶[hemolysis](#)

FORTAN (formula translating system): Computer languages with specific problem orientations.

Forward Chemical Genetics: Forward chemical genetics attempts the identification of new regulators of metabolic pathways and biochemical reactions and seeks molecular targets for therapeutic interventions.

Forward Mutation: Mutation from wild type to mutant allele. ▶[reversion](#)

fos: Murine osteosarcoma (chondrosarcoma) proto-oncogene, general transcription factor (AP1). The fos—jun heterodimers bind to the 5'-TGAGTCAA-3' sequence. Fos also controls complex behavioral traits such as nurturing and the development of the dorsal closure during embryogenesis in cooperation with *jun* in *Drosophila*. ▶[proto-oncogene](#), ▶[AP1](#), ▶[sarcoma](#), ▶[jun](#), ▶[apoptosis](#), ▶[FOS oncogene](#), ▶[apoptosis](#), ▶[JUN](#), ▶[transcription factors](#)

FOS Oncogene: The FOS oncogene in human chromosome 14q21–31 is homologous to the v-oncogene *fos*. The c-FOS protein is a transcription factor of the Jun family. The human FOS has a normal expression in fetal membranes almost as high as that is detectable in osteosarcomas of mouse. Products of FOS and Jun

contribute to the formation of the AP1 transcription factor and participate in multiple ways in tissue differentiation. Ca²⁺/CRE, SRE, SIE elements in the upstream regions of the gene regulate the c-FOS oncogene. These elements are under the control of neurotransmitters, neurotrophins, and cytokines, respectively. Recent studies indicate that Fos knock-outs in mice fail to nurse their pups. ▶[JUN](#), ▶[AP1](#), ▶[oncogenes knock-out](#), ▶[behavior genetics](#), ▶[apoptosis](#), ▶[CRE](#), ▶[SRE](#), ▶[SIE](#), ▶[neurotransmitters](#), ▶[neurotrophins](#), ▶[cytokines](#), ▶[signal transduction](#); Takeuchi K et al 2001 J Biol Chem 276:26077.

Fosmids: Very low, single copy number *E. coli* F replicon-based stable vectors, which are particularly useful for cloning large eukaryotic genes. ▶[F plasmid](#), ▶[vectors](#)

Fossil: Petrified remains or impression of an organism of past geological ages, preserved in the earth or rocky layers. ▶[fossil record](#), ▶[taphonomy](#)

Fossil Record: A fossil record is used to reveal the pattern of macroevolution (evolution of taxonomic categories above the species level) at the geological scale. Macroevolution was traditionally inferred from the paleontological data, the appearance of petrified taxa in the successive geological strata. The age of the remains is estimated by *radioisotope dating*. If the fossils are less than 40 thousand years old, their age is inferred from the amount of carbon-14 (¹⁴C) contained. This isotope is produced at a relatively constant rate from nitrogen-14 (¹⁴N) under the bombardment of cosmic radiation through the ages. This ¹⁴C is utilized by the organisms the same way as the more common ¹²C. The former is unstable, however, and it decays to half in each 5,730-year cycle. The amount of ¹⁴C in the organic material serves as a clock with an accuracy of ±1 to 2%. The age of fossils over 40,000 years is inferred from the age of the sedimentary rocks where the organism died (if that is the site of the fossil and it was not moved by geological changes in the strata). The age of the rocks is estimated by the decay of other isotopes. Uranium-238, e.g., decays into lead-206 with a half-life of 4.51 × 10⁹ years. Therefore, the proportion of these two elements in the rocks indicates their geological age. The evolutionary relation of the fossils can be better defined if protein and DNA analyses are also feasible. ▶[half-life](#), ▶[isotope](#)

Fossils, Genomic: Genomic fossils are inactive retroviral elements that are relics of past infections that occurred during evolution.

Foulbrood: A disease of the honeybee caused by *Bacillus alvei*. Resistance against it is based on homozygosity of two non-allelic recessive genes

determining behavior. One gene is responsible for uncapping the honeycombs when the larvae die, the other gene is responsible for the removal of the dead.
 ▶ [behavior genetics](#), ▶ [honeybee](#)

Foundation Stock: The foundation stock in rodents consists of 10–20 monogamous brother × sister pairs. This breeding/maintenance regime is necessitated so that the new, spontaneous, recessive mutations could be readily detected before they would spread through the multiplication stocks. In mice (i) breeding tests, (ii) skin grafts (immunological reaction), and (iii) biochemical tests (electrophoresis) can monitor authenticity/identity of the strain designation. In plant breeding, the elite seed from authentic registered varieties are multiplied. ▶ [multiplication stock](#)

Founder Cells: Early embryonic cells that contribute to the different cell lineages during differentiation and development. In *Caenorhabditis elegans*, five founder cells are generated during first cleavages of the embryo. The first of these cells (AB) gives rise to 389 of the total 558 nuclei present at hatching. The AB cell lineage is specified by at least five inductions before gastrulation. The inductions do not actually specify the final tissues but eight blastomeres, which contribute to the final body plan. The specification usually requires binary (0 or 1) switches. In the mature seed of *Arabidopsis*, there are 12–16 founder cells. ▶ [morphogenesis](#), ▶ [blastomere](#), ▶ [cell lineage](#), ▶ [fate map](#), ▶ [gastrula](#)

Founder Effect: Same as founder principle.

Founder Mouse: A chimeric animal obtained after transformation that may or may not involve the germline. ▶ [chimera](#), ▶ [germline](#), ▶ [microinjection](#)

Founder Principle: A new population descends from a limited number of immigrants (because of sampling error), resulting in genetic drift. It is called also founder effect. ▶ [effective population size](#), ▶ [drift genetic](#), ▶ [porphyria variegata](#)

Four-Cluster Analysis: A procedure for determining the evolutionary relationships among four large groups of organisms such as animals, plants, fungi, and protists without considering variations within each of

these groups. If we designate the four monophyletic groups as A, B, C, and D, three unrooted evolutionary trees can be generated. These are $T_1 = [(AB)(CD)]$, $T_2 = [(AC)(BD)]$, and $T_3 = [(AD)(BC)]$ from which one is expected to be correct on the basis that the correct construct would have the shortest sum of tree branch length. The three sums of branch lengths may be designated as S1, S2, and S3. An appropriate algorithm determines the differences S1-S2, S1-S3, and S2-S3. ▶ [evolutionary distance](#), ▶ [evolutionary tree](#), ▶ [least square methods](#), ▶ [neighbor joining method](#), ▶ [unrooted evolutionary trees](#); Rzhetsky A et al 1995 Mol Biol Evol 12:163.

Four-Gamete Test: The four-gamete test reveals in biallelic, linked two loci populations whether recombination occurred and all possible four products *AB*, *Ab*, *aB*, and *ab* are present. The proportions may be biased by differences in selective values, random drift, and possibly even by mutation. ▶ [recombination](#), ▶ [linkage](#), ▶ [disequilibrium](#)

Four-Hybrid System: A construct suitable for the activation of specific genes such as *HIS* or *lacZ* (see Fig. F38). The Cyclin, CDK, and MAT1 stable system is part of the general transcription factor TFIID or the cell cycle and the interaction turns on genes in the presence of the target protein X and the VP16 activator. ▶ [MAT1](#), ▶ [transcription factors](#), ▶ [VP16](#), ▶ [LexA](#), ▶ [two-hybrid system](#); Sandrock B, Egly J-M 2001 J Biol Chem 276:35328.

Fourier Method: ▶ [FT-IR](#)

Four-O'clock: ▶ [Mirabilis jalapa](#)

Foveal Dystrophy: An autosomal dominant lesion of the macula in the eye fundus that occurs along with aminoaciduria. ▶ [macula](#), ▶ [eye diseases](#)

Fox: These canid species are quite variable genetically and by chromosome number (see Figs. F39 and F40). *Vulpes velox* (kit fox) 2n = 50; *Vulpes vulpes* (red fox) 2n = 36; *Vulpes fulva* (American red fox) 2n = 34; *Urocyon cinereoargenteus* (gray fox) 2n = 66; *Otocyon megalotis* (bat-eared fox) 2n = 72; *Lyalopex vetulus* (hoary fox) 2n = 74; *Cerdocyon thous* (crab-eating fox) 2n = 74. The fur color varies from red to

Figure F38. Four-hybrid system

gray or grizzled. The Arctic fox is gray in the summer and white during winter. The ear size varies according to the ecological home of the species. The Arctic fox (*Alopex lagopus*) has shorter ears than the red fox, while the African fox (*Otocyon megalotis*) has much bigger ears. ▶wolf, ▶FKH

Figure F39. Fox

Figure F40. Red Fox

Fox (human homolog of forkhead): This family of transcription factors regulates the immune response, metabolism, and cell proliferation. Mutant Foxj1 is involved in systemic autoimmune inflammation. Foxo activation may lead to muscular atrophy. Acetylation of Foxo 1 by CREB-binding protein and NAD-dependent histone deacetylase silent information regulator 2 attenuates its ability to bind to DNA and sensitivity to phosphorylation (Matsuzaki H et al 2005 Proc Natl Acad Sci USA 102:11278). MST1/CST-1 and FOXO transcription factors can mediate oxidative stress and longevity (Lehtinen MK et al 2006 Cell 125:987). ▶autoimmune, ▶immune system, ▶Langerhans islets, ▶CREB, ▶histone deacetylase, ▶ecdysone, ▶longevity, ▶oxidative stress, ▶FKH, ▶transcription factors; Lin L et al 2004 Science 303:1017; Accili D, Arden KC 2004 Cell 117:421.

FPC: Finger-printed clone.

F-Pili (or F-pilus or sex pilus): The bacterial cell appendage that forms the conjugation tube through which the F element, conjugative plasmids, and the

Hfr bacterial chromosome is mobilized into the F⁻ cells. ▶F factor, ▶sex factor, ▶Hfr, ▶conjugation; Anthony KG et al 1999 J Bacteriol 181:5149.

FPR (FKB): ▶peptidyl-prolyl isomerase, ▶FK506

FPS (fixed pairing segment): A hypothesis that in eukaryotes, recombination is not entirely random but occurs in tracts which are either fixed at both, or one end, or in the middle. During a single meiosis, only a fraction of these segments pair and there is positive interference in their vicinities. ▶interference

fps: Chicken sarcoma oncogene. ▶sarcoma

FRA: FRA forms active heterodimer with Jun in the AP activator protein. ▶AP1

Fractals: Fractal geometry is considered to describe chaotic systems such as the complexities of many biological phenomena. Fractals emerge from interaction of self-similar entities. The two-dimensional squares can be resolved into many squares and the three-dimensional cubes into many smaller identical-looking cubes. Irregular shape objects also have self-similar fractions but they cannot be adequately described like the square or cube in two or three dimensions, but their characterization requires fractals—such as e.g., 2.2—rather than integers. ▶chaos, ▶networks; Song C et al 2005 Nature [Lond] 433:392.

Fractalkine: A CX3C type chemokine. ▶chemokines, ▶acquired immunodeficiency

Fraction 1 Protein: The old name of ribulose biphosphate carboxylase/oxygenase enzyme that is the largest single protein encoded by the plastid and forms about 50% of the proteins in the chloroplasts. ▶rubisco

Fractional Mutation: Fractional mutation displays mosaicism (variegation) in the tissues of the body. If the mutation was induced in the germ cells, it indicates that the mutagenic agent was associated with only one strand of the DNA and therefore mutant and non-mutant sectors arose and DNA repair occurred during the post-fertilization stage. Fractionals may also be due to unstable genes, mitotic recombination, nondisjunction, transposable elements, etc. ▶unstable genes, ▶mitotic recombination, ▶gene conversion, ▶nondisjunction, ▶transposable elements; Altenburg E, Browning LS 1961 Genetics 46:203.

Fractionated Dose: Irradiation is provided not in a chronic manner but with interruptions between each exposure although the doses are summed up. ▶chronic radiation

Fragile Sites: FRA occur in several human chromosomes (see Fig. F41). The overall frequency of autosomal fragile sites is about 2×10^{-3} .

Figure F41. Fragile site

F

Generally three types are distinguished: (i) folate sensitive [shows up if the cell culture medium is deficient in folate], (ii) elevated pH triggers their appearance and (iii) 5-bromodeoxyuridine (BdUR) is required for expression. The best studied is the fragile X syndrome. Fragile sites have been identified also at 2q11, 3p14.2, 6p23, 9p21, 9q32, 10q23 (folic acid sensitive), 10q 25 (BdUR sensitive), 11q23, 12q13, 16 p12, 16q22 (appeared only in the presence of Epstein-Barr virus [EBV] antigen), 17p12, and 20p11. Idiopathic (17q21.31) or fragile site (Xq27.3) mental retardation is known. The fragile sites are generally dominant and involve overlapping syndromes such as mental retardation, cancer susceptibility, and other symptoms. In the fragile X syndrome, the number of CGG repeats may run into hundreds whereas under normal conditions only about 30 repeats are found. In Friedreich's ataxia, GAA repeats are found in the introns of the frataxin gene. Five neurological disorders, spinal and bulbar muscular atrophy (Kennedy disease), spinocerebellar ataxia (olivopontocerebellar atrophy) Type 1, Huntington's chorea, dentatorubral-pallidoluysian atrophy, and Machado Joseph disease display poly CAG sequences within their genes and encode polyglutamine. Myotonic dystrophy is accompanied by CTG repeats in the untranslated last exon of a protein kinase gene. The recessive myoclonous epilepsy (human chromosome 21) contains multiple repeats at the 5' and 3' area of the promoter of the cystatin B gene. Fragile sites may occur upon incorporation of double minutes into the chromosome. Hypoxia favors the formation of fragile sites. Fragile sites seem to promote gene amplification and remodeling of the genome. In cancer, the most commonly amplified sites involve oncogenes ERBB, RAS, KRAS, MYC, and genes controlling the cell cycle. Fragile sites in humans and mice show rather high homology and conservation. In yeast, a pair of Ty elements are the preferred sites for double-strand breaks when DNA replication is compromised (Lemoine FJ et al 2005 Cell 120:587). When replication is inhibited by aphidicolin or condensation of the chromosome is promoted by calyculin (an inhibitor of phosphatases 1 and 2A), breaks may occur as a consequence of tension that may be

the source of cancer (Achkar EE et al 2005 Proc Natl Acad Sci USA 102:18069) (see Fig. F42).

Figure F42. Calyculin

Fragile X Chromosome (FRAXA): FRAXA displays poorly stainable sites under the light microscope. These sites are liable to breakage and may result in mental retardation and cancer. The affected individuals have also shown macrocephaly (large head), prominent jaws, macroorchidism (enlarged testes), and a high-pitched funny voice. The condition is caused by folate deficiency leading to low levels of thymidylate. It involves amplification (up to >200) of a CGG repeat in the FMR-1 (fragile site mental retardation) gene (at Xq27.3, Martin-Bell syndrome) that occurs in human populations at a frequency of ~1/1,250–4,000 in males and 1/2,500–6,000 in females. Under normal conditions, there are 6–50 of the repeats and in fully expressed FRAXA the number of repeats exceeds 200, which may become methylated later. When the number of repeats is between 50 and 200 (unmethylated, pre-mutation), there is ~50% risk for full expression in the progeny of females but not in the immediate offspring of males. The CGG tracts, usually after 8–12 repeats, are interrupted by AGGs, generally by two but sometimes by three. The AGG interruptions are key elements in the instability of the CGG sequences. These sequences stall the translation of the FMR mRNA and this seems to be the major cause of mental retardation (Napierala M et al 2005 Nucleic Acids Res 33:451). The FMR protein complex apparently

modulates actin dynamics, which is a key process in the morphogenesis of dendritic spines and synaptic structures in the brain (Castets M et al 2005 Hum Mol Genet 14:835). The pre-mutational condition is not always revealed by the phenotype but can be detected by Southern blotting or by PCR. Pre-mutational individuals may display cognitive and/or behavioral deficits and other neurodegenerative disorders of adult carriers as well as premature ovarian failure (Hagerman PJ, Hagerman RJ 2004 Am J Hum Genet 74:805). Pre-mutational transcripts, which are not translated into protein, and are expressed in the neurons, can cause RNA-induced degeneration (Zarnescu JP et al 2003 Neuron 39:739). Methylation and deacetylation of histones H3 and H4 and gene silencing follow the amplification. Treatment of the fragile X cells with 5-aza-2'deoxyctidine restores transcription. In a *Drosophila* model, the fragile X syndrome was treated with metabotropic glutamate receptor antagonists or lithium and the cognitive defects and courtship behavior were restored (McBride SMJ et al 2005 Neuron 45:753). Fragile X syndrome results in the absence of the RNA-binding FMR protein. The fragile X mental retardation seems to be physiologically linked to the RNA-induced silencing complex of RNAi (Gaudy AA et al 2002 Genes Dev 16:2491). The FRAXA protein (FMRP) defects appear to interfere with the translation template and thus with translation. FMRP binds intramolecular G quartets and this may result in dysregulation of the mRNA. FMR1 promoter is not active in FMR1 mental retardation and histone organization is also affected (Gheldof N et al 2006 Proc Natl Acad Sci USA 103:12463).

Trichostatin restores acetylation of H4 but that of H3 only minimally, and would not result in transcription. The males are predominantly affected (80%); about 1/3 of the carrier females are also mentally retarded. Usually, 20% of the males with this X-chromosome are phenotypically normal and their daughters are also normal but their grandsons display the chromosome and the phenotype. Prenatal diagnosis is feasible. On folate-deficient cell culture media, the critical X-chromosome displays a constriction at the Xq27-p28 site. Other fragile sites may account for some of the less common forms of the disease. Fragile X knockout mice could be normalized to some extent by enriched environment and the treatment increased the AMPA receptor too (Restivo L et al 2005 Proc Natl Acad Sci USA 102:11557). Fragile X Tremor/Ataxia syndrome (FXTAS) is a disease with the occurrence of progressive tremors and a decline in cognitive functions. It seems to be caused by increasing level of CGG repeats in the FMR mRNA, a premutation. The age of onset of the disease is about 50 years. Initially, the patients are

diagnosed with Parkinson disease. It afflicts men more frequently than women. Mothers of fragile-X males are generally the carriers of FXTAS. The incidence in the general population is about 1/3,000 men. Postmortem studies indicate protein inclusions in the neurons and in astrocytes of the diseased individuals.

►fragile sites, ►mental retardation, ►Jacobsen syndrome, ►trinucleotide repeats, ►head/face/brain defects, ►histones, ►azacytidine, ►trichostatin, ►histone deacetylase, ►Southern blot, ►PCR, ►G quartet, ►AMPA, ►astrocyte; Tassone F et al 2000 Am J Hum Genet 66:6; Toledano-Alhadeff H et al 2001 Am J Hum Genet 69:351; Li Z et al 2001 Nucleic Acids Res 29:2276; Brown V et al 2001 Cell 107:477; Darnell JC et al 2001 Cell 107:489; Dombrowski C et al 2002 Hum Mol Genet 11:371; pathophysiology: Penagarikano O et al 2007 Annu Rev Genomics Hum Genet 8:109.

Fragile X Syndrome: ►fragile X chromosome

Fragment: A gap-free, contiguous tract of the genome without any alien insert.

Fragment Recovery Probability: The fragment recovery probability indicates the number of genomic fragments to be screened in order to recover a desirable one with a chosen probability. Probability = $1 - (1 - f)^n$, where f = the size of an average fragment divided by the size of the genome, n = the required number of fragments to be cloned. Example: $P = 0.95$, average fragment size 1×10^6 Da, and the size of the genome is 2.6×10^9 Da. Then: $n = \ln(1 - P)/\ln(1 - f) = \ln(0.05)/\ln[1 - (1000000/2600000000)] \approx 7787$, i.e., about 7,787 clones will include the wanted one by a probability of 95%. ►restriction enzymes, ►DNA library

Fragmentation Ladder: A collection of peptide fragments of different length but common terminus. These can be produced during mass spectrometric analyses. ►mass spectrometry

Fragmentin-1: A cytotoxic serine protease; it can trigger apoptosis in combination with perforin. ►perforin, ►apoptosis, ►ICE, ►granzyme, ►RNK1-1; Jans DA et al 1998 J Cell Sci 111:2645.

Fragmentin-2 (granzyme B): Cytotoxic T cells and natural killer lymphocytes destroy their targets with the cooperation of perforin and fragmentins. ►fragmentin-1, ►T cells; Jans DA et al 1996 J Biol Chem 271:30781.

Fragrances: Fragrances occur in all types of organisms and serve various adaptive purposes. Among animals, the pheromones are a means of communication and are used both as attractants and repellents. In plants, the fragrances may be the means of aiding

Figure F43. *Levandula*

pollination or dispersal but also as insect repellents. Chemically, the fragrances are diverse. Many plant fragrances are mono-terpenes such as citral, thymole (in thyme), linalol, and 1,8-cineol (in lavender). In the *Menthas* carvon, piperitones, menthone, menthole, and terpene rings represent the scents. In the *Eucalyptus* species, geraniols and cineols occur. In petunia plants, benzenoids convey the sweet fragrance emitted in the evenings and night. It is regulated by gene ODORANT1, a member of the MYB family. The same gene can activate also the promoter of 5-enol-pyruvateshikimate-3-phosphate synthase involved in flower pigment synthesis (Verdonk JC et al 2005 Plant Cell 17:1612). In the majority of the species of plants, the fragrances represent chemical complexes. Their inheritance is usually complex and frequently in the hybrids, the parental fragrances are hard to recover. By inserting the linalol synthase gene into snapdragon, bergamot scent was expressed. ▶pheromones, ▶olfactogenetics,

▶shikimic acid, ▶bergamottin, ▶taste; Vainstein A et al 2001 Plant Physiol 127:1383; evolution of flavors and scents: Gang DR 2005 Annu Rev Plant Biol 56:301; plant and fungal volatiles and physiological roles: Science 311:803–819 [2006].

Fraility: Fraility is the unobserved heterogeneity among the individuals in a population or family that affects the survival times and may seriously affect the relative risk between or among groups, especially under certain stress conditions.

Frameshift Mutation: Insertion or deletion of bases changing the reading frame of the code words, leading to new amino acid sequences from the site toward the carboxyl end of the polypeptide (see Fig. F44). If one or two bases are either lost or gained, the genetic message from that site is generally garbled, whereas if the loss or gain involves triplets there is a possibility to continue reading in a normal manner. Frameshift mutations are caused frequently by acridine dyes and cross-linking mutagens. The discovery of frameshift mutagens contributed to the recognition that the genetic code relies on nucleotide triplets. Frame shift mutation can be represented by the following folly:

Frameshift can also occur post-transcriptionally during translation and can produce two proteins with overlapping sequences by modification of tRNA at the E site in viruses and in eukaryotes (Bekaert M, Rousset J-P 2005 Mol Cell 17:61). ▶mutation, ▶base substitution, ▶deletion mutation, ▶duplication, ▶insertional mutation, ▶genetic code, ▶codon, ▶reading frame, ▶SNIPS, ▶acridine dye, ▶cross-linking; Crick FHC, Brenner SJ 1967 J Mol Biol 26:361; Farabaugh PJ 1996 Annu Rev Genet 30:507; Hoffmann GR et al 2001 Mutation Res 493:127.

Frameshift Suppressor: Generally, insertion(s) or deletion(s) of nucleotides that are capable of restoring the normal reading frame within the gene. ▶frameshift mutation, ▶suppressor mutation, ▶reading frame

Frameshift, Translational: ▶overlapping genes

Frameshifting, Ribosomal: The ribosome changes the frame of reading of the mRNA. In some cases, it is

| | |

| Deletion & shift | JOE AND BOB ATE THE BIG HOT DOG AND IDN OTS IPI CET EA (lost D) |
| Addition restores | |
| meaning behind it | JOE AND BOB ATE THE BIG HOT DOG AND IDN OTS SIP ICE TEA (gained S) |

Figure F44. Frameshift mutation

called programmed frameshift because it is an efficient feature of the ribosome. Frameshifting occurs in viruses, prokaryotes and eukaryotes. It can shift upstream (−1) or downstream (+1) or it can even hop over a certain tract of nucleotides. As a consequence, the reading of the message may be normal in the upstream and downstream regions except the short tract involved in frameshifting. The protein product may appear as if it were based on two overlapping reading frames of the DNA. This mechanism can correct for frameshift mutations; its overall frequency has been estimated to 3×10^{-5} but in some gene its frequency may be much higher (Farabaugh PJ 1996 *Annu Rev Genet* 30:507). Pseudoknots may block the entry of the mRNA entrance to the ribosome and in the process, hinder the translocation of the mRNA and cause a deformation of the tRNA at the ribosomal P site. Also, it can affect the elongation factor eEF-2 (Namy O et al 2006 *Nature [Lond]* 441:244). ▶frameshift mutation, ▶eEF-2, ▶pseudoknot, ▶ribosome

Framework Amino Acids: The framework amino acids of antibodies secure the scaffolding of the hypervariable region but do not involve the CDR sequence. ▶antibody, ▶immunoglobulins, ▶CDR; Holmes MA et al 2001 *J Immunol* 167:296; Jung S et al 2001 *J Mol Biol* 309:701.

Framework Map: The framework map includes several (or only one) collection(s) of genes or DNA sequence groups (RFLP, microsatellites) that are used to position loci or sequences (STS) relative to these panels. ▶STS, ▶microsatellite, ▶RFLP, ▶radiation mapping, ▶skeletal map

Francisella tularensis: A bacterium has Gram-negative strains that cause tularemia, it is potentially a very dangerous agent of bioterrorism. It has two genes, *tolC* and *ftlC*, which determine multiple drug resistance. A sequence-defined, near-saturation transposon mutant library of *F. tularensis novicida*, a subspecies that causes a tularemia-like disease in rodents revealed 16,508 unique insertions, an average of >9 insertions per gene, which is a coverage nearly twice that of the greatest previously achieved for any bacterial species. Insertions were recovered in 84% (1,490) of the predicted genes. An analysis of genes lacking (or with few) insertions identified nearly 400 candidate essential genes, most of which are likely to be required for growth on rich medium and which represent potential therapeutic targets (Gallagher LA et al 2007 *Proc Natl Acad Sci USA* 104:1009). ▶bioterrorism, ▶biological weapons, ▶insertion elements; Gil H et al 2006 *Proc Natl Acad Sci USA* 103:12897; genomics: <http://bbrp.llnl.gov/bbrp/html/microbe.html>.

FRAP (TOR, RAFT1): ▶FK506

FRAP (fluorescence recovery after photo bleaching): In FRAP, cells are stained by fluorochromes and bleached locally by laser beams to study the organization of nuclei, diffusion of various proteins, and viscosity within the cell. ▶FRET, ▶FCS; Lippincott-Schwartz J et al 2001 *Nature Rev Mol Cell Biol* 2:444.

Fraser Syndrome (FRAS1, FS1, human chromosome 4q21): A heterogeneous malformation (4 loci in mouse) involving cryptophthalmos (eyeball is hidden by skin without differentiated eyelids), syndactyly, and kidney defects. The FS1 locus encodes mutations affecting the extracellular matrix by premature termination of this protein. The locus is homologous with *bl* in mice. The FS1 protein, the glutamate receptor interaction protein (GRIP1), and the cytoplasmic multi-PDZ scaffolding protein seem to jointly affect the Fraser symptoms (Takamiya K et al 2004 *Nature Genet* 36:172). ▶PDZ, ▶extracellular matrix, ▶cryptophthalmos; McGregor L et al 2003 *Nature Genet* 34:203.

Fraser-Like Syndrome (FREM2, 13q13.3): FREM2 syndrome is a heterogeneous disease and in mouse at least five loci exist (Jadeja S et al 2005 *Nature Genet* 37:520). ▶kidney disease, ▶genital anomaly syndromes, ▶hypertelorism, ▶Wilms tumor, ▶Denys-Drash syndrome

Frasier Syndrome (WT1, 11p13): A rare dominant/recessive male pseudohermaphroditism and progressive glomerulopathy displaying normal female external genitalia, streak gonads, and XY karyotype. It involves facial anomalies (hypertelorism), underdeveloped kidneys, fusion of the labia pudendi (the fleshy borders at the mons pubis of the external female genitalia), enlargement of the clitoris (the female erectile body [homologous to the penis of males]), defective fallopian tubes (connecting the ovaries with the uterus) and ovaries, etc. The affected individuals frequently develop gonadoblastoma. It is a mutation of the Wilms tumor gene. The WT1 gene encodes a zinc finger transcription factor. ▶kidney disease, ▶gonadoblastoma, ▶genital anomaly syndromes, ▶hypertelorism, ▶Wilms tumor, ▶Denys-Drash syndrome; Zugor V et al 2006 *Aktuelle Urol* 37 (1):64; Niaudet P and Gubler MC 2006 *Pediatr Nephrol* 21:1653.

Frataxin: ▶Friedreich ataxia

Fraternal: Fraternal refers to brothers; it is also used to describe dizygotic twins as fraternal twins, even when

one or both of the twins are girls (in the latter case, the biologically correct usage should be “sororal twins” but it is not used). ▶twins, ▶twinning

Fratricide (allolysis): Bacteria can evolve by taking up foreign DNA by a process of transformation. The DNA uptake is regulated by a quorum-sensing pathway and becomes competent for DNA internalization. Before reaching this state, the cells release a competence-stimulating peptide (CSP) into the environment. Genes of the *Com* operon (*ComDE*) sense CSP and further stimulate its expression. About two-dozen genes of the more than 100 *Com* are involved directly in the uptake. After secretion of CSP, the competent cells release the product of the *cibC* gene, *CibAB* (competence-induced bacteriocin). This bacteriocin lyses non-competent cells by the production of a hemolytic factor Ply. Ply also signals to the host through Toll-like receptor 4. The lysis of the fraternal cells apparently improves the fitness of the resistant cells by cannibalizing the contents of the lysed cells and making genetic transformation easier. Such fratricide occurs in *Streptococcus pneumoniae* and *Bacillus subtilis* (Guiral S et al 2005 Proc Natl Acad Sci USA 102:8710). ▶quorum, ▶sensing, ▶lysis, ▶bacteriocin, ▶transformation genetic, ▶competence of bacteria, ▶*Streptococcus pneumoniae*, ▶*Bacillus subtilis*

FRAX: Fragile X chromosome. ▶fragile X syndrome

FRAXA: ▶fragile X syndrome

FRAXE: A fragile X syndrome associated with the long arm of the human X chromosome based expansion of CCG repeat tracts and hypermethylation of a CpG island, resulting in a rare form of mental retardation. ▶trinucleotide repeats

Frazzled (*fra*, chromosome 2 of *Drosophila*): A netrin receptor expressed all over the embryo and one that distributes netrin in a pattern different from the place of expression of netrin. ▶netrin

Freckles: Freckles are ephelides, which are small, pigmented spots occurring usually on young, fair-skinned redheads or blonds and usually show up less conspicuously later. Solar lentigines are due to spotty photo-damage and increase in frequency with age (age spots). Stimulation of the melanocortin-1 receptor (MC1R, 16q24.3) by the α -melanocyte-stimulating hormone and pro-opiomelanocortin peptides may lead to increased synthesis of the black eumelanin instead of the red pheomelanin. The latter may promote the synthesis of free radicals in response to ultraviolet exposure and increase the risk of melanoma. There is substantial variation among MC1R alleles and susceptibility to melanoma.

Freckles may be due also to other several genes. ▶lentigine, ▶melanocyte, ▶melanocortin, ▶opiomelanocortin, ▶melanoma, ▶xeroderma pigmentosum; Bastiaens M et al 2001 Hum Mol Genet 10:1701.

Free Energy (G): The energy that can be obtained from a system for other purposes. Metabolism can accumulate energy by synthesis of ATP, which in turn drives many cellular processes. ▶entropy, ▶enthalpy, ▶ATP

Free Radical: An atom or group of atoms with an unpaired electron, and is therefore extremely reactive. Free radicals may be produced by exposure of wet tissues to ionizing radiation and thus leading to physiological and genetic damage of the cells. ▶superoxide, ▶ROS

Freeman-Sheldon Syndrome (arthrogryposis): is characterized by deformities (contractures) of the limbs, face, and other structures. Mutations (MYH3, 17p13.1) in the embryonic myosin heavy chain can account for it (Toydemir RM et al 2006 Nature Genet 38:561). One form has been mapped to human chromosome 5.5-pter-15p1. Distal arthrogryposis (Sheldon-Hall syndrome) displays clinical symptoms of finger and toe abnormalities (clenched fist, camptodactyly, etc) caused by defects in troponin, and is encoded at 11p15.5 or by myosin heavy chain 3 (MYH3). ▶arthrogryposis, ▶camptodactyly, ▶troponin

Freemartin: A somewhat masculinized sterile bovine (cattle, sheep, goat, pig, etc.) female born as twin with a male. The sterility is attributed to the circulation of blood containing male-specific antigens and hormones (see Fig. F45). Freemartins do not occur in humans, although women treated with male hormones to prevent miscarriage have been reported to

Figure F45. Somewhat masculinized freemartin cow

deliver female babies that after puberty might have shown some secondary virile characteristics. Hormonal interactions between opposite-sex human fetuses known to influence female morphology and behavior can also have negative effects on daughter fecundity and, hence, maternal fitness (Lumma A et al 2007 Proc Natl Acad Sci USA 104:10915).

The exact origin of the term is unclear. In old English, a spayed heifer (neutered bovine female) was called martin. Also, St. Martin has been regarded as a protector of rogues (off-type creatures, deviants). In Scottish, ferry-cow means a cow [temporarily] barren. ►hormones in sex determination, ►puberty, ►spaying; Ennis S et al 1999 Res Vet Sci 67:111; Kobayashi J et al 1998 Mol Reprod Dev 51(4):390; Vigier B et al 1988 Reprod Nutr Dev 28(4B):1113.

Freeze Drying (lyophilization): A procedure for the preservation of biological specimens, bacteria, and enzymes that involves freezing at about -50°C and dehydrating under high vacuum in a specially constructed equipment. The preserved samples are usually sealed in glass under vacuum for further storage. Generally, the activity of the enzymes is well maintained and the bacterial cells can be revived even after years of storage. Animal sperm may be preserved this way, stored at room temperature and used for fertilization by intracytoplasmic injection into eggs.

Freeze Etching: Freeze etching is different from freeze fracture inasmuch as it allows the electronmicroscopic study of membrane surfaces rather than internal structures. The specimens are frozen in liquid nitrogen, the material is cracked, and the water is removed by sublimation in a freeze dryer. The etched parts are shadowed and viewed in the electron microscope. An improved version of this procedure involves *rapid freezing* with a copper block (-269°C , liquid helium) after being slammed against it and then lyophilized. This way the internal cell parts and filaments can be well visualized. ►freeze drying, ►electronmicroscopy, ►membranes

Freeze Fracture: A technique for preparing membrane-containing specimens for electronmicroscopic examinations. The specimen is frozen in liquid nitrogen under the protection of antifreeze (cryoprotectant) to prevent ice crystal formation and concomitant distortion. After cracking the frozen blocks, some surfaces of the broken pieces expose the interior of cellular membrane bilayers. The membrane faces are then shadowed with platinum, and after the organic material is removed, it can be viewed by electronmicroscopy. ►electronmicroscopy, ►shadowing, ►membranes

French Pressure Cell: Used for breaking up cell suspensions in combination with a hydraulic press at $\sim 20,000$ lb/inch pressure.

Frequency-Dependent Selection: ►selection types, ►apostatic selection

Frequency Distribution: Representation of a population in classes according to the frequency of individuals in each class. ►normal distribution, ►Poisson distribution, ►negative binomial

Frequentist: A statistical test of the likelihood of a hypothesis by weighting the number of supporting hypotheses against all hypotheses tested. (See Schimek MG 2004 Methods Inf Med 43:439).

FRET (fluorescent resonance energy transfer): A fluorophore donor molecule, which has an absorption maximum at a shorter wavelength, can be excited and then can transfer the energy of an adsorbed photon non-radioactively to an acceptor molecule which has an excitation maximum at a longer wavelength. The distance over which FRET can be measured is about 40 to 100 Å, and in general it depends on the 1/6 power of the distance but it is modified by several factors. This technology enables visual monitoring of protein interactions. ►fluorochromes, ►DABCYL acid, ►two-hybrid system, ►FRAP, ►FCS, ►nanotechnology; Periasamy A, Day RN 1999 Methods Cell Biol 58:293; Jares-Erijman EA, Jovin TM 2003 Nature Biotechnol 21:1387.

Freund Adjuvant: is a water—light-weight mineral oil emulsion. An antigen is added into water phase and the oil phase contains an emulsifier. Sometimes dry, dead *Mycobacterium butyricum* is also added to the oil. This preparation boosts the immune reaction in case of weak or small amounts of the antigen. ►antigen

Friedreich Ataxia (FRDA): FRDA, along with optic nerve atrophy and deafness, is an autosomal dominant disease at 6p23. An autosomal recessive form (9q13) is a rare ($\sim 2 \times 10^{-5}$) brain-spinal chord degenerative malfunction, characterized by hypoaffective knee and ankle jerks, poor coordination of the limbs, spasms, etc. The heterozygosity for the recessive form is as high as $\sim 10^{-2}$. Most of the cases are point mutation in the gene encoding the 210 amino acid frataxin iron-binding protein, but this condition frequently involves GAA repeats in the first exon/introns. The normal range of the FRDA repeats is 7–22 but in disease this increases to 200–900 or more. The increase of the trinucleotide repeats interferes with transcription. Some special polyamides may increase transcription by altering DNA conformation of genes with GAA repeats or by chromatin opening (Burnett R et al 2006 Proc Natl

Acad Sci USA 103:11497). The DNA forms a triplex structure, which leads also to increased mutability. The defect is concerned with a phosphatidylinositol-4-phosphate kinase and mitochondrial iron homeostasis. Frataxin may be associated with insulin resistant diabetes. The critical protein has been located to the mitochondria where it increases the concentration of iron and decreases respiration; it is an iron protein chaperone and protects aconitase (Bulteau A-L et al 2004 Science 305:242). The accumulated iron reacts with H_2O_2 resulting in lesions to proteins, lipids and mtDNA. ▶ **fragile sites**, ▶ **ataxia telangiectasia**, ▶ **epilepsy**, ▶ **phosphatidylinositol**, ▶ **trinucleotide repeats**, ▶ **diabetes**, ▶ **AVED**, ▶ **aconitase**; Bradley JL et al 2000 Hum Mol Genet 9:275; Patel PI, Isaya G 2001 Amer J Hum Genet 69:15; Salkamoto N et al 2001 J Biol Chem 276:27171; Puccio H, Koenig M 2002 Current Op Genet Dev 12:272.

Friend Murine Leukemia: Friend Murine leukemia is caused by the replication competent helper virus, F-MuLV (Friend murine leukemia RNA virus) and the replication-defective spleen focus-forming virus (SFFV). Pathogenicity depends on the chimeric SFFV envelope protein, gp55 in the presence of the erythropoietin receptor. Susceptibility is controlled by several Fv (Friend virus) loci. ▶ **FMS**, ▶ **oncogene**, ▶ **leukemias**

Frizzled: The *frizzled* gene determines the orientation of the hair follicles and its mutation leads to waves, whorls, and tufts, each comprising many hundreds of hairs in mice. ▶ **polarity**, ▶ **Wingless**; Strutt DI 2000 Mol Cell 7:367.

Frog: *Rana pipiens* $2n = 26$, *Rana temporaria* $2n = 26$. *R. esculenta* and *R. catesbeiana* are considered food delicacies, but some toads secrete poisonous or irritating substances as a defense. ▶ **toad**; <http://vize222.zo.utexas.edu/frog.html>.

Frond: A leaf-like thallus of lichens or leaves of ferns.

Frontonasal Dysplasia: Sporadic, multifactorial, or dominant head lesions (cranium bifidum), hypertelorism; it is frequently associated with other syndromes. ▶ **cranium bifidum**, ▶ **hypertelorism**

Frontotemporal Dementia and Parkinsonism: ▶ **Pick disease**

FRP: A human phosphatidylinositol kinase. ▶ **PIK**

FRS: Fos-regulating kinase. ▶ **FOS**

Fructanes: Fructose polymers in plants. ▶ **inulin**

fru (fruitless): *Drosophila* mutation determining courtship behavior of males. It is not expressed in females. It is involved with male-specific neural circuitry in

the brain (Kimura K-I et al 2005 Nature [Lond] 438:229). ▶ **sex determination**, ▶ **pheromones**

Fructose: A monoketo-hexose, present in the disaccharide saccharose. It plays key roles in metabolism through phosphorylated derivatives (fructose-1-phosphate, fructose-6-phosphate, fructose-1,6-bisphosphate, etc.). Fructose utilization is not impaired in diabetes (see Fig. F46). Fructose is about twice as sweet-tasting as glucose and its use may reduce the caloric intake. The “corn sweeteners” contain fructose, industrially produced from starch. Fructose and fructose-containing food and beverages, especially at acid pH and by heating or just by long storage may liberate furans, furaldehyde, and levulinic acid that may be toxic. The Fig. F47 displays the breakdown products of fructose, autoclaved for 20 minutes; HMF = hydroxymethyl furfural, HAF = hydroxyacetyl furan. Furfural is actually an insecticide. Levulinic acid LD₅₀ intraperitoneally is 450 mg/kg for mouse. ▶ **fructose intolerance**, ▶ **fructosuria**, ▶ **aspartame**, ▶ **saccharin**, ▶ **diabesity**; Rédei GP 1974 Annals Bot 38:287; carbohydrate pyrolysis product toxicity detection: Glatt H et al 2005 Mutation Res 580:41.

Figure F46. Fructose

Fructose-2,6-Bisphosphatase: The bisphosphatase breaks down fructose-2,6-bisphosphate. It is a tissue-specific bifunctional enzyme also possessing 6-phosphofructo-2-kinase activity. ▶ **phosphofructokinase**; Lee Y-H et al 2003 J Biol Chem 278:523.

Fructose Intolerance (hereditary fructose intolerance): A human chromosome 9q22.3 recessive disorder caused by a deficiency of the enzyme fructose-1-phosphate aldolase. The patients begin to sweat, tremble, feel dizzy and nauseous 20 minutes after ingesting fructose. The immediate clinical findings are fructosuria, hypophosphatemia (abnormally low amounts of phosphate in the blood), aminoaciduria (amino acids in urine), fructosuria (moderate amounts of fructose in urine), hyperbilirubinemia (excess of bilirubin [red bile pigment] in blood), etc. The chronic symptoms include jaundice, enlargement of the liver (hepatomegaly), vomiting, dehydration, edema (excessive fluid in the tissues), ascites (fluids in the abdominal cavity), seizures, fructose accumulation in the urine (fructosuria) and in the blood

Figure F47. Heat-induced degradation products of fructose

(fructosemia), cirrhosis (destruction of cells and increase of connective tissues) in the liver, etc. The patients may be quite normal on a diet low on fruits, honey, or fructose-containing sweeteners, but consuming fructose may make them sick and infants may even die if the feeding formula contains fructose. The breakdown products (mainly furfural) of autoclaving cause the apparent toxic effect of fructose in plant cell cultures. Bacteria deficient in the phosphoenolpyruvate/glycose phosphotransferase system are unable to utilize fructose. ▶[fructosuria](#), ▶[aldolase](#); Santamaria R et al 2001 *Biochem J* 359(pt3):823.

Fructosuria (essential fructosuria, 2p23.3-p23.2): A rare autosomal disorder (prevalence is about 8×10^{-6}). The biochemical basis of this non-debilitating anomaly is a deficiency of fructokinase.

Fruit: The matured ovary of plants (may include also other parts of the flower); with the exception of the seed within, it is genetically maternal tissue. ▶[flower differentiation](#), ▶[gametogenesis in plants](#)

Fruit Fly: *Drosophila melanogaster* $2n = 8$; *D. ananassae* $2n = 10$; *D. melanica* $2n = 10$; *D. obscura* $2n = 10$; *D. pseudoobscura* $2n = 10$; *D. virilis* $2n = 10$; *D. willistonii* $2n = 6$. ▶[Drosophila](#), ▶[karyotype evolution](#)

Fruit Ripening: The consequence of changes in the composition and softening of the cell walls of fruits. The increase in respiration involves an increase in the production of the plant hormone ethylene, which affects the expression of a number of genes, notably polygalacturonase (PG), 1-aminocyclopropane 1-carboxylic acid synthase (ACCS), and 1-amino cyclopropane 1-carboxylic acid oxidase (ACCO; tomato gene pTOM13). By transforming tomatoes with a single PG antisense construct, PG activity could be reduced to 1%. However, for a more efficient control of ripening, the amount of the other enzymes should also be reduced to decrease ripening that is under polygenic control. For commercially effective storage without softening ripe-harvested tomato fruits, the use of the antisense RNA of the LE-ACS2 and LE-ACS4 loci was required. The berries stored at 20°C remained firm for months but could mature fully, when exposed either to ethylene (C_2H_4) or its analog (C_3H_6). The fruits so handled were practically indistinguishable by color, scent, and

consistency from vine-ripened fresh fruits. ▶[anti-sense technology](#), ▶[plant hormones](#), ▶[ethylene](#); Ferrándiz C et al 1999 *Annu Rev Biochem* 68:321; Giovannoni J 2001 *Annu Rev Plant Physiol Plant Mol Biol* 52:725.

Fruiting Body: The collective name of fungal organs (perithecium, cleistothecium, apothecium, locule) containing the haploid reproductive spores. (See mentioned items).

Frustration: Interference by the phagocytotic activity of opsonins. ▶[opsonins](#)

Frye Test: A legal ruling concerning admissible scientific evidence to the court. According to the *Frye v. United States* (D.C. Cir. [1923] 293 Fed. 1013) ruling, new scientific methods must be generally accepted by the scientific community before evidence from such methods is admissible in the courts. This became a highly controversial issue because “general acceptance” is difficult to define. Criminal defense lawyers frequently argue that electrophoretic pattern of proteins and DNA fingerprints, and their statistical evaluation should not be presented to the jury because some scientists may dissent about certain aspects of the data. ▶[forensic genetics](#), ▶[DNA fingerprinting](#), ▶[ceiling principle](#), ▶[Daubert rule](#)

FrzE: *Myxococcus xanthus* kinase affects FrzE and FrzG proteins regulating bacterial motility and development. (See McBride MJ 2001 *Annu Rev Microbiol* 55:49).

FSH (follicle stimulating hormone or follitropin, 2p21-p16): FSH controls ovarian follicles, estrogen secretion, menstrual cycles, spermatogenesis, and D2 cyclin. Ovarian and testicular tumors have high levels of cyclin D mRNA. FSH deficient males have small testes, yet fertile to a variable degree. The 54-kb gene has 10 exons and encodes the 695-amino acid protein. ▶[animal hormone](#), ▶[follicle](#), ▶[ovary](#), ▶[menstruation](#), ▶[gametogenesis](#), ▶[differentiation](#), ▶[NGFI-A](#), ▶[cell cycle](#), ▶[gonadal dysgenesis](#); Driancourt MA 2001 *Theriogenology* 55:1211; FSH structure: Fan QR, Hendrickson WA 2005 *Nature [Lond]* 433:269.

F_{ST}: An index for population diversity. For human autosomal loci it is ~15–20%, for mtDNA ~19%,

and for the Y chromosome ~65%. The complement of these percents indicates approximately the variations shared by any random-picked population and the rest of the human race. F_{ST} for diploids = $1/(1 + 4Nv)$, and for Y and mitochondrial [haploid] systems $F_{ST} = 1/(1 + Nv)$, where N is the effective population size (N_e), v = the sum of migration and mutation (or more precisely $m + \mu - m\mu = v$). ▶Eve foremother, ▶Y chromosome, ▶mutation rate, ▶migration, ▶effective population size, ▶diversity, ▶coalescent, ▶ G_{ST} , ▶ R_{ST} ; Weir BS, Hill WG 2002 Annu Rev Genet 36:721.

F

F-Statistics: ▶F

F-Table: ▶F distribution

FTDP-17: ▶Pick disease, ▶tau

F-Test: ▶F distribution

FTICR (Fourier-transformed ion cyclotron resonance mass spectrometer): FTICR is used for the determination of the molecular masses of hundreds of proteins in one run (see Fig. F48). ▶MALDI; Schmid DG et al 2000–2001 Biotechnol Bioeng M71:149.

Figure F48. Part of protein mass spectrum

FT-IR (Fourier transform infrared spectroscopy): A very sensitive method for the detection of intramolecular changes as function of time is converted into function of angular frequencies. ▶Raman spectroscopy, ▶tumorigenesis, ▶electron density map

FTMS (Fourier transform mass spectrometry): FTMS is suitable for the identification of the mass of intact proteins. This type of analysis is particularly useful because it can obviate bias in mass due to alterations during the purification, e.g., oxidation of methionine

residues. ▶proteomics; Jensen PK et al 1999 Anal Chem 71:2076.

FTP (file transfer protocol): Ftp enables the connection between computers and Internet.

FtsK: FtsK mediates coupling bacterial chromosome segregation with cell division.

FtsY: Prokaryotic transport chaperone protein, related to mammalian SRP54. The related bacterial Ffh is ribonucleoprotein, binding to FtsY in a GTP-dependent manner. ▶SRP, ▶GTP, ▶protein sorting; Millman JS et al 2001 J Biol Chem 276:25982.

FtsZ: ▶tubulins

Fuchsia: The ornamental plant which Gregor Mendel was examining while being photographed in 1862 with his monasterial colleagues (see Fig. F49). This plant has 2n chromosome numbers 22, 56, 66, and 77. It was lucky for Mendel that he did not experiment further with this erratic material, which would not have permitted the type of studies he conducted with the stable pea.

Figure F49. This ornamental species has large number of variations in flower shape and color and probably that fact attracted Mendel's interest

Fuchsin (triaminotrimethylmethane): A red cytological stain.

Fucose: A 6-deoxy sugar. It is present in several antigenic glycoproteins and may be associated with several immunoglobulins and present in plant cell walls (see Fig. F50).

Figure F50. L-fucose

Fucosidase (FUCA2, 6q25-qter): A regulator of α -fucosidase in plasma and fibroblasts. It hydrolyzes fucose linkages in glycoproteins and glycosphingolipids. ▶sphingolipids

Fucosidosis (FUCA1): A recessive, human chromosome 1p34 (and a pseudogene at 2q31) defect of α -fucosidase, causing neurodegeneration and angiokeratoma, although some forms are less detrimental. It is a lysosomal storage disease. The accumulation of fucose is detectable in the amniotic fluid. ▶amniocentesis, ▶angiokeratoma, ▶lysosomal storage diseases

Fucosyltransferase (FUT2, FUT1, 19q13.3): In fucosyltransferase, deficiency, the H blood antigen is absent. There are at least seven other FUT genes in the human genome, scattered among the chromosomes. O-fucosyltransferase 1 also acts as a chaperone for the folding of the Notch receptor (Okajima T et al 2005 Science 307:1599). ▶Bombay blood group, ▶ABH antigen, ▶Secretor, ▶CD15, ▶chaperone, ▶Notch

Fugu rubripes: ▶pufferfish

Fukuyama Muscular Dystrophy: ▶muscular dystrophy

Full Mutation: In trinucleotide repeats the entire length of the repeat is altered rather than a part of it. ▶trinucleotide repeats, ▶FMR1

Full Sib: Brothers/sisters with identical mother and father. ▶sib

Fumagillin (C₂₆H₃₄O₇): Fungal antibiotic and inhibitor of angiogenesis. It inhibits methionine aminopeptidase-2, a metalloenzyme cleaving methionine from the N end of proteins. ▶angiogenesis; Owa T et al 2001 Curr Med Chem 8:1487.

Fumarate Hydratase (fumarase, FH): FH is encoded in human chromosome 1q42.1, but both cytoplasmic and mitochondrial forms of the enzyme exist; probably due to the alternative processing of the transcript. Its deficiency results in mental and physical impairment. ▶mitochondrial diseases in

humans, ▶leiomyoma; Sass E et al 2001 J Biol Chem 276:46111.

FUN GENES (functions unknown genes): ▶orphan genes, ▶orphan receptor

Funaria hygrometrica (Bryophyte): The chromosome numbers of bryophytes vary, 14, 28, 56.

Functional Cloning: In the first step of functional cloning, the protein encoded by the gene is isolated, its amino acid sequence is then determined, and on that basis synthetic probes are generated. With the aid of the probe the gene is fished out from a DNA library. ▶gene isolation, ▶synthetic probe

Functional Genomics: Functional genomics studies the function of all open reading frames revealed by DNA genome-wide sequencing. For this purpose, transposable elements, chemical and physical mutagenesis, and knockouts are being used. All techniques are currently not applicable to all organisms. In *Drosophila* insertional mutations (using P elements) has been accomplished for >25% of the vital genes by 1999 and ~85% is expected. ▶genomics, ▶hybrid dysgenesis, ▶insertional mutation, ▶knockout; Spradling AC et al 1999 Genetics 153:135.

Functional Networks: Functional networks display functional relations among several (many) proteins based on *rosetta stone sequences*, *phylogenetic profiles*, and if applicable, *gene neighbor methods* (see Fig. F51). Eventually, the over-simplified relations of protein ① to other numbered proteins can be represented as shown by the chart. ▶networks

Figure F51. Functional network

Functional Redundancy: According to this hypothesis, relevant functions may be carried out by gene products with highly similar activity but the genes being members of separate regulatory circuits would make the system more flexible than a combinatorial control of development. ▶combinatorial gene control

Functionality of Mutagens: The number of chemical groups reacting in mutagenesis. ▶nitrogen mustard, ▶sulfur mustard

Function-Valued Trait: A function-valued trait can be best described by a function of some variable(s), e.g., by the phenotypic changes during aging.

Fundamental Theorem of Natural Selection: ►natural selection

Fundamentalism: The religious or ideological belief that regard as the only absolute right what is written in holy books (Bible, Koran), or in the works of the basic ideologues (e.g., Marx, Engels, Lenin). Accordingly, only creationism explains correctly the genesis of life, provides specific guidelines to human ethics and ideology or political or economical theory, respectively. ►creationism, ►lysenkoism; Bouchard TJ et al 1999 Twin Res 2(2):88.

Fundus Flavimaculatus: ►ABC transporters

Fungal Diseases in Humans: Fungal diseases can occur due to primary infectious agents or opportunistic fungi. Infection and pathogenicity is affected by a number of factors of the pathogen and the host. Fungal infections became more relevant in humans due to the spread of acquired immunodeficiency. Dectin-1, a mammalian ITAM-containing, non-Toll-like receptor, recognizes fungal zymosan, a cell wall component containing β -glucans, α -mannan, and mannoproteins. Card9 is a key transducer of Dectin-1 signaling and controls innate anti-fungal immunity. An alternative receptor is Carma1 (Narayan P et al 2006 Mol Cell Biol 26:2337). Both Dectin-1 and Carma1 activate the NF- κ B pathway to the T cell receptor with coupling to Bcl10 and MALT1 proteins (Gross O et al 2006 Nature [Lond] 442:651). ►acquired immunodeficiency, ►CARD, ►ITAM, ►Toll, ►NF- κ B, ►BCL, ►MALT, ►glucan, ►mannan, ►innate immunity; van Burik J-AH, Magee PT 2001 Annu Rev Microbiol 55:743; Hull CM, Heitman J 2002 Annu Rev Genet 36:557.

Fungal Incompatibility: Fungal incompatibility is based on the interaction of the products of non-allelic genes, and thus prevents self-fertilization, similar to the outcome of S alleles of plants. In *Ustilago maydis* (a pathogen of maize), stable dikaryons can be formed only between different mating type alleles of a multiallelic *b* locus recognized by pheromones. The same *b* locus is also responsible for plant pathogenicity. The *bE* and *bW* alleles encode different homeodomain proteins. The E variants and W variants differ primarily in the N-terminal amino acids. Activity requires that the E and W allele products dimerize and this can happen only in appropriate allelic combinations; the majority of the over 300 combinations are active. In other fungi several multiallelic gene pairs coding for interacting homeodomains have been discovered; in yeast only two

mating types *a* and α exist. *Vegetative incompatibility* prevents the fusion of hyphae in case of *het* alleles or alleles carrying non-allelic *het* genes in their nuclei. ►fungal life cycle, ►incompatibility vegetative, ►dikaryon, ►heterokaryon incompatibility; Glass NL et al 2000 Annu Rev Genet 34:165.

Fungal Life Cycles: Fungal life cycles display an enormous variety of specializations in the various taxonomic groups and cannot be represented here (see Fig. F52). The general scheme is, however, relatively simple and shared by all fungi. ►hypha

Figure F52. Fungal life cycle. The approximately 2,000 genera of fungi have a variety of modes of reproductions that share some basic similarities. Between 9 o'clock and 3 o'clock are the haploid phases (*n*). Haploid cells fuse at 3 o'clock (plasmogamy) but the nuclei are still separate and a dikaryon (*n* + *n*) is formed. In a following step, at 6 o'clock nuclear fusion takes place (karyogamy) and the cell becomes diploid (*2n*). This is followed by meiosis (9 o'clock) yielding four haploid sexual spores that may divide again by mitosis (12 o'clock) before the spores are released. These sexual spores may differentiate and the cycle is reinitiated

Fungi Imperfecti: Fungi without known sexual reproduction mechanism. (See Taylor JW et al 1999 Annu Rev Phytopath 37:197).

Fungus (plural fungi): Eukaryotic thallophytes, yet separate subkingdom from plants and bacteria. Fungi include many saprophytic, parasitic, and pathogenic species of enormous variety in structure and function. Fungal genetics has provided and is providing understanding for basic genetic phenomena such as recombination, biochemical pathways, cell cycle, etc. Yeasts and other ascomycetes are among the most important tools of modern genetic research. (See early fungal phylogeny: James TY et al 2006 Nature [Lond] 443:818; genomes: <http://www.fgsc.net/outlink.html>).

Funiculus: A vascular stalk of the plant ovule (see arrow); a cord-like structure, and in animals also including the umbilical cord, etc. (see Fig. F53).

Figure F53. Funiculus

Fur Color: The color of the fur of animals is determined by the melanin pigments formed in the melanocytes and the migration of the melanoblasts. The various genes involved then modify, reduce, or intensify pigmentation. In addition, the actual visible color depends on the dorso-ventral distribution of the pheomelanin and eumelanin pigments. Superimposed on these are species- or genotype-specific striping, spotting, lyonization, temperature-sensitivity, etc. ▶melanin, ▶pigmentation of animals, ▶hair color, ▶agouti; <http://www.informatics.jax.org/wksilvers/>.

Furanocoumarins: ▶bergamottin, ▶grapefruit

Furin: A Golgi-associated proteinase; it may activate stromelysin and activation of virulence factors of pathogens. Furin has an important role in antigen processing for presentation to the cytotoxic T lymphocytes. Furin processes the BRI-L and BRI-D fibrillogenic precursors of dementia peptides. A furin-like protein mediates the cleavage of Notch receptor and furin convertase defect leads to hypertension. ▶Golgi, ▶dementia, ▶stromelysin, ▶T cell, ▶antigen processing and presentation, ▶Notch, ▶anthrax; Gil-Torregosa BC et al 1998 J Exp Med 188:1105; Bassi DE et al 2001 Proc Natl Acad Sci USA 98:10326; Thomas G 2002 Nature Rev Mol Cell Biol 3:753.

FUS3: A protein kinase of the MAPK family. Indirectly, it arrests yeast cells in G1 prior to mating and it down-regulates Ty transposition. *Fus*^{-/-} mutants of mice develop B cell defects, chromosomal instability, and perinatal death. ▶signal transduction, ▶MAPK, ▶STE, ▶Kss, ▶Ty; Cherkasova V, Elion EA 2001 Curr Genet 40:13.

Fusarium species: Plant pathogenic fungi. *F. oxysporum* can also cause skin and eye infection in animals and humans. They form septate hyphae, chlamydospores, and macroconidia. (See *Fusarium graminearum* database: <http://mips.gsf.de/genre/proj/fusarium/>).

Fushi tarazu (ftz): *Drosophila* mutation of the pair-rule class; every other body segment is missing at the blastoderm stage. The photograph (courtesy of Dr. Y. Nishida et al. 1999 Genetics 153:763) displays the seven wild type segments encoded by the gene (see Fig. F54). ▶morphogenesis in *Drosophila*, ▶SF-1, ▶pair rule genes

Figure F54. *Fushi tarazu*

Fusicoccin: The toxin of the fungus *Fusicoccus amygdali*; an activator of plasma membrane H⁺ ATP-ases. It causes H⁺ secretion, and K⁺ influx into guard cells and thus opening of stomata of plants. (Meinhard M, Schnabl H 2001 Plant Sci 160:635)

Fusidic Acid (C₃₁H₄₈O₆): An antibiotic (ramycin) isolated from *Fusidium coccineum*. This compound mimics the effect of the *rel*⁻ (relaxed control) mutations and also permits the synthesis of guanosine polyphosphates (ppGpp, pppGpp), ribosomal RNA, and ribosomal protein. Tetracycline has a similar effect. ▶antibiotics, ▶stringent control, ▶relaxed control; Duvold T et al 2001 J Med Chem 44:3125.

Fusigenic Liposome: The fusigenic liposomes are similar to the liposome vectors, except they are engineered to carry on their surface hemagglutinating neuroaminidase (HNA) and a fusion protein. The hemagglutinating Japanese virus (HVJ) and the Sendai virus produce these proteins and make them capable of fusing with the cell membrane at neutral pH. HNA is required for binding to cell receptors containing sialoglycoproteins or sialolipids. The fusion protein is in an inactive form until it is hydrolyzed to two polypeptides, F1 and F2; F1 interacts with cholesterol to facilitate fusion, and then the DNA carried by the liposome is delivered into the cell. ▶liposome, ▶sialic acid, ▶Sendai virus, ▶hemagglutinin, ▶cholesterol, ▶cytofectin; Kono K et al 2001 Gene Ther 8:5.

Fusin (LESTR, HUMSTR, CXCR4, stromal-derived factor [SDF1]): A co-receptor of the CD4 antigens

required for fusion with the membrane and entry of a virus (HIV) into a cell. It is a heterotrimeric GTP-binding protein. ▶CD4, ▶CD8, ▶HIV, ▶acquired immunodeficiency syndrome, ▶RANTES, ▶MIP; Dragic T 2001 J Gen Virol 82(p8):1807.

Fusion of Somatic Cells: (see Fig. F55) ▶cell fusion

Figure F55. Soybean (short) and Vetch (long) chromosomes in fused somatic cells. (Courtesy of Dr. O.L. Gamborg et al. 1977 C.R. Hebd. Séances Acad. Sci. Paris Ser. D. 285:319)

Fusion Protein: A fusion protein is synthesized when neighboring genes are transcribed and translated together. It contains full or incomplete parts of two normal proteins. It may also refer to a group of proteins mediating membrane fusion in cells. Fusion of ligands (e.g., transferrin) for lymphocyte cell surface receptors with particular immunoglobulins (IgG3) may potentiate the delivery of antibody beyond certain (e.g., brain) barriers to the blood. Antibody_cytokine fusion may be useful in targeting tumors for destruction. Fusion of proteins with autofluorescent proteins is a powerful tool for the study of protein-protein interactions, conformational changes and other aspects of protein dynamics (Keppler A et al 2004 Proc Natl Acad Sci USA 101:9955). ▶gene fusion, ▶transcriptional gene fusion vectors, ▶translational gene fusion vectors, ▶read-through proteins, ▶chromosome breakage, ▶cancer, ▶leukemias, ▶ferritin, ▶immunoglobulins; labeling in vivo: Keppler A et al 2003 Nature Biotechnol 21:86.

Fusion Transcript: A fusion transcript may result from transcription of chromosomal translocations, retroposon insertion, and transcriptional gene fusion brought about by insertion of transformation vectors. Fusion transcripts are detectable by paired-end diTAG analysis.

Fusome: A structure that is formed in the germline cell of insects during the mitotic divisions. It anchors the mitotic divisions leading to the formation of the nurse cells and the oocyte. After the divisions are completed, it fades away. Antibodies to spectrin, a filamentous membrane protein, can detect its existence. ▶nurse cell, ▶morphogenesis, ▶spectrin; Grieder NC et al 2000 Development 127:4253.

Futile Cycle: An apparently useless chemical reaction in the cell, e.g., fructose-6-phosphate is phosphorylated to fructose diphosphate and simultaneously it is hydrolyzed back to fructose-6-phosphate, resulting in cleavage of ATP into ADP and Pi (unnecessary ATPase activity). The futile cycles may, however, confer regulatory role in functional networks. ▶substrate cycle; Samoilov M et al 2005 Proc Natl Acad Sci USA 102:2310.

Fuzzy Inheritance: A statistical term used for cases when linkage information is computed by allele sets and by using set recoding. (See Nature Genetics 11:402[1995]).

Fuzzy Logic: As per fuzzy logic, either one, or another different event can occur, e.g., frameshift or in-frame decoding of the mRNA, or the translation is either terminated or read through. ▶recoding, ▶pseudo-knot; Zimmermann HJ 1996 Fuzzy Set Theory and Its Applications, Kluwer, Boston, Massachusetts.

Fv (fragment variable): A functional antibody molecule, composed of light and heavy chain antigen-binding sites of one region of the antibody separated from the rest by proteolysis. The single-chain (scFvs) of the light (V_L) and heavy chains (V_H) can be engineered to bind together by 8–15 amino acid linkages and can be cloned by various vectors. These engineered antibodies have, however, somewhat reduced immunogenicity. These molecules may have applicability for radiolabeling and imaging of tumors and for the generation of immunotoxins. ▶antibody, ▶antibody engineering

Fv Protein: A homodimeric 175-kDa sialoprotein binding to the variable domains of immuno-globulin heavy chains. ▶sialic acid, ▶immunoglobulins

FVB Mouse: The FVB mouse is a not-inbred strain; frequently used for genetic transformation.

φX174: A single-stranded DNA bacteriophage with overlapping genes. Its genome has been the first to be completely sequenced (see Fig. F56) (Sanger F et al 1978 J Mol Biol 125:225).

Because of the simplicity of its genome (5,386 bases), it has been used for many purposes in genetics. Recently mice cell lines transgenic for φX174 have been promising in the study of

Figure F56. The physical map of bacteriophage ϕ X174 with 10 genes *a* to *h*. although some of the genes overlap each other (or included), there are non-genic (intergenic) sequences (shown in solid black). The related G4 phage is similar. (Courtesy of Godson, N.G. 1980, Stadler Symp. 12:143)

chemically induced forward mutation (Valentine CR et al 2002 Environ Mol Mutagen 39:55). The entire functional ϕ X174 genome has been assembled from synthetic oligonucleotides (Smith HO et al 2003 Proc Natl acad Sci USA 100:15440). ▶bacteriophages, ▶poliovirus, ▶synthetic genes

FXR (fragile x-related protein): A part of the RISC complex. ▶RISC, ▶fragile X chromosome; Caudy A et al 2002 Genes Dev 16:2491.

FXTAS: ▶fragile X chromosome

Fyb: ▶SLAP; Griffith EK et al 2001 Science 293:2260.

FYN: The FYN oncogene is a member of the Src non-receptor protein tyrosine kinase gene family. The protein controls memory and learning. Low level of Fyn results in greater sensitivity to alcohol effects. ▶Src, ▶Csk, ▶protein tyrosine kinase, ▶palmitoylation; Arold ST et al 2001 J Biol Chem 276:17199.

FYVE: A protein domain of phosphatidylinositol-3-phosphate-containing membrane proteins recruiting other proteins involved in signal transduction. ▶signal transduction; Stahelin RV et al 2002 J Biol Chem 277:26379.

Historical vignette

Mary F Lyon 2002 Annu Rev Genomics Hum Genet 3:1

...“Cambridge also had as Professor of Genetics, RA Fisher, the eminent statistician and mathematical geneticist. He is known now in mouse genetics for Fisher’s exact test and the maximum likelihood method of linkage estimation. He gave a course of lectures, which were largely incomprehensible.”

G

G: ▶ **guanine**. G also denotes generations after mutagenic treatment of mice, G₀, G₁, G₂, etc. This designation is somewhat confusing with the pre-empted cell cycle symbols. ▶ **cell cycle**

g: General intelligence. ▶ **intelligence quotient**, ▶ **human intelligence**

γ: ▶ **gamma**

g²: ▶ **genetic determination**

G418 (C₂₀H₄₀N₄O₁₀ · 2H₂SO₄): An aminoglycoside antibiotic. ▶ **geneticin**

G3139: An 18-mer full-phosphorothioate deoxyoligonucleotide (5'-TCTCCCAGCGTGC GCCAT-3' *Genta*, San Diego, California) with sequence antisense to the first six codons of the open reading of gene BCL-2, and it is used for therapy of lymphomas. ▶ **Bcl-1**, ▶ **lymphoma**, ▶ **antisense technologies**, ▶ **phosphorothioate**

G3854: A 20-mer full-phosphorothioate deoxyoligonucleotide with sequence antisense to open reading frame of gene BCL-2, and it is used for therapy of lymphomas. It is similar to G3139 but two nucleotides longer. ▶ **Bcl-1**, ▶ **lymphoma**, ▶ **antisense technologies**, ▶ **phosphorothioate**

G Banding: A chromosome staining method using Giemsa stain (a complex basic dyes, containing azures, eosin, glycerol and methanol), after pretreatment with the proteolytic enzyme, trypsin, it permits the identification of dark cross-bands that vary among the individual eukaryotic chromosomes and usually facilitates their identification even when their length and arm ratio is similar (see Fig. G1). The darkly stained bands represent (AT-rich) heterochromatin. ▶ **chromosome banding**, ▶ **stains**, ▶ **rye**

Figure G1. G-Banded human chromosome

G Box: A guanine-rich upstream cis element regulating transcription. Commonly it has the structure GA [CAACGTC] GC. The G-box activator protein binds to the framed core sequence. It is commonly found in environmentally sensitive genes. ▶ **Simian**

Gbuilder: A nucleotide sequence visualization tool based on Java application of DNA clusters in EST data. ▶ **Java**, ▶ **EST**; Muilu J et al 2001 *Genome Res* 11:179.

G Element: ▶ **non-viral retrotransposable element**, ▶ **retrotransposons**, ▶ **retroposons**

g Factor: ▶ **human intelligence**

g Force: ▶ **centrifuge**

G₀ Phase: The state of a pause for the cell before it enters the G₁ phase and until divisional activities start again after mitosis. ▶ **cell cycle**

G₁ Phase: The first phase of the cell cycle following mitosis (C value = 2). ▶ **cell cycle**

G₂ Phase: The phase following DNA replication during the cell cycle (C value = 4). ▶ **cell cycle**; O'Connell MJ et al 2000 *Trends Cell Biol* 10[7]:296.

G4 Phage: A single-stranded DNA phage (5507 bases), ~67% related to φX174. ▶ **bacteriophages**, φX174; Godson GN et al 1978 *Nature [Lond]* 276:236.

G Proteins: They are guanine nucleotide binding proteins that serve as intermediaries in biological signaling pathways. The signal is received by *receptors* and the *G-proteins* forward it by mediation of different number of intermediaries to the *effectors* that regulate genes in response to the signals. G-proteins are activated by aluminum fluoride and the α subunit can be ADP-ribosylated by mediation with the aid of bacterial toxins (cholera, pertussis).

The large G-proteins are heterotrimeric (α, β, γ) and control the opening and closing of the signal transduction pathways by changing the attached GDP ⇌ GTP. In the GTP-associated form, they have key role in signal transduction from receptors to effectors. The proteolysis of the large G proteins is regulated by RGS protein signaling and subject to N-end rule (Lee MJ et al 2005 *Proc Natl Acad Sci USA* 102:15030). There are also low molecular weight small G-proteins with a single (α) subunit. G-protein (G_s) is involved in the regulation of the level of the enzyme adenylyl cyclase and thus cAMP and cAMP-dependent protein kinase. The G_i form is involved in the inhibition of adenylyl cyclase; G_{iia2} is required for insulin function. The light-activated GTPase activity is mediated by the G_t-protein, also called transducin. G-proteins stimulate the hydrolysis of phosphoinositides with the aid of phospholipase C. Ca²⁺ also mediates by G-proteins and cAMP degradation by cyclic nucleotide phosphodiesterase indirectly. G-proteins also regulate ion channels.

When a proper ligand binds to a transmembrane receptor, the trimeric G-protein dissociates into a β and an α subunit. The α subunit stimulates adenylyl cyclase, the first the transition of GDP to GTP, and later the transition of GTP to GDP through the mild GTPase activity. In the G-GDP state reassociation of the three subunits follows. G-proteins regulate also Ca^{2+} metabolism and indirectly control allosteric effector proteins. Several human diseases are associated with defects in the G proteins (pituitary tumors, McCune-Albright syndrome, Albright hereditary osteodystrophy, puberty precocious) or with defects in the G protein receptors (hypercalcemia, hypercalciuria, hyperparathyroidism, diabetes insipidus, retinitis pigmentosa, color blindness, glucocorticoid deficiency, opiate addiction, hypertension, myocardial ischemia, chronic heart disease). The human genome seems to include 800 to 1,000 G protein receptors. The most common among them ($\sim 89\%$) are rhodopsin-like molecules, the secretin-like molecules ($\sim 7\%$) and the metabotropic-glutamate-receptor-like proteins ($\sim 4\%$). These proteins, because of their key role in the regulation of metabolic pathways and disease development are important targets of existing and future drugs. Dozens of genes are involved with coding and regulation of G protein subunits, scattered among several human chromosomes. Many of the G protein-coupled receptors are without introns suggesting that retrogenes code for them. Mutations in exons may alter splicing sites remote from the mutation and thus create new variants. G proteins have important roles in both animal and plant cells, however, plants have much fewer genes encoding the trimeric G protein subunits. Several human diseases implicate G protein malfunctions. ▶G region, ▶G' region, ▶G'' region, ▶ G_α , ▶ G_i , ▶ G_q , ▶ G_s , ▶ G_o , ▶ G_i -protein, ▶GTPase, ▶cAMP, ▶adenylate cyclase, ▶rhodopsin, ▶signal transduction, ▶N-end rule, ▶calmoduline, ▶receptor, ▶effector, ▶cholera toxin, ▶pertussis toxin, ▶GTP, ▶phosphodiesterase, ▶ion channel, ▶adenylate cyclase, ▶cell cycle, ▶retrogene, see also the mentioned diseases under separate entries; Sp SR 1997 Annu Rev Biochem 66:639; Bockaert J, Pin JP 1999 EMBO J 18:1723; Farfel Z et al 1999 New England J Med 340:1012; Dohlman HG, Thorner J 2002 Annu Rev Biochem 70:703; Knoblich JA 2001 Cell 107:183; Peterson YK et al 2002 J Biol Chem 277:6767; Assmann SM 2002 Plant Cell 14:S355; Chalmers DT, Behan DP 2002 Nature Rev Drug Discover 1:599; G proteins in plants: Assmann SM 2005 Science 310:71; G protein signaling in yeast: Slessareva JE, Dohlman HG 2006 Science 314:1412; GEF and GAP regulation of G proteins: Bos JL et al 2007 Cell 129:865; http://www.hsls.pitt.edu/guides/genetics/tools/protein/information/URL1118091522/info?print_format=false;

G protein ligands: <http://gdds.pharm.kyoto-u.ac.jp/services/glida/>.

G Quartet (guanine quartet): Guanine-rich nucleotide sequences may form four-stranded complexes, stabilized in Hogsteen structures. The G quartets may be formed in phosphorothioate octamers such as $\text{S-T}_2\text{G}_4\text{T}_2$ or from other sequences like $\text{GTG}_2\text{TG}_3\text{-TG}_3\text{TG}_3\text{T}$ (see Fig. G2). These quartets or double quartets may be potent viral inhibitors. The latter may block HIV1 integrase. Guanine-rich sequences are common in the telomeres, transcription regulatory regions, and immunoglobulin switching areas, etc. Antisense RNAs containing G quartets seem to suppress to various degrees MYC and MYB cellular oncogenes, HIV integrase, etc. G quartets may regulate the translation of the mRNA transcript of Fragile X gene and thus, control synaptic activity of neurons in the brain. Despite the presence of well-defined non-guanine base quartets in a number of NMR and X-ray structures, the data suggests that most non-guanine quartets do not participate favorably in structural stability, and that these quartets are formed only by virtue of the docking platform provided by neighboring G-quartets (Gros G et al 2007 Nucleic Acids Res 35:30:64). ▶antisense technologies, ▶Hogsteen pairs, ▶oncogenes, ▶HIV, ▶immunoglobulins, ▶Fragile X chromosome, ▶NMR; Horvath MP, Schultz SC 2001 J Mol Biol 310:367; G-quartet-rich sequences: <http://bioinformatics.ramapo.edu/grsdb/index.php>.

Figure G2. Quartet

G''Region: G'' region in RAS interacts with GTP through the E-T-S-A-K (see Amino Acid Symbols) consensus. In some G-proteins H(F/M)-T-C-A

(T/V)-D-T may be the corresponding functional area.

► **G-proteins**

G8 RNA: ► **thermal tolerance**

γ Satellite: The repetitive heterochromatin in the pericentromeric area.

G Test: It is a goodness of fit test but instead of calculating the χ^2 in the common way the probability of p is divided by $\hat{p} = L$ (likelihood), and $G = 2 \ln(L) = 2(\ln 10) \log L$ and the distribution is approximated by the χ^2 distribution in large samples. Instead of G sometimes the symbol I (information) is used. ► **chi square**, ► **information**; Sokal RR, Rohlf FJ 1969 Biometry, Freeman, San Francisco, California.

GA: ► **gibberellic acid**, ► **plant hormones** (see Fig. G3).

Figure G3. Gibberellic acid

G_α: The G-protein involved in hormonal stimulation of adenylate cyclase and may regulate ion channels or phospholipase C. The human G_s 1α gene contains 13 exons and 12 introns in a total size of 20 kbp. G_α types: G_iα, G_oα, G_xα, G_tα, G_α₁₂ and G_α₁₃ are subunits, which are stimulated by the p115 RhoGEF. The latter bound to p115RhoGEF catalyzes G nucleotide exchange on RHO but this may be inhibited by activated by G_α₁₃. These are very highly conserved proteins across phylogenetic ranges. In G_sα only 1/394 amino acid difference was found between man and rat, and the protein is entirely identical between humans and bovines. ► **G-proteins**, ► **RGS**, ► **p115**

GABA (γ-aminobutyric acid): It plays an important role in neurotransmission of vertebrates and invertebrates. In the nematode *Caenorhabditis* a series of *unc* (uncoordinated movement) genes respond to GABAergic neuronal effects. GABA_A receptors mediate synaptic inhibition but upon intense activation, they may excite rather than inhibit neurons. GABA controls Cl⁻ ion channels by efflux (depolarization and excitation of the nerve cell) and by influx (hyperpolarization and reduced excitability). By an increase of the level of GABA_A receptor α4

premenstrual anxiety and susceptibility to seizures decrease. Progesterone also acts as a sedative by enhancing GABA function. Heteromeric GABA receptors (GABA_BR1a/b—GABA_BR2), in cooperation with G proteins, regulate potassium and calcium ion channels. The nineteenth century alcoholic beverage, absinthe, containing wormwood oil (thujone) is antagonistic to the GABA_A receptor channels and that explains its convulsant and other neurological effects. GABA transaminase (16p13.3) is responsible for the catabolism of GABA and its deficiency leads to neuronal disorders. There are at least 13 GABA receptors encoded in different human chromosomes. It seems that GABA has a role also in the guidance of pollen tube to the plant ovule. ► **glutamate decarboxylase deficiency disease**, ► **epilepsy**, ► **Caenorhabditis**, ► **neuron**, ► **cleft palate**, ► **neurotransmitter**, ► **ion channels**; Ganguly K et al 2001 Cell 105:521.

Gαβγ: Heterotrimeric G-proteins and the three subunits are of 39–52, 35–36 and 7–10 kDa size, respectively. In mammalian cells, several genes are known for each subunit and their cDNAs may generate additional variations by alternative splicing. ► **G proteins**, ► **splicing**

GABA Transaminase: (16p13.3): ► **GABA aminobutyrate transaminase**

GABP: These are GAA sequence- (or their extension) binding heterotetrameric DNA-binding proteins (GABPα/β), members of ETS domain protein families (about 40) regulating gene transcription in a combinatorial manner with other proteins. The α subunit actually binds DNA whereas the ankyrin repeats in β recruit other protein domains. ► **transcription factors**, ► **ETS oncogenes**, ► **ankyrin**, ► **combinatorial gene control**

GABRIEL: A computer program designed to apply domain-specific and procedural knowledge for the analysis of DNA microarray data (Pan K-H et al 2005 Proc Natl Acad Sci USA 99:2118).

GAD: (Genetic Association Database, <http://geneticassociationdb.nih.gov>, <http://hpcio.cit.nih.gov/gad.html>): GAD contains information on association of genes with human diseases, primarily for medical professionals and also for the public. Anyone can submit information that will be reviewed before inclusion.

GADD45: It is a p53-inducible protein. It also binds PCNA. Deficiency of Gadd45a in mice leads to chromosomal instability, increased radiation sensitivity (cancer), and exencephaly. The GADD genes are induced by stress, inflammatory cytokines, tumor necrosis factor, transforming growth factor, and several cytokines. ► **PCNA**, ► **p53**, ► **exencephaly**; Takahashi S et al 2001 Cancer Res 61:1187; Kovalsky O et al 2001 J Biol Chem 276:39330.

GADD153 (growth arrest and DNA damage): A cellular enhancer-binding protein mediating stress of growth and differentiation. Under stress, it may be activated by phosphorylation of Ser⁷⁸ and Ser⁸¹ residues and consequently enhanced transcription and inhibited adipose cell differentiation. It is the same as CHOP. GADD is activated under varied stress conditions. It may act also as an oncoprotein by suppressing differentiation, especially in various gene fusions brought about by chromosomal translocations. ► [enhancer](#), ► [DNA repair](#), ► [chromosome breakage](#), ► [cancer](#); O'Reilly et al 2000 *Am J Physiol Lung Cell Mol Physiol* 278:L552; Jousse C et al 2001 *Nucleic Acids Res* 29:4341; Lu B et al 2004 *Nature Immunol* 5:38.

GAF: A DNA satellite-binding regulatory protein.

GAG: ► [glycosaminoglycan](#)

gag: Group-specific antigen, a viral coat protein. ► [retroviruses](#)

GAGA: A multipurpose transcriptional activator binding to the GA/CT sites in the promoter. Its major function may be to rearrange the chromatin to facilitate transcription. GAGA activates chaperones and binds to the promoter of the *Ultrabithorax* and other *Drosophila* genes. ► [position effect](#), ► [morphogenesis in Drosophila](#), ► [heat-shock proteins](#), ► [heterochromatin](#); Basturia A et al 2001 *Development* 128:2163.

GAIA Theory: Organisms contribute to a self-regulating feedback that keeps the environment stable and suitable for life. The global environment (living and non-living) determines, however, the outcome of natural selection through interacting feedback processes. (See Downing K, Zvirinsky P 1999 *Artif Life* 5[4]:291).

Gain: A practical measure of heritability, frequently used by animal breeders. By this criterion heritability, $h^2 = (\text{gain})/(\text{selection differential})$. See graphical representation (After Lerner IM, Libby WJ 1976 *Heredity, Evolution and Society*, Freeman, San Francisco). The selection differential is the difference between the mean of the parental population and the mean of a portion of the parents selected for further reproduction to improve the herd. The gain/selection differential is often called *realized heritability*. The breeder may improve the gain either by increased heritability or by enhanced intensity of selection. Heritability estimates improve if environmental variation is kept at a low level by proper feeding and health care of the animals or appropriate tillage, fertilization,

weed and pest control in plants. The intensity of selection is increased if the proportion of the individuals selected for parents is reduced. Although this may appear to be an easy approach to improve selection gains, the small populations may increase inbreeding and becomes counterproductive. In large mammals, the males generally have more offspring than the females. By the use of artificial insemination, the breeding value of the males can be determined even more precisely than that of the dams (see Fig. G4). Generally, the estimates improve with the age of the animals because larger number of offspring is available for evaluation. In practice, the selection is aimed simultaneously at several traits. Often these traits are negatively correlated because high performance may make the animals (plants) more susceptible to disease. Thus, the gain in one trait may mean a loss in the others. Therefore, breeders frequently use a *selection index* that weighs each trait by a score and the total of the scores becomes the basis of the selection value. There are statistical methods for predicting the quantitative performance in a selective breeding program: $Y_o = \bar{Y} + Hn(Y_p - \bar{Y})$ where Y_o is the predicted average performance of the progeny, Y_p is the average of the two parental families selected, \bar{Y} = the average of the original population, Hn is heritability in the narrow sense. Example: the average number of eggs laid per year in a flock of chickens is 250, the heritability is 0.25, the average of the selected family of parents is 274, then the expectation for the offspring $Y_o = 250 + 0.25(274 - 250) = 256$. The genetic gain from mass selection is computed from the covariance: $(XY) = w = (1/2) 2\sigma_A$. For determining the covariance see correlation; σ^2_A = additive variance (see genetic variances); the plot-to-plot environmental variance is σ^2_e and the plant-to-plant environmental variance = $\sigma^2_{we} = \sigma^2_{wf} + \sigma^2_{me}$ and the genotype environmental variance, $\sigma^2_{G \times E} = \sigma^2_{A \times E} + \sigma^2_{D \times E}$.

If we consider the within-family variance = 0, then the gain for mass selection,

$$\Delta G_m = \frac{\frac{1}{2} i^2 A}{\sqrt{\sigma_A^2 + \sigma_D^2 + \sigma_{A \times E}^2 + \sigma_{D \times E}^2 + \sigma_e^2 + \sigma_{me}^2}}$$

and i = selection intensity, σ_D^2 = the dominance, $\sigma_{A \times E}^2$ = additive x environment, and $\sigma_{D \times E}^2$ = dominance x environment variances. This procedure is applicable to large populations at relative ease. In case of phenotypic recurrent selection, the equation for gain in mass selection above for cycle needs to be multiplied by 2 because the selection is applied to both parents. Additional formulas for other types of selection are to be found in Moreno-González J, Cubero, *J Plant Breeding*, pp. 281–313; Hayward MD et al eds 1993, Chapman & Hall, London, New York. ► [polygenes](#), ► [breeding value](#), ► [selection index](#),

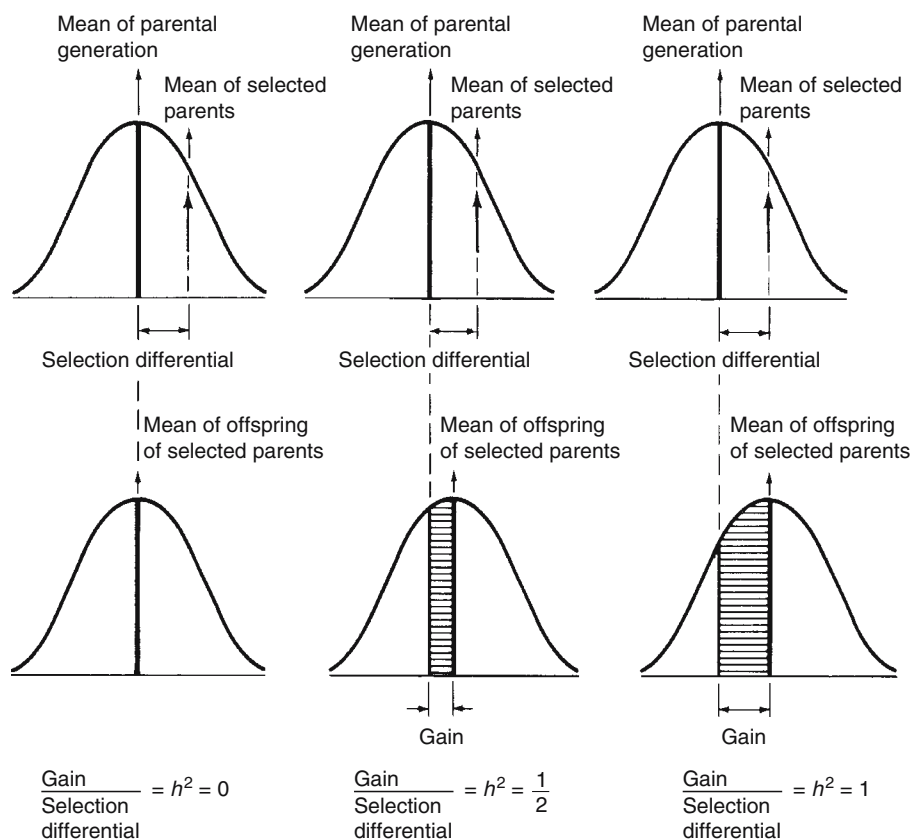

Figure G4. Gain

►quantitative genes, ►heritability, ►intraclass correlation, ►correlation

GAIN (Genetic Association Information Network): It involves private companies (Pfizer, Perlegen, Affymetrix, etc.) in a collaborative effort with the NIH to carry out genome-wide association studies for several common diseases. ►genetic association, ►genome-wide functional analysis, ►genome-wide location; http://www.fnih.org/GAIN/GAIN_home.shtml.

Gain-of-Function Mutations: Generally, mutations lead to loss of structures (for e.g., hairs or bristles) or certain function (e.g., auxotrophy). However, some of the homeotic mutants gain additional structures such as extra petals or stamens in flowers or legs on the head in *Drosophila*. These “gains” are the result of homeotic transdetermination regulated by altered transcription and/or transcript processing. ►transdetermination, ►transcription, ►processing, ►Huntington chorea, ►muscular dystrophy, ►homeotic genes, ►flower differentiation, ►loss-of-function mutation, ►dominant negative

GAL: ►galactose utilization

GAL4: A positive regulatory protein of the yeast galactose genes, it binds to a specific upstream regulatory DNA sequence. *GAL4* is activated by the interaction of Gal80p and Gal3p in the cytoplasm. In various constructs, introduced by transformation into other organisms, its activator domain is frequently utilized to boost the expression of selected reporter genes. Ubiquitylation of Gal4 seems to be required for elongation of mRNA. The F-box protein, Dsg1/Mdm30 mediates this turnover (Muratani M et al 2005 Cell 120:887). ►galactose utilization, ►activator proteins, ►reporter gene, ►transcriptional activator, ►Gene-Switch, ►p65, ►two-hybrid method, ►F-box; Hartley KO et al 2002 Proc Natl Acad Sci USA 99:1377; Peng G, Hopper JE 2002 Proc Natl Acad Sci USA 99: 8548; GAL3 and GAL80 regulatory functions: Ramsey SA et al 2006 Nature Genet 38:1082.

Gal α 1-3Gal: The terminal antigens present on the endothelial lining of blood vessels of majority of mammals, except humans and most primates because the latter higher animals do not have a functional 1,3-galactosyl transferase (GT). These antigens have the major role in organ graft rejection. In order to reduce

rejection, antisense technology may be used to block the synthesis of GT mRNA. Alternatively, an inhibitory ligand (aptamer) or an enzyme (H transferase) is used to add fucose (rather than galactose) to the molecule to compete in the reaction. The use of α -galactosidase may destroy the antigenic galactose terminals. ►immunity, ►xenotransplantation, ►grafting in medicine

Galactans: These are polymers of galactose. ►galactose, ►hyperacute reaction

Galactokinase Deficiency: Can be due to autosomal recessive defects at GALK1 (human chromosome 17q24) or GALK2 (chr. 15). Cataracts at infancy and hypergalactosemia occur due to this deficiency. Galactokinase converts galactose into galactose-1-phosphate. ►galactosemias, ►galactose

Galactose: One of the most common six-carbon monosaccharides differing from glucose only sterically at carbon-4 chiral centers (an epimer of glucose). It can be converted to glucose by an epimerase enzyme (UDP-Gal \rightarrow UDP-Glucose) (see Fig. G5). Galactosyl groups are present in some anthocyanin, collagens, and immunoglobulins. Lactose (the milk sugar) is a disaccharide of galactose + glucose, split by the enzyme lactase. ►galactosemias, ►galactose utilization, ►chirality, ►epimers, ►galactosidase, ►galactose [see formula], ►galactose utilization, ►epilepsy, ►eye diseases, ►genetic screening

Figure G5. Galactose and glucose

Galactose Operon: ►galactose utilization

Galactose Utilization: Coordinately regulated in prokaryotes and eukaryotes. The galactose genes of *E. coli* are either clustered (*galE* [UDP-galactose-4-epimerase], *galEo* [operator], *galElp* [promoter], *galE2p* [promoter of *galEK*], *galK* [galactokinase], *galT* [galactose-1-phosphate uridylyltransferase]) all at map position 17 or *galR* [galactose regulator] at map position 61, *galP* [galactose permease] at map position 63, and *galU* [glucose-1-phosphate uridylyltransferase] at map position 27. In yeast, the uptake

of galactose is mediated by galactose permease (gene *GAL2*). In the presence of ATP, galactose is phosphorylated (Gal-1-P) by galactokinase (gene *GAL*). Galactose-1-phosphate (Gal-1-P) + uridine-diphosphoglucose (UDP-glucose) generate UDP-galactose + glucose-1-phosphate by the action of galactose-1-phosphate uridylyltransferase (gene *GAL7*) while the UDP-galactose-4-epimerase (gene *GAL10*) mediates the formation of UDP-glucose from UDP-galactose. Genes *GAL1*, *GAL7* and *GAL10* form a cluster in yeast chromosome 2 and *GAL2* is in chromosome 12. These yeast genes are coordinately inducible up to a 1000 fold by the presence of galactose although they are transcribed from separate promoters. Gene *GAL4* (linkage group 16) and gene *GAL80* (linkage group 13) regulate the GAL enzymes. *GAL4* is apparently a positive regulator of genes 1, 2, 7, and 10 whereas some *GAL80* mutations abolish the need for induction of the same genes and convert them either to constitutive forms or make them non-inducible. It is assumed that the normal role of the product of gene *GAL80* is to prevent the transcriptional activation by *GAL4* but the combination of the GAL1 protein with GAL80 protein inactivates the latter and then GAL1 activates GAL4, the activator of the system. This GAL1 protein is an enzyme as well as a regulator of transcription. The activation by *GAL4* depends on *upstream activating sequences* (UAS) located 200 to 400 base pair upstream of the genes, 1, 2, 7, 10 and *GAL80*. The presence of two UAS is sufficient for full expression (see Fig. G6). The consensus within the 17 bp palindromic (\leftrightarrow) UAS is:

Figure G6. Galactose UAS palindrome

The protein product of gene *GAL4* is about 100-kDA and it contains three essential domains. Amino acids from 1–65 are involved in DNA binding, residues 65–94 are concerned with dimerization. Amino acids 148–196 and 768–881 mediate activation of transcription (activation domain) and at the C-terminus, the sequence 851–881 also binds the *GAL80* gene. At the N-terminus, amino acid residues 10–32 display a Zinc-finger motif, common to binding proteins. At the C-terminus, there is a high density of acidic amino acids, a characteristics of regulatory proteins. The presence of inactivation by insertion elements in bacterial genomes was first recognized by a study of the *gal* operon in *E. coli*. ►galactose, ►operon, ►coordinated regulation, ►UAS, ►palindrome, ►IS elements, ►regulation of gene activity, ►Zinc fingers, ►binding proteins,

►two-hybrid method, ►galactosemia; Weickert MJ, Adhya S 1993 Mol Microbiol 10:245; Frey PA 1996 FASEB J 10:461.

Galactosemias: Autosomal hereditary diseases in humans caused by the deficiency of either the enzyme galactokinase (GALK, human chromosome 17q24) or more commonly galactose-1-phosphate uridylyltransferase (GALT, 9p1, 4q263). Consequently, galactose cannot be transformed into glucose. Since the milk sugar is a disaccharide of galactose and glucose, galactose accumulates in the blood and is excreted in the urine. The accumulating galactose causes severe intestinal problems and the accumulating galactose-1-phosphate may damage the liver, brain, eye lens (cataracts) and other organs. Unless this anomaly is detected right after birth, infant death may result. By a diet free of any source of galactose, damage may be prevented. This condition is quite common, about 4×10^{-4} . A human galactokinase gene GALK is responsible also for cataracts. Deficiency of the enzyme that converts UDP-galactose \rightleftharpoons UDP-glucose, galactose epimerase (GALE, chromosome 1p35-p36) also leads to galactosemia. GALT deficiency may cause neurological dysfunctions because the reduction of galactose available for galactosyl ceramides and glycosphingolipids and the accumulation of their precursors such as glucosyl ceramides. Deficiency of UDP-galactose:ceramide galactosyltransferase (CGT, 4q26) results in thinner myelin sheets and mild ataxias, low IQ, memory deficit, reduced visuo-motor coordination, etc. Galactosemia (GALT) may cause ovary dysfunction because of the higher than normal levels of the follicle stimulating (FSH) and luteinizing hormones. ►ceramides, ►myelin, ►ataxia, ►human intelligence, ►animal hormones, ►ceramides, ►sphingolipids, ►sphingolipidoses, ►lipid; Riehm K et al 2001 J Biol Chem 276:10634.

Galactosidase- β : Probably the best studied bacterial gene, *lac* involves the determination and control of the enzyme β -galactosidase (see ►*lac operon*). The enzyme α -galactosidase an α -galactosyl hydrolase (melibiase, α -galactoside galactohydrolase, ceramide trihexosidase) is deficient in patients suffering from Fabry's disease (Xq22). In the plasma and in most of the tissues the trihexosyl ceramides Gal-Gal-Glc-Cer or Gal-Gal-Cer (Gal = galactose, Glc = glucose, Cer = ceramide) accumulate in the tissues. In various organs, extensive deposition of lipids occur and the patients suffer skin lesions, pain, paresthesia (burning, prickling sensation). In the extremities, ectasia (dilation, distention) in the skin vessels, edema (accumulation of fluids) in the legs, hypohidrosis (diminished sweating), albuminuria (protein accumulation in the urine), hyposthenuria (lowered amounts of solids in the urine) occurs. Death

may result from renal failure. The disease is X-chromosome linked (q22). Heterozygous females have the same symptoms as hemizygous males but at reduced level. β -Galactosidase (a group of enzymes splitting galactosides, galactose linkages) activity is greatly reduced in patients affected by a group of human diseases called *gangliosidoses*. β -Galactosidase is a biological marker for cellular senescence. The general symptoms involve deterioration of psychomotor (brain and movement) activities, severe bony deformities and generally death by the age of two. These diseases occur in all ethnic groups as incurable autosomal recessive defects. Heterozygotes may be detected by β -galactosidase assays and the diseases can be identified by amniocentesis. ►galactose utilization, ►Fabry's disease sphingolipidoses, ►gangliosidosis general, ►Krabbe's leukodystrophy, ►lactosyl ceramidosis, ►*Lac operon*, ►Xgal; Pshezhetsky AV, Ashmarina M 2001 Progr Nucleic Acid Res Mol Biol 69:81)

Galactosyl Ceramide Lipidosis: ►Krabbe's leukodystrophy

1,3-Galactosyltransferase, α : Synthesizes α 1-3-galactose epitopes, which are the major antigens causing rejection of pig to human xenotransplants. Knocking out or mutation in the gene responsible for the enzyme may render the organs more suitable for xenotransplantation. The majority of mammals—with the exception of humans, apes and Old World monkeys—carry a gene for this enzyme. ►xenotransplantation; Phelps CJ et al 2003 Science 299:411.

Galago: ►Lorisidae

Galanin: A bioreactive peptide (in humans Gly-Trp-Thr-Leu-Asn-Ser-Ala-Gly-Tyr-Leu-Leu-Gly-Pro-His-Ala-Val-Gly-Asn-His-Arg-Ser-Asp-Lys-Asn-Gly-Leu-Thr-Ser). Its composition is somewhat different in pigs or rats. In humans, it inhibits acetylcholine and glutamic acid release. It also reduces excitability of spinal neurons and blocks voltage-activated Ca^{2+} -channels. It may be involved in behavioral and cognitive deficits in Alzheimer disease. Its effects in other mammals are similar. ►ion channels, ►Alzheimer disease, ►acetylcholine, ►glutamica; Steiner RA et al 2001 Proc Natl Acad Sci USA 98:4184.

Galectin: A β -galactoside binding protein regulating growth and immunological responses. It may induce apoptosis in activated human T cells. Galectin-1 and -3 are part of the spliceosome where they interact with the Gemin4 protein. ►apoptosis, ►T cell; Park JW et al 2001 Nucleic Acids Res 29:3595; Wang JL et al 2004 Biochim Biophys Acta 1673:75.

Gallstone: ► [cholelithiasis](#)

GALT (gut-associated lymphoid tissue): ► [Peyer's patches](#)

Galtonian Inheritance: Francis Galton (1822–1911), father of quantitative genetics formulated the rules for Galtonian Inheritance in different ways. He recognized that his ideas on “ancestral heredity” were partly inconsistent with the observed facts. His application of the concept of regression to the inheritance of multifactorial traits remained essentially correct and contributed to the modern concepts of heritability. By rejecting Darwin's pangenesis and suggesting the concept of “stirpes”, he essentially laid the path to the concepts of hard heredity and particulate inheritance. His idea may still be applicable to the inheritance of organelle-coded functions: “We appear, to be severally built up out of a host of minute particles, of whose nature we know nothing, any one of which may be derived from any one progenitor, but which usually transmitted in aggregates, considerable groups being derived from the same progenitor. It would seem that while the embryo is developing itself, the particles, more or less qualified for each post, as it were in competition to obtain it. Also, the particle that succeeds must owe its success partly to accident of position and partly of being better qualified than any equally well-placed competitor to gain lodgment.” (Galton F 1889 *Natural Inheritance*, New York). ► [polygenic inheritance](#), ► [correlation](#), ► [heritability](#), ► [hard heredity](#), ► [sorting out](#), ► [pangenesis](#); Roberts HF 1965 *Plant Hybridization Before Mendel*. GAMBIT (genomic analysis and mapping by in vitro transposition): By knowing the sequence of the genome and specificity of the target of a transposon, using transposons all the essential genes containing the target sequence can be inactivated and thus their function revealed. ► [targeting genes](#), ► [insertional mutation](#), ► [saturation mutagenesis](#); Kamichhane G et al 2003 *Proc Natl Acad Sci USA* 100:7213.

Gamborg Medium (B5): Developed for plant tissue culture, it is suitable for growing callus and different plant organs. Composition mg/L: KNO₃ 2500, CaCl₂·2H₂O 150, MgSO₄·7H₂O 250, (NH₄)₂SO₄ 134, NaH₂PO₄·H₂O 150, KI 0.75, H₃BO₃ 3.0, MnSO₄·H₂O 10, ZnSO₄·7H₂O 2.0, Na₂MoO₄·2H₂O 0.25, CuSO₄·5H₂O 0.025, CoCl₂·6H₂O 0.025,

Ferric-EDTA 43, sucrose 2%, pH 5.5, inositol 100, nicotinic acid 1.0, pyridoxine.HCl 1.0, thiamine. HCl 10, kinetin 0.1, 2,4-D 0.1 - 1.0. The microelements, vitamins and hormones may be prepared in a stock solution and added before use. For kinetin other cytokinins may be substituted such as 6-benzylamino purine (BA) or isopentenyl adenine (or its nucleoside), for 2,4-D (dichloro-phenoxy acetic acid), naphthalene acetic acid (NAA) or indole acetic acid (IAA) may be substituted or a combination of the hormones may be used in concentrations that is best suited for the plant and the purpose of the culture. For solid media use agar or gellan gum. Heat labile components are sterilized by filtering through 0.45 µm syringe filters. This medium may be purchased from commercial suppliers in a dry mix ready to dissolve. ► [Murashige & Skoog medium](#), ► [embryo culture](#), ► [cell culture](#), ► [cell fusion](#), ► [agar](#), ► [gellan gum](#), ► [plant hormones](#); Wetter LR, Constabel F (Eds) 1982 *Plant Tissue Culture Methods* Prairie Res Lab Saskatchewan, Canada.

Game Theory: Deals with decision-making under uncertainty. Before a decision is made, the probabilities of a set of actions, e.g., p(1) and p(2) must be assessed, generally by a subjective manner. An essential feature is a strategy that assures the maximal rewards for the good decisions. Such a procedure is most widely used in the business world (marketing) under competitive conditions. It may be applied also to natural sciences and evolution where exact statistical methods are not practical due to the variability and uncertainty of the conditions.

Decision-making involves computational tasks of the human brain and the Bayesian theorem provides statistical tools for the assessment of the roles of various kinds of uncertainties. In the neocortex and hippocampus of the brain, acetylcholine and norepinephrine have synergistic and permissive roles in assessing the *expected uncertainty* of environmental cues whereas norepinephrine is involved in the *uncertainty of the unexpected* based on a priory experience. Michel I. Posner, neurobiologist posited that a cue predicts a certain target by some degree of probability, called *cue validity*. Correctly cued target stimuli are processed more rapidly than incorrect ones. Acetylcholine level inversely varies with cue validity and thus indicates expected uncertainty. Physiological experiments with rodents and primates support this conclusion. Norepinephrine, in contrast, does not consistently interact with the probabilistic cuing task after the initial acquisition (Yu AJ, Dayan P 2005 *Neuron* 46:681). This model combines the physiological effects of neuromodulators and sensory cues for decision-making. ► [prisoner's dilemma](#), ► [winner's curse](#), ► [Bayes' theorem](#), ► [acetylcholine](#), ► [animal hormones](#); Binmore K, Samuelson L 2001

Gamergate: Exceptional worker (reproductive female) in social insects that mates and can lay eggs. ► [social insects](#)

Gametangia: Sex organs of fungi; oogonium in the “female” and antheridium in the “male.”

Gamete: Haploid male or female generative cell (egg, sperm). Gametic fusion (formation of the zygote) takes place during sexual reproduction. The zygote (2n) has twice the number of chromosomes of the haploid (n) gametes. ► [gametogenesis](#), ► [fertilization](#), ► [germ cell](#)

Gamete Competition: If multiple gametes are available, their success in fertilization may be determined by genetically controlled viability or vigor. It occurs commonly among sperms of animals and plants, pollen tubes (certation) and also among eggs in multiparous animals or in plants where more than one megaspore of the tetrad may produce the egg. ► [certation](#), ► [meiotic drive](#), ► [selective fertilization](#), ► [preferential segregation](#), ► [segregation distorter](#)

Gametic Array: Gametic array of diploids, in case of independent segregation, can be determined by different procedures:

In a dihybrid: $(A + a) \times (B + b) = AB, Ab, aB, ab$ in a trihybrid: $(A + a) \times (B + b) \times (C + c) = ABC, ABc, AbC, Abc, aBC, aBc, abC, abc$ or using any type of gene symbols such as I/i, R/r A/a the combinations can be read from left to right by following the paths of the arrows and at right we obtain the gametic arrays (see Fig. G7). In general, in diploids, in case of independent segregation, the gametic output can be determined by $2n$ where n corresponds to the number of allelic pairs, e.g., in a trihybrid cross $2n = 2^3 = 8$ as derived above. For gametic array in autopolyploids and trisomics see autopolyploidy and trisomy, respectively. ► [Mendelian segregation](#)

Figure G7. Derivation of gametic combinations

Gametic Lethal: Death at the egg or sperm stage. ► [zygotic lethal](#)

Gametocide: Any chemical that causes male sterility. They may be used in plant breeding to sparse the efforts of emasculation in large-scale hybridization or may be used as birth-control agents when applied shortly before copulation. Some gametocidal genes induce chromosome breakage during interphase. ► [male sterility](#)

Gametocyte: A cell that produces gametes. ► [Plasmodium](#)

Gametogenesis: The animal egg is formed by differentiation without further cell division from a haploid product of meiosis and so do the spermatozoa from the spermatids. (See Fig. G8 for development of the female and male gametes of higher animals and plants) Basically, gametogenesis in animals and plants shows substantial similarities because in both cases it is based on meiosis. The processes of gametogenesis are regulated in a complex manner by various hormones. In animals, the primordial germ cells colonize the gonads (spermatocytes and oocytes) through the mediation of chemokines such the stromal cell-derived factor-1 and its receptor CXCR4 (Ara T et al 2003 Proc Natl Acad Sci USA 10:5319). These chemokines control diverse other developmental processes too. More than 2,300 genes produce germ cell-specific transcripts (Schultz N et al 2003 Proc Natl Acad Sci USA 1000:12201). In *Caenorhabditis*, according to one study, 132 proteins are enriched during spermatogenesis and 444 during oogenesis whereas 370 are enriched during the formation of both types of gametes (Chu DS et al 2006 Nature [Lond] 443:101). Sparmatogonial stem cells transplanted into immature testes produce viable sperm cells even when the donor is rat and the recipient is mouse. Through such a procedure the xenogeneically produced spermatozoa yielded viable rat offspring when microinjected into rat oocytes (Shinohara T et al 2006 Proc Natl Acad Sci USA 103:13624). In mice in addition to “actual stem cells”, which are normally self-renewing, a second population (“potential stem cells”) also exists, which is capable of self-renewing but do not self-renew in the normal situation. Potential stem cells rapidly turn over in normal testes, suggesting that they belong to the transit-amplifying, rather than the dormant, population. During the long natural course, actual stem cells are occasionally lost and compensated for by progeny of their neighbors (Nakagawa T et al 2007 Dev Cell 12:195). ► [spermiogenesis](#), ► [gametophyte](#), ► [germ cells](#), ► [histone variants](#), ► [protamines](#), ► [animal hormones](#), ► [GDNF](#), ► [Wolffian ducts](#), ► [Müllerian ducts](#), ► [hedgehog](#), ► [azoospermia](#), ► [atresia](#), ► [synergid](#), ► [CXCR](#), ► [SDF](#), ► [stem cells](#)

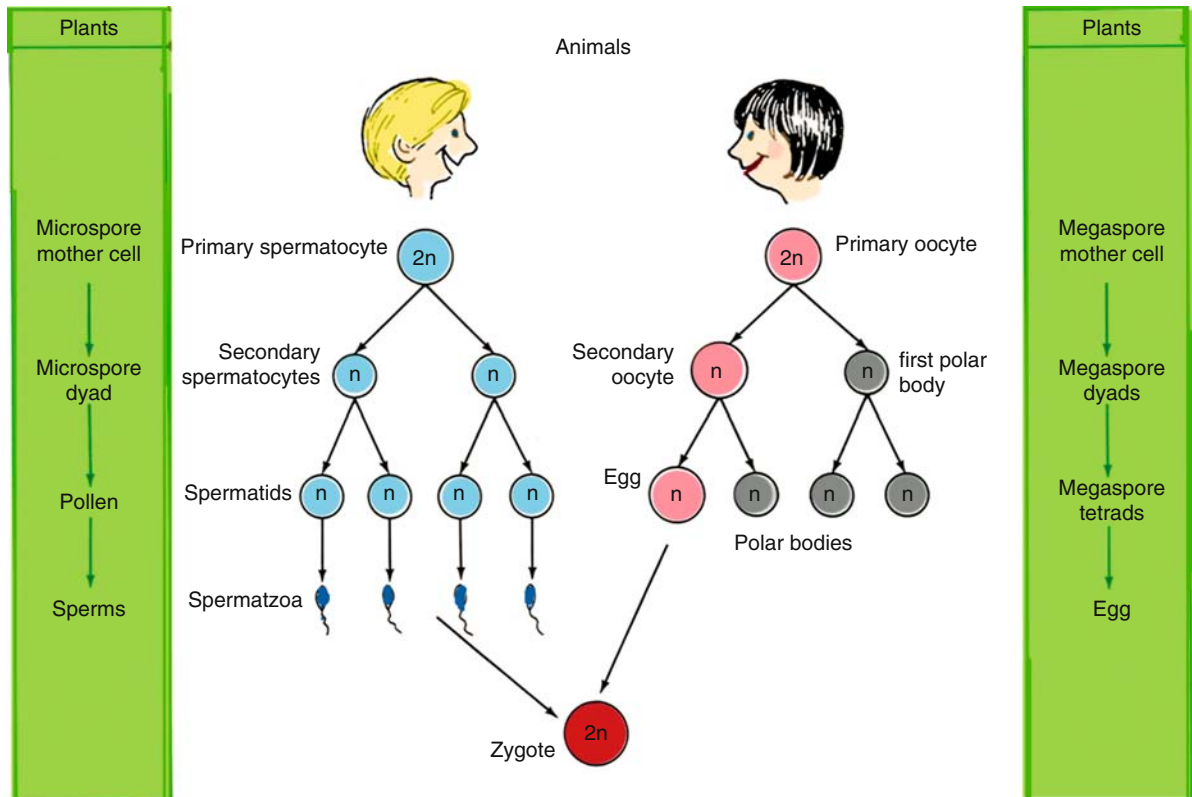

Figure G8. Comparative view of animal and plant gametogenesis

Gametophore: Leafy shoots of mosses bearing gametangia. ►gametangia

Gametophyte: The cells resulting from the meiosis of plants that have half the chromosome number of the zygotes. The gametophytes (megaspores, microspores) will form the gametes (egg and sperm). Selection at the gametophyte level is much more effective than in the sporophytic generation when the intended target of the selection is expressed at this developmental stage. The effectiveness of selection is particularly needed when the frequency of the gene selected for is low. Selection at the haploid level was apparently successful for tolerance to herbicides, toxins secreted by pathogens, alcohol dehydrogenase mutations, and possibly against certain stress effects. There are evolutionary variations in gametophyte structures (Friedman WE 2006 Nature [Lond] 441:337).

CHR11 chromatin remodeling factor is essential for the development of the female gametophyte in *Arabidopsis* (Huanca-Mamani W et al 2005 Proc Natl Acad Sci USA 102:17231). The effectiveness of selection is particularly needed when the frequency of the gene selected for is low. Selection at the haploid level.

In the somatic cells of flowering plants a germline-restrictive silencing factor (GRSF) suppresses the

expression of genes required for the function of the sperms by binding to the promoter of silencing sequences in lily and *Arabidopsis* (Haerizadeh F et al 2006 Science 313:496). Mutant *cdka1* pollen has only a single nucleus, which results in lack of fertilization of the diploid endosperm and consequently in seed sterility in *Arabidopsis* (Nowack MK et al 2006 Nature Genet 38:63). In the absence of the *FIS*-class genes the *cdka1* plants can produce reduced size maternal endosperm, which is smaller yet weakly functional (Nowack MK et al 2007 Nature [Lond] 447:312). See Figs. G9 and G10; ►sporophyte, ►cytoplasmic male sterility, ►male sterility, ►pollen competition, ►certation, ►gametophyte factor, ►incompatibility alleles

Gametophyte Factor: Affects the haploid gametophyte and may be responsible for reduced transmission of the chromosome (gamete) that carries it in a heterozygote. Gametophyte factors generally have more detrimental effect on the male but in rare cases the female is also influenced to various degrees. ►certation, ►gametophyte, ►meiotic drive, ►preferential segregation, ►selective fertilization, ►zygotic lethal, ►pollen-pistil interactions; Swanson R et al 2004 Annu Rev Genet 38:793.

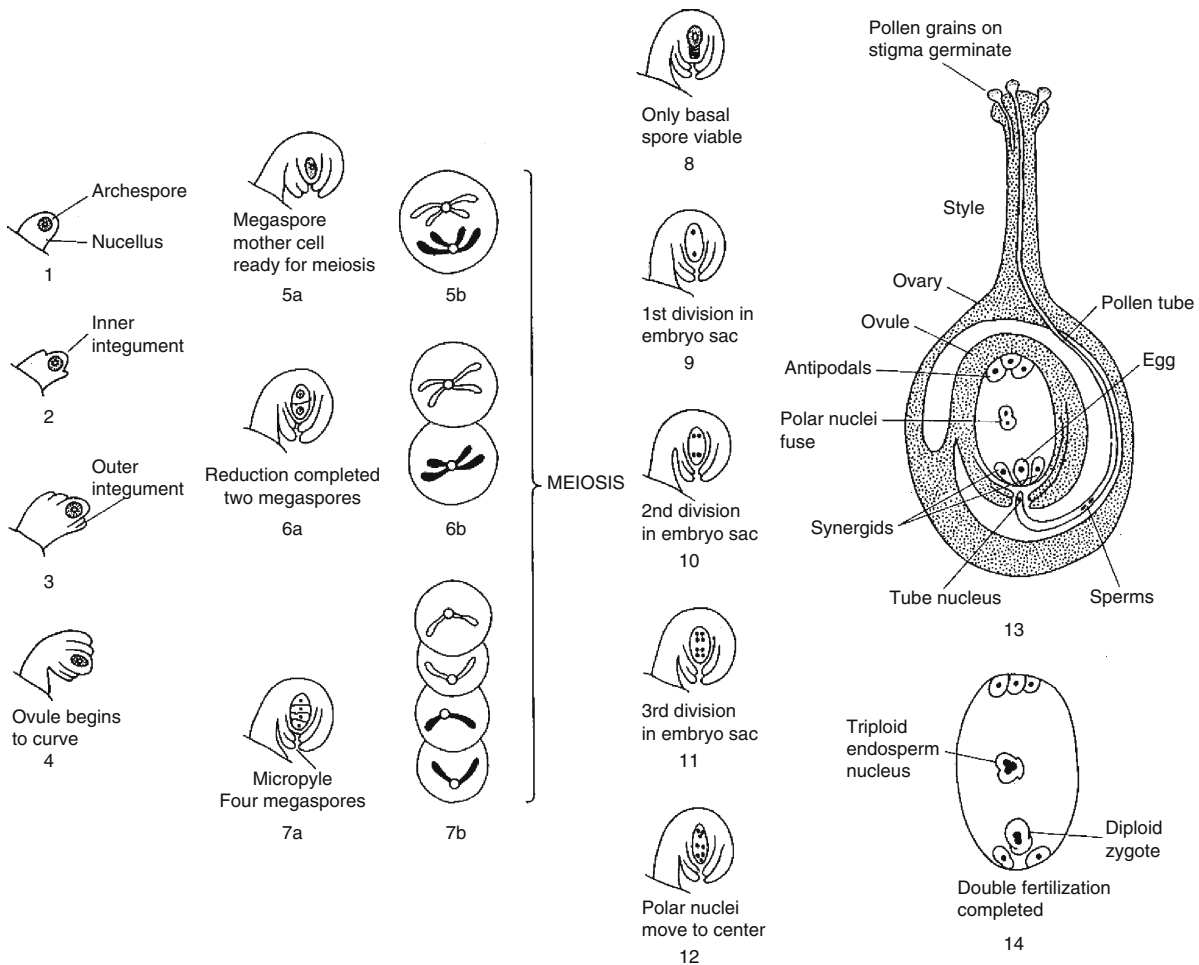

Figure G9. Development of the female gametophyte of higher plants. (The meiotic stages show only one bivalent)

Gamma (γ): The risk for a disease or other attribute associated with a particular genotype. ►[risk](#)

Gamma Distribution: Distribution of the amount of time until the x^{th} occurrence of an event by the Poisson distribution. It has been used to fit the evolutionary rate variation among protein sites. The gamma distribution and similar statistical concepts serve for the theoretical

$$f(x) = \frac{1}{\Gamma(n)} e^{-x} x^{n-1}, \text{ the } \Gamma(n) = \int_0^{\infty} e^{-x} x^{n-1} dx,$$

when n is an integer $\Gamma(n) = (n-1)!$

foundations for the t-distribution, F-test and chi square frequently used in genetic analyses. ►[Poisson distribution](#), ►[t-test](#), ►[F-test](#)

Gamma Field: An area or space where chronic exposure is usually provided from a source of electromagnetic radiation (e.g., ^{60}Co). Such a field may help in studies assessing the effects of long-term exposures on

various biological materials (mutation, chromosome breakage, physiological changes) in case of nuclear accidents. ►[electromagnetic radiation](#), ►[radiation effects](#), ►[radiation hazard assessment](#), ►[radiation protection](#), ►[gamma rays](#)

Gammaglobulin: An immunoglobulin (IgG) consisting of either the light chains κ or γ and the heavy chains have one of the $C_{\gamma 3}$, $C_{\gamma 1}$, $C_{\gamma 2}$, $C_{\gamma 4}$ coded constant regions. ▶antibody, ▶immunoglobulins, ▶agammaglobulinemia, ▶immunodeficiency

Gammopathy: A condition of defective immunoglobulin (gammaglobulin) synthesis.

Gamodeme ▶deme

Gancyclovir: (GCV): A guanine analog, 9-[1,3-dihydroxy]-2-propoxymethylguanine) and a derivative of gancyclovir (2-amino-1,9-dihydro-9-[(2-hydroxyethoxy)methyl]-6-H-purine-6-one, DCV). Both are antiviral (herpes) and anticancer drugs when incorporated into DNA because the analogs will prevent further replication of the genetic material

(see Fig. G11). GCV requires activation, usually by herpes virus thymidine kinase (HSV-TK) that converts it to a monophosphate form and subsequently cellular kinases mediate the production of the toxic triphosphate. ▶suicide vector, ▶adoptive cell therapy, ▶see shingles for acyclovir structure

Figure G11. Gancyclovir.

Ganglion: A group of nerve cells outside the central nervous system.

Ganglioneuromatosis: ►MEN, ►tyrosine receptor kinase

Gangliosides: These are sphingolipids containing several units of acidic sugars attached to the fatty acid chain; they are common in nerve tissues. Their synthetic pathway is:

Uridine-diphosphate[UDP]-glucose + ceramide → glucosyl ceramide + UDP-galactose → galactosyl-glucosyl ceramide. Galactosyl-glucosyl ceramide + cytidine monophosphate-N-acetyl-neuraminic acid (CMP-NANA) → ganglioside G_{M3} . Ganglioside G_{M3} + UDP-N acetyl-galactosamine → ganglioside G_{M2} + UDP. Ganglioside G_{M2} + UDP galactose → ganglioside G_{M1} + UDP. Ganglioside G_{M1} + nCMP-NANA → higher gangliosides. If the sialic acid group (acetyl neuraminic acid, glucosyl neuraminic acid) is removed, asialogangliosides are generated. Several diseases, sphingolipidoses, are involved in their accumulation and breakdown. Ganglioside synthesis is indispensable for the normal development of the central nervous system and its absence leads to neurodegeneration and death. ►sphingolipids, ►sphingolipidoses, ►gangliosidoses, ►unfolded protein response, ►cancer gene therapy, ►Tay-Sachs disease; Kolter T et al 2002 J Biol Chem 277:25859.

Gangliosidoses: It includes a variety of forms. The general gangliosidosis Type I is β -galactosidase deficiency (3p21.33) disease leading to severe, progressive degeneration of the brain and death by the age of two. The overall symptoms resemble the Tay-Sachs disease caused by hexosaminidase A deficiency and the Niemann-Pick disease brought about by sphingomyelinase deficiency. The newborns already show abnormally low activity accompanied by facial and other edemas (fluid accumulation). The distance between the upper lip and nose is enlarged, the ears are set low, there is light hairiness on the front and neck, the spinal column is deformed, the fingers are short, poor appetite and lethargy and general weakness. The liver and spleen become enlarged. Type II juvenile gangliosidosis has a later onset, and death is delayed to age four to five. This form has also very low β -galactosidase levels yet another enzyme seems to be involved. In contrast to Type I disease, in Type II liver and spleen enlargement as well as bone deformities are absent. The heterozygotes can be identified by β -galactosidase assay and the recurrence may be avoided by genetic counseling. Type III is an adult form and it is controlled by a locus different from that of type I. Besides the autosomal Type III, there is an X-linked GM3-gangliosidosis and the latter affects young children. The classification of gangliosidoses

is quite complicated. ►GM-gangliosidoses, ►galactosidase, ►sphingolipidoses, ►sphingolipids, ►Tay-Sachs disease, ►Sandhoff's disease, ►spleen

Gap: An unknown sequence in between contigs, gapped genome. Before a first-draft sequence is produced filling must close the gaps in the sequences that may exist between contigs. ►contig, ►first-draft sequence, ►genome projects; Frohme M et al 2001 Genome, Res 11:901.

GAP: GTPase activating protein is encoded in the long arm of human chromosome 5. Tyrosine-phosphorylated GAP is in the cell membrane whereas the unphosphorylated is mainly in the cytosol. RHO and RAS-related GTPases are abundant in the cells and they regulate signal transduction and the cytoskeleton. ►RAS, ►RHO, ►GTP, ►signal transduction, ►GED, ►von Recklinghausen disease, ►RanGTPase; Ross EM, Wilkie TM 2000 Annu Rev Biochem 69:795.

GAP Genes: Gap genes in *Drosophila* have some segments missing or have fused segments (see Fig. G12). The body pattern is along the longitudinal axis (posterior→ anterior) of the wild type *Drosophila* embryo. Some of the gap mutations delete and/or modify the segments. ►morphogenesis, ►morphogenesis in *Drosophila*, ►knirps, ►Krüppel

Figure G12. Body segments

Gap Junctions: The connecting channels (made of connexins) between apposed cells that permit the transfer of molecules and electric signals between cells. Peptides, such as the class I MHC molecules, up to 1,800 molecular weight may be transmitted between neighboring cells unless the three-dimensional structure interferes (Neijssen J et al 2005 Nature [Lond] 434:83). The same task in plants is assigned to plasmodesmata. Carcinogenic agents may block gap junctions. The function of gap junction can be monitored through transfer of fluorescent dyes or by complementation of nutrients. ►connexin, ►hemichannel, ►innexins, ►plasmodesma, ►CAM, ►MHC, ►Charcot-Marie-Tooth disease, ►oculodentodigital dysplasia; Kumar NM, Gilula NB 1996 Cell 84:381; connection formation: Shaw RM et al 2007 Cell 128:547.

Gap Penalty: When similarities are sought in nucleotide alignments for the sake of construction of evolutionary trees (or determine relatedness) and gaps are encountered, these are subtracted from the matches to avoid unwarranted conclusions regarding homologies.

GAPO Syndrome: Autosomal recessive defect characterized by retarded growth, reduced hair development (alopecia) toothlessness (pseudoanodontia) and progressive wasting of the optical nerves. It bears similarity to progeria. ►progeria, ►growth retardation, ►Gombo syndrome

G

Garden of Eden: The evolutionary theory supposes that the human population originated from single group and about 100,000 years ago, after passing through several bottlenecks, they differentiated into several subpopulations and dispersed from Africa. ►out-of-Africa hypothesis, ►multi-regional origin; Ambrose SH 1998 J Hum Evol 34:623.

Gardner Syndrome (APC, adenomatous polyposis of the colon; mutation in FAP): An autosomal dominant (human chromosome 5q21-q22, 8535 bp) familial polyposis of the colon (FPC). Mutation or deletion occurring at a frequency of about $2-3 \times 10^{-5}$ (in Ashkenazim populations the carrier frequency may exceed 7%), and it may cause adenomatous intestinal polyposis (a cancer) and breast cancer. Penetrance is very high and the prevalence in the general population is $\sim 1/8,000$. The syndrome includes several symptoms, especially if the genetic lesion extends to a larger segment in the region of several genes nearby. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) may be an early diagnostic sign. In some cases, the polyps are limited only to the colon but there are cases where other parts of the intestinal tract, the stomach, the forehead, soft bony tissues, epidermal cysts may also become tumorous. Some forms were associated with increased ornithine decarboxylase activity. Pre-symptomatic diagnosis may detect deletions by the use of appropriate DNA markers. Gene targeting experiments revealed the deletion of exon 14 of APC leads to rapid development of adenomas in mice. In the absence of the WNT morphogenetic signal, APC interacts with glycogen synthase kinase (GSK) and β -catenin. In this case, the Tcf (T cell transcription factor) and Lef (lymphoid enhancer factor) are blocked and the complex leads to tumor suppression. If APC is inactivated monomeric β -catenin appears in the cytoplasm and tumors are formed. Catenin seems to be a transcriptional co-activator of Tcf and Lef. The APC tumor suppressor has apparently a nuclear export function. The c-MYC oncogene is repressed by the wild type APC protein but activated by β -catenin

through Tcf-4 binding sites in the MYC promoter. APC appears to link microtubules (spindle fibers) to the kinetochore, more specifically the Bub protein, a mitotic checkpoint control kinase. This large gene locus includes 15 exons with phenotypic difference among the different allelic mutations/deletions and this causes some ambiguity in the nomenclature. APC is generally associated with chromosomal instabilities because mutation in the APC protein no longer controls the regular function of the kinetochore and its association with the spindle fibers. ►colorectal cancer, ►FAP, ►skin diseases, ►cancer, ►polyposis, ►Turcot syndrome, ►Muir-Torre syndrome, ►targeting gene, ►Cre/LoxP, ►exon, ►adenoma, ►WNT, ►catenins, ►conductin, ►kinetochore, ►spindle fibers, ►GSK, ►MYC, ►hereditary non-polyposis colorectal cancer, ►desmoid disease hereditary, ►mismatch repair; Bienz M, Clevers H 2000 Cell 103:311; Su L-K et al 2000 Am J Hum Genet 67:582; Livingston DM 2002 Nature [Lond] 410:536; Fearnhead NS et al 2001 Hum Mol Genet 10:721; Haigis KM, Dove WF 2003 Nature Genet 33:33.

Gargoylism: A defect in L-iduronidase such as in the Hurler and Hunter syndromes. ►mucopolysaccharidosis

Garlic (*Allium sativum*): A spice, $2n = 16$. Its alliin (allicin) component inhibits cystein proteinases and thereby may exert antibiotic effects on some parasitic microorganisms (see Fig. G13). Its ajoene (sulfur-rich) extract may be antimitotic, microtubule-regulatory, anti-hypertension and anticarcinogenic. ►onion; Li M et al 2002 Carcinogenesis 23:523; Ledezma E et al 2004 Cancer Lett 206:35; Macpherson LJ et al 2005 Current Biol 15:929.

GAS: ►gamma interferon activation site, ►interferons, ►signal transduction

Gas Chromatography: ►chromatography, ►gas-liquid chromatography

Gas-Liquid Chromatography (GLC): GLC is suited for the separation of volatile compounds according to their ability to be dissolved in the material of the column bed. An inert gas (helium) driven through the column carries the volatile compounds, and they are sequentially eluted and collected. Some material must be converted to more volatile derivatives before applied to the columns. This method has been

extensively used to separate and isolate fatty acids and other compounds. ►[chromatography](#)

Gastric Cancer (hereditary diffuse gastric cancer, HDGC, 16q22.1, 5q31.1): As the chromosomal locations indicate two forms of gastric cancer are known. One of them involves a methylation of 6–18 CpG nucleotides in the cadherin1 (CDH1, 16q22) promoter leading to inactivation. Predisposing genes: non-polypoid colon cancer, familial adenomatous polyposis, Peutz-Jeghers syndrome and the Cowden disease. ►[cadherins](#), ►[hereditary nonpolyposis colon cancer](#), ►[Gardner syndrome](#), ►[polyposis hamartomatous](#), ►[multiple hamartoma syndrome](#)

Gastrin: Hormones of 14 to 34 amino acid residues, released in the stomach and regulate stomach acid secretion, other enzymes and esophageal and gall bladder contraction.

Gastroenteritis: Inflammation of the lining of the stomach and intestines.

Gastrointestinal Stromal Tumor, Familial: ►[KIT oncogene](#)

Gastroschisis: A fissure of the abdominal cavity and some of the intestines are protruded through failure of the wall of the abdomen. The pattern of inheritance is unclear. ►[omphalocele](#)

Gastrula: An early stage of embryonic development following the blastula. Gastrulation patterns vary in different animal taxa. The general pattern is an invagination of the epithelial layer into the blastocoel (at the so-called vegetal pole) forming the endoderm that gives rise later to the gut. The outer layer, the epithelium, becomes the ectoderm that will form the epidermis and the nervous system. The cells in-between these two layers develop into a mesoderm that will differentiate into the notochord (a vertebral column or its substitute), into the connective tissues, bones, cartilages, fibers, muscles, the urogenital system and the vascular system, including the heart and blood vessels. Gastrulation of the human embryo takes place during the third week of embryonal development (in mice 6–7 days post coitum). In arthropods, gastrulation is followed by anterior-posterior segmentation and dorsal-ventral, medial-lateral identification of embryonal regions. ►[blastula](#), ►[morphogenesis](#), ►[coitus](#), ►[organizer](#), ►[embryo node](#), ►[p38](#)

GATA: Mammalian transcription factors mediating the formation of erythrocytes. GATA-1 (Xp11.23) recognizes the ^{GTATAG}_{ACTATC} or very similar upstream DNA sequences. Several other GATA factors have been identified also in other vertebrates. GATA-3 (10p15) is a human hematopoietic factor responsible also for the

differentiation of T cells of the immune system. Loss of GATA3 results in noradrenaline deficiency and embryonic lethality in mice. GATA factors may include 4 Zinc finger domains. Mutation in GATA1 results in dyserythropoietic anemia and thrombocytopenia. GATA-2 and GATA-3 regulate adipocyte differentiation and their deficiency may lead to obesity. GATA-4 (8p22-p23), GATA-5 and GATA-6 are expressed on the developing heart. ►[transcription factors](#), ►[hematopoiesis](#), ►[T cell](#), ►[T-bet](#), ►[DNA-binding protein domains](#), ►[erythropoietin](#), ►[dyserythropoietic anemia](#), ►[thrombocytopenia](#), ►[obesity](#), ►[transcriptional priming](#), ►[DiGeorge syndrome](#), ►[noradrenaline](#); Charron F, Nemer M 1999 *Semin Cell Dev Biol* 120:85; Molkenin JD 2000 *J Biol Chem* 275:38949; Patient RK, McGhee JD 2002 *Current Opin Genet Dev* 12:416.

Gatekeeper: ►[selectivity filter](#)

Gatekeeper Gene: It acts in the pathway of carcinogenesis by representing a certain threshold that must be passed before mutation of the tumor suppressor or activator gene(s) can mediate the development of the recognizable oncogenic transformation. Genes preventing other cellular processes are also called gatekeepers. ►[oncogenic transformation](#), ►[oncogenes](#), ►[transformation oncogenic](#), ►[progression](#), ►[cancer](#), ►[phorbol esters](#), ►[caretaker gene](#); Kinzler KW, Vogelstein B 1997 *Nature [Lond]* 386:761; Gomis-Ruth FX, Coll M2001 *Int J Biochem Cell Biol* 33 (9):939.

Gating in Cytometry: Used for typing different cells (e.g., CD4⁺, CD8⁺ lymphocytes) in cytometers. The gates permit the selective identification and counting of specific type on the basis of fluorochromes or antibody, etc. labels. The procedure may facilitate the clinical evaluation of the status of, e.g., AIDS patients. ►[acquired immunodeficiency](#); Bergeron M et al 2002 *Cytometry* 50:53.

Gateway Cloning: A procedure for large-scale identification of open reading frames (ORFeome) in order to annotate the genome and determine the protein-coding open reading frames. The outline of the protocol: 1. Collect a large set of open reading frames from databases. 2. Establish a large number of appropriate primers. 3. Carry out PCR on the cDNA library. 4. Clone recombinant sequences into *E. coli* plasmid vector. 5. Isolate the cloned plasmids. 6. Sequence tagged ORFs (OSTs) and obtain Phred score. 7. Align the ORFs on genomic sequences. 8. Identify thus the location of ORFs and can enter them into a database (Reboul J et al 2003 *Nature Genet* 34:35). ►[ORF](#), ►[ORFeome](#), ►[OST](#), ►[polymerase chain reaction](#), ►[Phred](#)

Gaucher Disease: A chromosome 1q21 recessive complex of glucosyl ceramide lipidoses. There are six genes and two pseudogenes within a 75 kb region and ten different crossing over sites and shared CACCA recombinational hot spots were detected (Tayebi N et al 2003 Am J Hum Genet 72:519). Glucosyl ceramide sphingolipids accumulate in the reticuloendothelial “Gaucher cells” because of deficiency of a β -glucosidase (glucosylceramidase). These Gaucher cells occur in the lymphoid tissues, spleen, bone marrow, inside the veins, lung alveoli and other tissues. The Type I disease occurs in various age groups and the most characteristic symptoms are enlargement of the spleen and bone anomalies. The neuronopathic or malignant Type II form appears before age of six months and results in death by the age of two. The cranial nerves and the brain stem are attacked although there is not much lipid accumulation in these tissues. The less severe juvenile form (Type III) may permit survival to the age of thirty years. Gaucher’s disease is of relatively common occurrence. Cure can be provided by enzyme replacement therapy. A mouse model indicates that transplantation of bone marrow or gene therapy through retroviral transduction either prevented or corrected the disease (Berglin Enquist I et al 2006 Proc Natl Acad Sci USA 103:13819). Prenatal diagnosis is feasible by the use of RFLP and enzyme assays. ▶sphingolipid, ▶sphingolipidoses, ▶glucosidase, ▶RFLP, ▶prenatal diagnosis, ▶lysosomal storage disease Jews and genetic diseases, ▶enzyme replacement therapy, Lewy body; Koprivica V et al 2000 Am J Hum Genet 66:1777.

Gaudens: *Oenothera lamarckiana* contains a ring of 12 translocation chromosomes and one bivalent (see Fig. G14). The translocations contain two complexes, *gaudens* (happy) conveys green color and *velans* (concealing) determines narrow leaves, pale color and disease susceptibility. The (complex) heterozygotes

appear normal. Because of the translocations and the recessive lethal genes they carry, half of the progeny is inviable (*gaudens/gaudens* and *velans/velans* homozygotes) and the other half (the balanced lethal translocation heterozygotes) breeds true and is of normal phenotype. ▶multiple translocations, ▶complex heterozygote, ▶*Oenothera*

Gaussian Distribution: ▶normal distribution

Gazella: In the Dorcas gazella (*Gazella dorcas*) and the Grant’s gazella (*Gazella granti*) the male has 31 chromosomes the female 30. In the *Gazella leptoceros* the males are $2n = 33$, the females $2n = 32$. The Thomson’s gazella (*Gazella thomsoni*) is $2n = 58$.

G_β: ▶G_{αβγ}

G-BASE: Genomic database of mouse, for access see Mouse Genome Database, Encyclopedia of the Mouse Genome. ▶mouse, ▶databases

G-Box Element: An upstream binding site (GA-CAACGTGGC) in plants of which the critical part is the CAACGTG core sequence that binds the G-box protein, a transcriptional activator.

GBP: GSK binding protein. ▶GSK

GC Box: GC BOX in eukaryotic promoters generally contain the 5'-GGGCGG-3' motif, a binding site for transcriptional regulator proteins.

GC (guanine-cytosine) Content: GC content of DNA contributes to the higher buoyant density of the molecules. In the DNA of the majority of eukaryotes, the GC content is about 40%. Higher organisms seem to display higher GC content yet genome size among eukaryotes does not involve higher GC content. It has been suggested that higher GC content affects the expression of genes but it could not be confirmed by more extensive analysis (Sémon M et al 2005 Hum Mol Genet. 14:421). ▶buoyant density, ▶density gradient centrifugation, ▶ultracentrifugation,

►DNA, ►base composition; GC identification tool:
<http://tubic.tju.edu.cn/GC-Profile/>.

GC Skew: $(G - C)/(G + C)$ indicating the not entirely random distribution of G and C on the two DNA strands. In *E. coli* there is 26.22% G in the leading strand whereas in the lagging strand it is 24.58%.

►DNA replication prokaryotes

GC-MS: Gas-liquid chromatography combined with mass spectrometry is an analytical procedure. ►gas-liquid chromatography, ►mass spectrum

GCN1/GCN20: A ribosome-binding complex bound by the N domain of GCN2 and it required for activation of the latter in starved yeast cells. (See Kubota H et al 2001 J Biol Chem 276:17591).

GCN2: It is dimeric and is required for the activation of GCN4. It has ribosome-binding, tRNA-binding, protein kinase and GCN2/GCN20-binding domains. Heatshock protein 90 assists its maturation folding. Its sequence is conserved across fungi, insects and mammals. (See Marbach I et al 2001 J Biol Chem 276:16944).

GCN4: The yeast transcription factor of a leucine zipper structure controlling the transcription of several genes. Its transcription is triggered by amino acid starvation when eukaryotic peptide elongation factor GCN2•eIF-2a becomes phosphorylated. The DNA binding site consensus for GCN4 is: $\begin{matrix} \text{ATGACTCAT} \\ \text{TACTGAGTA} \end{matrix}$ (See ►leucine zipper, ►eIF-2a, ►HRI, ►PEK; Yu L et al 2001 J Biol Chem 276:33257; Natarajan K et al 2001 Mol Cell Biol 21:4347).

GCN5: A yeast transcriptional co-activator with a histone acetyl transferase domain including amino acids 99–262 of the 439-amino acid protein (see Fig. G15). It consists of four antiparallel β-strands, an α-helix and a fifth β-strand. This domain is shared by other histone acetyltransferases as well as by other acetyltransferases such as an aminoglycoside 3-*N*-acetyltransferase and serotonin *N*-acetyltransferase belonging to the GNAT superfamily. It consists of four antiparallel β-strands, an α-helix and a fifth β-strand. This domain is shared by other histone acetyltransferases as well as by other acetyltransferases such as an aminoglycoside 3-*N*-acetyltransferase and serotonin *N*-acetyltransferase belonging to the GNAT superfamily. These enzymes transfer an acetyl group from Acetyl-CoA to a primary but different amino group. ►histone acetyl transferase, ►p300, ►aminoglycosides, ►acetyl CoA, ►TAF_{II}, ►transcriptional activators, ►enhanceosome; Kuo MH et al 2000 Mol Cell 6:1309.

Figure G15. Crystal structure of GCN5 showing the four acetyl transferases. Courtesy of Drs. Sternglanz R and Shindelin H 1999 Proc. Natl. Acad. Sci. USA 96: 8807

G

GCR: G protein coupled receptor. ►G proteins

G-CSF (granulocyte-colony stimulating growth factor): A lymphokine, modulating the effect of growth factors, fetal and post-natal development. ►GM-CSF, ►M-CSF

GCSF (G-CSF): ►granulocyte colony stimulating factor, ►lymphokine

GD: ►hybrid dysgenesis

γδ Element (Tn1000): An insertion element (IE) of the bacterial F plasmid that may produce various Hfr bacterial strains either by co-integration or recombination. The pDUAL/pDelta vector series of the γδ family vectors have been successfully used for generating (nested) deletions in both strands of a cloned insertion sequence. The plasmid replication origin and γsome selectable marker(s) are located in both strands in such a way that none of the essential information would be outside the transposon. ►co-integration, ►Hfr, ►F factor, ►F plasmid, ►Tn3 family, ►nested; Broom J et al 1995 DNA Seq 5 [3]:185; Kumar P et al 2004 Biochemistry 43:247.

γδ T Cells: Express any of the Vγ and Vδ immunoglobulin genes, recognize non-peptidic antigens and the antigen. The γδ T cells do not need professional antigen presenting cells and do not require processing by MHC class I or class II molecules and their ligands in order to be recognized by them in contrast to the αβ T cells (Brandes M et al 2005 Science 309:264). The γδ T cells (~2–10% of all T cells) are very different from the most prevalent αβ T cells and they can be stimulated also by non-peptide antigens such as

phosphocarbohydrates, X-uridine and X-thymidine-5'-triphosphates (TUBBag3 and TUBbag4, respectively) and isopentenyl pyrophosphate. The $\gamma\delta$ T cell differentiation is promoted by the Sox13 transcription factor of the thymocytes whereas the same transcription factor opposes the development of the $\alpha\beta$ T cells (Melichar HJ et al 2007 Science 315:230). The molecules may be the product of nucleic acid salvage pathways and intermediates of the lipid metabolism. The $\gamma\delta$ T cells mount primarily an innate immune response but because they stimulate chemokines and secrete cytokines they promote also the acquired immune system ($\alpha\beta$ T cells). In the absence of $\gamma\delta$ T cells IgE and IgG1, IL-5 and eosinophils are reduced and mice in this condition does not show allergic asthma of the airways in response to peptidic allergens. The $\gamma\delta$ T cell receptor is different from that of the $\alpha\beta$ T cell receptor (Adams EJ et al 2005 Science 308:227). ▶ immunoglobulins, ▶ T cells, ▶ $\alpha\beta$ T cells, ▶ T cell receptor, ▶ salvage pathway, ▶ HLA, ▶ immune system, ▶ eosinophil, ▶ IL-5, ▶ allergen, ▶ asthma; Silva-Santos B et al 2004 Science 307:925; Allison TJ et al 2001 Nature [Lond] 411:820.

GDB: Genome database, the official depository of information of the human genome project. It can be accessed by Internet <http://gdbwww.gdb.org/>. (See also <http://www.ncbi.nlm.nih.gov/Entrez/>).

GDF (growth and differentiation factor): A member of the bone morphogenetic protein family. GDF5 mutations cause chondrodysplasia. ▶ BMP

GDEPT: Gene delivered enzyme-prodrug therapy. ▶ prodrug

GDI (guanine nucleotide dissociation inhibitor): GDI inhibits the dissociation of GDP from certain G proteins. ▶ G protein, ▶ signal transduction, ▶ GEF

GDLD (gelatinous drop-like corneal dystrophy): A rare hereditary amyloidosis. ▶ amyloidosis

gDNA: ▶ genomic DNA

GNDF (glial-cell-line-derived neurotrophic factor): Assists in the maintenance of central dopaminergic, noradrenergic and motor neurons and peripheral and sympathetic neurons. It is a family with several functional members neurturin, perefirin and artemin. This protein is structurally related to the transforming growth factor (TGF- β) family and GDNF is a receptor tyrosine kinase. GDNF function requires a glycosylphosphatidylinositol-linked protein (GDNFR- α) and RET. It has been considered as a potential drug for Parkinson's disease, amyotrophic lateral sclerosis and Alzheimer's disease. GDNF also regulates spermatogenesis. ▶ dopamine, ▶ neuron, ▶ receptor tyrosine kinase, ▶ Parkinson's disease, ▶ amyotrophic lateral

sclerosis, ▶ Alzheimer's disease, ▶ kinase, ▶ TGF, ▶ RET oncogene, ▶ MEN; Hashino E et al 2001 Development 128:3773; Bahuau M et al 2001 J Med Genet 38:638; Lee CS et al 2005 Exp Neurol 191:65.

GDRDA: ▶ genetically directed representational difference analysis

GDP: Guanosine 5'-diphosphate

GE81112: An antibiotic consisting of four amino acids (3-hydroxyisovaleric acid, 2-amino-5-[(aminocarbonyl)oxy]-4-hydroxypentanoic acid, histidine and 5-chloro-2-imidazolyserine). It inhibits specifically peptide initiation on the 30S prokaryotic ribosomal subunit by interfering with the binding of the fMet-tRNA (Brandi L et al 2006 Proc Natl Acad Sci USA 103:39). ▶ antibiotics

GENC (genetically effective cell number): ▶ genetically effective cells

GED: GTPase effector domain located at the C-end of dynamin. ▶ dynamin, ▶ GTPase, ▶ GAP

GEF: Translation factor similar in function to eIF-2B. ▶ eI factors, ▶ TU

GEF (guanine nucleotide exchange [release] factor): It facilitates the dissociation of GDP from G proteins. It is similar to ▶ Cdc25. ▶ GDI, ▶ GAP, ▶ Cdc25, ▶ G protein, ▶ signal transduction, ▶ SOS, ▶ ARF, ▶ faciogenital dysplasia, ▶ cytohesins, ▶ SOS; Vetter IR, Wittinghofer A 2001 Science 294:1299; Brugnera E et al 2002 Nature Cell Biol 4:574; Vazquez-Prado J et al 2004 Methods Enzymol 390:259.

GEFITINIB: ▶ Iressa

Geiger Counter (Geiger-Müller counter): Registers the rate of disintegration of radioactive isotopes. They are necessary in all isotope laboratories, also for monitoring contamination and spillage (see Fig. G16). The counter also detects environmental pollution of radioactivity in case of fallout. It measures β radiation with efficiency of 30–45% and for γ radiation (shield closed) 5,000 counts per minute per milliröntgen (mR). A typical full-scale reading is 0.2 to 20 mR/hr. It is very useful equipment for surveying because of good sensitivity and within seconds response. Its shortcomings are energy dependence, saturation at high rates and interference by ultraviolet and microwave radiations. A special adaptation of the Geiger counter is the strip counter that detects radiation in chromatograms, membrane filters, blots, etc. ▶ scintillation counters, ▶ ionization chambers, ▶ radiation hazard assessment

Figure G16. Geiger counter

Geitonogamy: Pollination by neighboring plants of basically the same genetic constitution.

Gel Electrophoresis: Nucleic acid fragments are electrophoresed in agarose and polyacrylamide gels, depending on the size of the fragment. In agarose larger, in polyacrylamide smaller fragments can be separated, e. g., in 0.3% agarose 5–60 kb, in 0.7% 0.8–10-kb fragments can be analyzed. In 5% polyacrylamide 0.5–0.8-kb, in 2% 0.04–0.1-kb fragments can be resolved (see DNA fingerprinting). Proteins can be electrophoresed in various media (paper, starch, polyacrylamide) by charge or by size in polyacrylamide-sodium dodecylsulfate (SDS) gels. ▶[electrophoresis](#), ▶[two-dimensional gel electrophoresis](#)

Gel Filtration: Porous polymers such as Sephadex, Bio-Gel (commercially available in various pore sizes) can be used to separate high molecular weight DNA or proteins from smaller molecules (unincorporated dNTPs, linkers, etc.) The large molecule is excluded while the smaller fragments are retained on the gel during chromatography. For rapid purification it can be used in syringes. ▶[Sephadex](#), ▶[linker](#)

Gel Mobility Assay: ▶[gel retardation assay](#)

Gel Retardation Assay: Compared to DNA alone, DNA-bound protein retards the movement of the complex in the electrophoretic field (band shifting), and this way DNA-binding proteins can be isolated and analyzed. To the protein bound to DNA, other protein(s) may also bind making the complex increasingly slow moving from the start site. This process is called *supershift*. A more specific test uses DNA affinity chromatography. ▶[DNA-binding domains](#), ▶[DNA binding proteins](#), ▶[affinity chromatography](#), ▶[electrophoresis](#)

Gelatinase: ▶[metalloproteinases](#)

Gelding: Castrated male horse. ▶[castration](#)

Geleophysic Dysplasia: A mucopolysaccharidosis with happy face, dysotosis and heart problems. ▶[mucopolysaccharidosis](#); Wraith et al 1990 Am J Med Genet 35:153.

Gellan Gum: A synthetic polysaccharide, used for solidifying plant tissue and bacterial culture media (instead of agar). ▶[agar](#), ▶[embryo culture](#)

Gelsolin: An actin-binding protein that regulates the cytoskeleton. ▶[actin](#), ▶[cytoskeleton](#), ▶[amyloidosis](#), ▶[fodrin](#)

Gem: A GTP-binding protein, induced by mitogens; it is related to RAS. ▶[GTP](#), ▶[mitogen](#), ▶[RAS](#)

GEM91: A 25-mer antisense phosphorothioate. ▶[antisense technologies](#), ▶[phosphorothioates](#)

Gemini of Coiled Bodies: These consist of heterogeneous nuclear ribosomal proteins (hnRNP), coiled bodies, and “survival-of-motor-neuron” proteins (SMN). SMN forms are tightly associated with protein SIP1 (SMN interacting protein). SMN1 is located in human chromosome 5q13 and SMN2 is almost identical to SMN1 but lacks an exon-7 domain. SMN1 is frequently replaced by SMN2 in spinal muscular atrophy. ▶[coiled bodies](#), ▶[hnRNP](#), ▶[spinal muscular atrophy](#); Matera AG, Frey MR 1998 Am J Hum Genet 63:317.

Geminin: A ~25-kDa protein preventing aberrant replication of the chromosomes after the S phase of mitosis. It keeps in check Cdc6/18 and Cdt1. It accumulates during mitosis but it is degraded at the transition from metaphase to anaphase. After it is degraded, Cdc6/18 and Cdt1 rebuild and associate with the chromatin in preparation for the S phase. ▶[mitosis](#), ▶[cell cycle](#), ▶[Cdc6](#), ▶[Cdc18](#), ▶[Cdt](#), ▶[MCM](#), ▶[ORC](#), ▶[replication licensing factor](#); Wohlschelegel JA et al 2000 Science 290:2309; Luo L 2004 Nature [Lond] 427:749.

Geminiviruses: These contain single-stranded small DNA genomes (~2.7 kb). Some can infect monocots others infect dicots (see Fig. G17). Their capsules may be geminate (doubled) or their DNA may exist in two partially-identical (200 bases) rings. They may be used for plant vector construction. ▶[agroinfection](#); Lazarowitz SG 1992 Crit Rev Plant Sci 11:327.

Figure G17. Geminiviruses particles

Gemmules: An ancient term for hereditary units.

GenBank: Data bank for information on nucleic acid and protein sequences, Los Alamos Natl. Laboratory, Group T-10, Mail Stop K710, Los Alamos, NM 87545, USA, Tel: (505) 665–2177, e-mail: general inquiries genbank%life@lanl.gov, sequence submission and forms: gb-sub%life@lanl.gov. ▶[EMBL](#),

Genboree: Human Genome Sequencing Consortium sequencing and annotation programs. (See <http://www.genboree.org/java-bin/login.jsp>).

Gencode: An integrated annotation of existing cDNA and protein resources to define transcripts with both manual review and experimental testing procedures.

Gender: The sexual type, e.g., female or male in societal or lexicographic context; in physiology or genetics the word sex is more appropriate.

Gender Dimorphism: Separate individuals represent the two sexes.

Gender Discrimination: The difference between males and females is a biological fact yet that does not justify the ethical and moral principle that equal contribution must be equally rewarded. It is unfair, however, to evaluate men and women by identical criteria because the majority of the social criteria are male-oriented and disadvantageous for women. In general, males and females carry the same chromosomes except the gene-poor Y chromosome and the dosage of the X chromosomes, which are in duplicate in a normal female but the X is present only in a single dose in the normal males and dosage compensation may not be perfect. Both male and female attributes have special advantages. Maleness, in general, have been associated with more aggressiveness, less empathy compared with femaleness. There is no evidence, however, for differences in originality of thinking or creativeness, therefore for the frequently found lower appreciation for women in leadership or scientific contribution is not justified. In certain positions, males (e.g., when great physical strength is an advantage) and in others female characteristics (e.g., dealing with young children) are more desirable. The social differences between the sexes are frequently called gender gap. The gender gap was historically larger than it is today and it is steadily diminishing in business and academics. During the last 30 years among 4,227 life-scientists, patenting by women was only 40% of that by men (Ding WW et al 2006 Science 313:665). ►discrimination genetic, ►dosage compensation; Lawrence PA 2006 PLoS Biol 4[1]:e19.

Gender Preselection: Separation of X- and Y-bearing sperms before fertilization. Success in such a procedure may prevent the transmission of X-chromosome linked genetic defects. It may become an alternative to ethically or morally objectionable procedures of negative eugenics (Anyhow, it should be called sex preselection.) ►eugenics, ►abortion; Fertility & Sterility 75:861–864 [2001].

Gender Trading: In hermaphroditic animals the individuals may donate sperm or oocyte or both.

Gene: A specific functional unit of the DNA (or RNA) potentially transcribed into RNA or coding for protein. A group of co-transcribed exons but due to alternative splicing, or exon shuffling, or overlapping, or using more than one promoter or termination signal, the same nucleic acid sequence may encode more than a single protein. A common structural organization of protein encoding genes in eukaryotes: ►enhancer, ►promoter, ►leader, ►exons, ►introns, ►termination signal, ►polyadenylation signal, ►downstream regulators

The vast majority of human genes are ‘mosaics’ containing 7–9 exons of 120–150 bps, each. In some genes the exon number and size can be much larger. In between exons there are 1000 to 3,500 bp long introns. The size of the introns may also be several times larger. The number of coding nucleotides varies between 1,100 to 1,300 but the larger genes may have much larger coding sequences. The exons + introns + 5′ and 3′ untranslated sequences combined, the genomic genes, in general, extend to 14–27 kb DNA. A large fraction of the human genes is alternatively spliced and thus the same “gene” may be translated into three or more kinds of proteins. In human chromosome 10, the average known gene has 4.76 transcripts but the *adducin 3* gene has 22 variants. The organization of other eukaryotic genes may vary quantitatively. Genic sequences are richer in GC nucleotides than the non-coding tracts. In prokaryotes, introns are rare and the size of the genes is smaller. Computational procedures might assist the identification of promoters and first exons in the human (and other) genomes. Genes generally originate by duplication that is followed by mutational alterations to gain a new function. Alternatively, new functions may arise by reorganization of exons or modules or by emergence of functional sequences from non-coding DNA tracts. Lateral transfer delivers genes from one organism to another. Although the gene is a rather stable complex molecule, its function is mediated, modulated and controlled by several proteins. The potential role of epigenesis in gene expression and development is steadily increasing. The concept of the gene is undergoing now further complications since it became known that most of

the DNA (rather than a small “genic” fraction) is transcribed into RNA and these RNAs seem to have hitherto not completely understood function in controlling the expression of genes (Kapranov P et al 2007 Science 316:1484). A new definition of the classical ‘beads on a string’ concept of gene has now emerged: “A gene is a union of genomic sequences encoding a coherent set of potentially overlapping functional products” (Gerstein MB et al 2007 Genome Res 17:699). The idea of “number of genes” is becoming difficult to define not because of problems of sequences and annotation. The final product of gene expression can be somewhat elusive because transcripts of exons and introns are overlapping in different contexts. In addition, some components of an expressed gene may be situated away from the core and can be in a different chromosome. Thus, the number of genes may greatly increase if we do not count the components of these systems but the variety of intertwined products. Paradoxically, if the genes are counted according to the number of these expression modules, the number of genes becomes much fewer (Gerstein MB et al 2007 Genome Res 17:669). It is now understandable why the prescience of Richard Goldschmidt (1958) questioned whether corpuscular genes may actually exist and rather we have to accept that complex position effects and interacting systems determine the function of the genes. ▶[reaction norm](#), ▶[one gene—one enzyme](#), ▶[splicing](#), ▶[dystrophin](#), ▶[titin](#), ▶[gene number](#), ▶[ORF](#), ▶[pseudogene](#), ▶[lateral transfer](#), ▶[mosaic genes](#), ▶[epigenetics](#), ▶[microRNA](#), ▶[RNAi](#), ▶[overlapping genes](#), ▶[operon](#), ▶[regulon](#), ▶[gene-associated region](#), ▶[non-Mendelian inheritance](#), ▶[ENCODE](#); Snyder M, Gerstein M 2003 Science 300:248; Wolfe KH, Li W-H 2003 Nature Gen 33 (Suppl):255; Rédei GP et al 2006; Advances Genet 56:53; gene location–function: <http://www.cmbi.ru.nl/GeneSeeker/>, gene records of more than 3,500 taxa: http://www.ncbi.nlm.nih.gov/projects/Gene/gentrez_stats.cgi.

Gene Action: The type and mechanism of expression of genes.

Gene Activation: Turning genes on; initiates expression of genes.

Gene Activator Proteins: ▶[transcriptional activators](#)

Gene Alignment: Arranging the nucleotide sequences of functionally or by evolution-related genes, in such a manner that the homologous and non-homologous stretches of nucleotides can be assessed. ▶[homology](#), ▶[dot matrix](#)

Gene Amplification: ▶[amplification](#)

Gene and Protein Names: See <http://www.ba.cnr.it/keynet.html>.

Gene Assignment: Locating genes to chromosomes.

Gene-Associated Regions: Regions not part of the classical gene, yet retain an important role in gene function. Furthermore, they can contribute to the expression of several genes. Examples for such long-range elements are the Locus Control Regions (LCR) of beta-globin that contributes to the expression of several genes, and will likely be the case for many other enhancers as their true gene targets are mapped. It can also be applied to untranslated regions that contribute to multiple gene loci, such as the long spliced transcripts observed in the ENCODE region and *trans*-spliced exons (Gerstein MB et al 2007 Genome Res 17:669).

Gene Bank: ▶[GenBank](#), ▶[DDBJ](#), ▶[EMBL](#), ▶[sperm bank](#), ▶[databases](#)

Gene Block: A group of syntenic genes. Gene blocks can be preserved in their original linkage phase if they are within inversions because the single recombinants are generally inviable and the double recombinants are very rare within short regions. Paracentric inversion testers have been used to locate advantageous gene blocks for utilization in plant breeding projects. Inversion homozygotes are backcrossed with inbred stocks, and the F₁ is backcrossed with the inversion-homozygote tester. This progeny is half homozygous for the inversion and half is heterozygous for it. The two groups can be easily distinguished by genetic markers or by semisterility of the heterozygotes (if any crossing over takes place). If the heterozygotes surpass the parental forms in quantitative traits, the good performance is attributed to the inverted segment tested. Favorable gene blocks (quantitative gene loci, QTL) may also be identified by linkage to RFLP markers. During evolution, some gene blocks were rather well preserved. In chicken after > 300 million years of separation from the human lineages 13 segments still represent 72% of human chromosome 12. About 87% of chimpanzee and rhesus macaque sequences can be aligned with human chromosome 12 (Scherer SE et al 2006 Nature [Lond] 440:346). ▶[inversions](#), ▶[QTL](#), ▶[operon](#), ▶[gene cluster](#), ▶[RFLP](#)

Gene Cassette: A special type mobile genetic element, which carries, most commonly, only a single gene (e.g., antibiotic resistance) and a recombination sequence. For mobility, it depends on another element, the integron. ▶[integron](#); Recchia GD, Hall RM 1997 Trends Microbiol 5:389.

Gene Center: The geographical area where the greatest genetic diversity within a species is found, and

therefore it is considered as the evolutionary cradle of that species. ►evolution; Vavilov NI 1928 Verhandl V Internat Kongr Vererbungswiss Berlin, 1:342.

Gene-Centromere Distance: ►centromere mapping, ►tetrad analysis, ►alpha parameter

Gene Chips: ►DNA chips, ►microarray hybridization

Gene Circuits: A collection of genetically encoded proteins with regulated expression. In the *elementary gene circuit*, only a single specific transcription factor operates the gene under the influence of a signal. In a biological system the number of players may extend to numerous (hundreds) of proteins. ►Gene-Switch cassette, ►networks, ►oscillator, ►genetic network, ►synthetic biology; Sprinzak D, Elowitz MB 2005 Nature [Lond] 438:443.

Gene Cloning: The propagation of a piece of DNA, in identical copies, in a bacterial, viral or yeast (or other) vectors in order to increase its quantity. It is the same as molecular cloning.

Gene Cluster: Juxtapositioned genes sometimes with related function. ►operon, ►regulon, ►transcripton, ►immunoglobulin genes

Gene Conversion: A biological event that results in the change of one allele to another present in the homologous chromosome. It is a specific type of non-reciprocal recombination. As a consequence, the meiotic output is changing from 2:2 to 3:1 or if the conversion takes place in the opposite direction, to 1:3. In case an additional mitotic division following meiosis forms octads, other types of conversion asci can be identified (see Fig. G18: the left-most octad is normal; the other five indicate gene conversions). Gene conversion within a locus proceeds in a polarized fashion, following the direction of DNA replication. Gene conversion may involve *map expansion* because within very short distances the neighboring sites may be co-converted and thus reducing the chance of their separation. This is in contrast to classical recombination when the presence of multiple markers permits the detection of higher number of recombinational events. The conversion is characterized by *fidelity*, i.e., the converter and the converted alleles are identical. The 3:1 and 1:3 spore ratios in the tetrads generally occur with equal frequency, and this was named *parity*. Mitotic gene conversion may produce somatic sector(s). Although gene conversion is not a classical recombinational event itself, it is accompanied by exchange of markers at the flanking region in about half of the cases. It has been assumed that gene conversion not associated with recombination of flanking markers, the donor of genetic information may be a cDNA.

In yeast genes *RAD51*, *RAD55*, and *RAD57* activity is involved in mitotic recombination and gene conversion between two DNA molecules. In RNA-mediated gene conversion these are dispensable but gene *RAD1* (encoding an endonuclease) is required.

Figure G18. Gene conversion asci

Originally, gene conversion was discovered in ascomycetes, now it is believed to occur in other eukaryotes too but the identification of gene conversion is still the easiest on the basis of tetrad data (or half tetrads in *Drosophila* with attached X-chromosomes). The frequency of gene conversion may be highly variable from gene to gene ranging from less than 0.5% to a few percent in yeast. The average size of the converted segment may extend to 1000 bp. Not all aberrant spore output can be attributed to gene conversion. Polysomy, polyploidy, nondisjunction, premeiotic mitotic recombination, suppressor mutations, etc. may all produce aberrant asci similar to the results of gene conversion. The different types of gene conversions are best identified in the asci where meiosis is followed by an additional mitosis. The detection of gene conversion is relatively simple in organisms where the (pollen) tetrads are preserved (*Salpiglossis* or *Arabidopsis* mutants).

In some instances in human c4IIs, the frequency of gene conversion much exceeded that of homologous reciprocal recombination, verified by molecular analysis. Actually, at special hot spots within short chromosomal regions (HLA-DBP1 and the PAR pseudoautosomal region of the human Y chromosome) the frequency of recombination by crossing over was lower than that by gene conversion ($0.9\text{--}1.2 \times 10^{-3}$ versus $1.3\text{--}3.4 \times 10^{-3}$, respectively). At some other regions, the frequency of conversion was in the range of 5×10^{-5} . The conversion tract observed was minimum 300 bp to a maximum of 1,091 bp. The conversion appeared limited to sperm (meiosis) and was not observed in blood (mitosis). Other investigations detected gene conversion in somatic cells of animals. The conversion rate declined very rapidly

with increased distance. Sperm typing by PCR was used for the studies. The use of PCR technology may permit the detection of converted sequences within any eukaryotic gene even in the absence of tetrad analysis. The center of conversion events overlapped with the crossing over peaks. The results suggest similarities in the mechanism of gene conversion and crossing over (Jeffreys AJ, May CA 2004 *Nature Genet* 36:151). The mismatch repair of double-strand breaks may involve gene conversion. ▶[conversion asci](#), ▶[half conversion](#), ▶[recombination mechanisms](#), ▶[recombination models](#), ▶[sex circle model](#), ▶[PCR](#), ▶[mismatch repair](#), ▶[sperm typing](#); Fogel S et al 1971 *Stadler Symp* 1–2:89; Quintana PJE et al 2001 *Genetics* 158:757.

Gene Conversion, Ectopic: The interpretation for the variations in the non-recombining regions of the X and Y chromosomes in feline species. Since chromosome pairing is a requisite for the classical gene conversion, it is hypothesized that accidental pairing may occur. (See Slattery JP et al 2000 *Proc Natl Acad Sci USA* 97:5307).

Gene Copy Numbers: In lower organisms, the majority of the genes occur in single copies per genome yet, even in bacteria, ribosomal genes may be present in seven copies. In the amphibian oocytes, during the great need for protein synthesis ribosomal genes may be amplified 1,000 to 1,500 fold and form more than a thousand nucleoli. After meiosis this excessive amount of rRNA genes are discarded. In maize plants, there may be 10,000 to 20,000 copies of ribosomal genes per diploid cells. *Xenopus* may have 24,000 copies of the rRNA genes and 200 copies of each of the tRNA genes. *Drosophila* has about 500 copies of 5S RNA genes in the right arm of chromosome 2. Some particular sequences (SINE and LINE) occur in all eukaryotes in high numbers. In many higher eukaryotes, repetitive sequences may exceed 80% of the genome. Decreased copy number of the *Fcgr3* gene of rodents or the human homolog FCGR3B predisposes to glomerulonephritis in systemic lupus erythematosus (Aitman TJ et al 2006 *Nature [Lond]* 439:851). ▶[amplification](#), ▶[glomerulonephritis](#), ▶[lupus erythematosus](#), ▶[SINE](#), ▶[LINE](#), ▶[gene number](#); Romero D, Palacios R 1997 *Annu Rev Genet* 31:91.

Gene Delivery: The system of introduction of foreign gene(s) into a cell(s). ▶[transformation genetic](#), ▶[transfection](#), ▶[microinjection](#), ▶[biolistic transformation](#), ▶[electroporation](#), ▶[vectors](#), ▶[receptor-mediated gene transfer](#), ▶[cytofectin](#), ▶[liposomes](#), ▶[endocytosis](#)

Gene Density: In *Drosophila* 1/13.4 kb was reported but it is variable (1/5.6 to 1/78 kb); in the plant *Arabidopsis* 1/4.5 kb. It appears that in the human nucleus, the chromosomes with large gene density (e.g., 19/Mb) are more centrally located whereas the chromosomes with lower gene density (e.g., 18) are situated more at the periphery. The size of the chromosomes does not affect their position. The average human gene density is about 10/Mb, in chromosome 13 being 6.5 and in chromosome 22 being 26. In human chromosome 12 the size of the gene clusters vary; there 9 natural killer cell genes at 12p13.2-p12.3 and 14 keratin II genes at 12q13.3 whereas there are 3 aquaporin genes at 12q13.1 (Scherer SE et al 2006 *Nature [Lond]* 440:346). The marine chordate, *Oikopleura dioica*, has a minimum genome size of 51 Mb, about 15,000 genes and a very short life cycle (two to four days, depending on the temperature). Its gene density appeared only 1/5 kb, the lowest among chordates. Persistently open chromatin domains have more essential genes that enable reduced noise by avoiding transcriptional fluctuation associated with chromatin remodeling. Essential genes are rare in subtelomeric regions (Batada NN, Hurst LD 2007 *Nature Genet* 39:945). (See Boyle S et al 2001 *Hum Mol Genet* 10:211; Seo H-C et al 2001 *Science* 294:2506).

Gene Discovery: The completion of genome sequencing still does not reveal the function of all open reading frames. Functional genomics seeks the identification of what the individual or clusters of genes do within the cell. Because genes are expressed in complex networks new functions will be discovered for times to come. ▶[EST](#), ▶[UniGene](#), ▶[normalization](#), ▶[subtraction](#), ▶[genetic networks](#); Giallourakis; C et al 2005 *Annu Rev Genomics Hum Genet* 6:381; <http://www.geneatlas.org>.

Gene Disruption: ▶[insertional mutation](#), ▶[targeting genes](#), ▶[insertion elements](#), ▶[transposons](#)

Gene Distribution: Gene distribution in prokaryotes (*E. coli*, *Bacillus subtilis*) is unequal between the leading and lagging strands. The majority of the essential genes are expressed in the leading strand and the essentiality of function, and not the expression level, determines this strand bias. Some chromosomes and chromosomal regions display higher or lower gene density than the average. ▶[leading strand](#), ▶[lagging strand](#); Rocha EPC, Danchin A 2003 *Nature Genet* 34:377.

Gene Diversity: Estimated on the basis of allelic frequencies in a population. H = gene diversity at a locus, n = number of individuals, m = number of alleles at the locus, x_i = the frequency of the i th allele. For self-fertilizing species $n/(n-1)$ replaces $2n/2n-1$.

►evolutionary distance, ►diversity; Nei M Roychoudhury AK 1974 Genetics 76:379; Nei M 1987 Molecular Evolutionary Genetics. Columbia University Press, New York.

$$H = \frac{2n}{(2n-1)} \left(1 - \sum_{i=1}^m x_i^2 \right)$$

Gene Dosage: The number of identical and repeated genes in the genome. ►polyploidy

Gene Duplication: ►duplication

Gene Editing: Parts of natural genes are replaced or completed by synthetic DNA chains or a natural repair process eliminates gaps or mismatches in the DNA (called also proofreading). ►editing, ►DNA polymerases, ►mtDNA, ►RNA editing

Gene Evolution: The process by which once similar genes diverged or different genes assumed similar structure and function. The starting material is usually the duplication of gene or a chromosomal segment. During evolution, some genes are lost because their function is no longer needed in the altered environment. Parasites may exploit host functions and let some of their own functions and genes lapse. In some instances, host proteins are either hijacked for use by mobile elements or recruited to defend against them. Some yeast genes (e.g., those involved in DNA repair) may be subject to selective pressures imposed by mobile elements and could favor alleles that might be otherwise deleterious for their normal roles related to genome stability. NHEJ genes could have profound consequences for genome integrity in many organisms, making mutations that are subtly deleterious for NHEJ function nonetheless selectively favored because of their ability to combat mobile element insertions (Sawyer SL, Malik HS 2006 Proc Natl Acad Sci USA 103:17614). ►divergence, ►convergence of genes, ►duplication, ►NHEJ

Gene Expression: The realization of the genetic blueprint encoded in the nucleic acids. Gene expression may be modified, enhanced, silenced, and timed by the regulatory mechanism of the cell responding to internal and external factors. The *expression capacity* is the ratio of the maximal to minimal level of expression in response to signals. Usually it is the transcription of DNA into RNA. The number of genes expressed in one or more copies in human cell lines was estimated by 'massively parallel signature sequencing' to be 10,000 to 15,000. About 1/3 to 1/2 of the genes displayed cell specificity whereas half or more were generally expressed (Jongeneel CV et al 2003 Proc Natl Acad Sci USA 100:4702). Using RNAi technology, the 19,075 genes of *Caenorhabditis* were targeted. The data

indicate that about 40% of the genes are expressed at the early embryonic stage, 36% in the late embryos, 16% in the larvae, and 8% in the adults (Sönnichsen B et al 2005 Nature [Lond] 434:462). Interestingly, in *Arabidopsis* plants only 12% of the ethylmethane sulfonate induced mutations expressed at adult plant stages when 89.2% of the total estimated genes displayed mutant phenotype (Rédei GP et al 1984, p. 285, Mutation, Cancer, and Malformations; Chu HY, Generoso WM eds Plenum, New York).

Analysis of the sequence of regulatory elements 800 bp upstream of genes provides high probability for the prediction of their level of expression (Beer MA, Tavazoie S 2004 Cell 117:185). Regulation of gene expression differentiates evolutionary categories more distinctly than the base sequences of the DNA (Rifkin SA et al 2003 Nature Genet, 33:138). By the use of the *lac* bacterial gene or the aequorin (*GFP*) gene, gene activity can be visualized in living cells and the dynamics of transcription, RNA processing and DNA repair can be optically traced (Tsukamoto T et al 2000 Nature Cell Biol 2:871). Large scale co-expression of genes can be detected by regression analysis of microarray hybridization data (Persson S et al 2005 Proc Natl Acad Sci USA 102:8633). ►regulation of gene activity, ►protein synthesis, ►SAGE, ►FANTOM, ►microarray hybridization, ►massively parallel signature sequencing; Whitfield ML et al 2002 Mol Biol Cell 13:1977; Levsky JM et al 2002 Science 297:836; Bar-Joseph Z et al 2003 Proc Natl Acad Sci USA 100:10146; Gene Resource Locator; GEO [Gene Expression Omnibus]: <http://www.ncbi.nlm.nih.gov/geo/>; <http://www.HugeIndex.org/>; <http://www.biotech.nologycenter.org/hio/>; <http://expression.gnf.org/cgi-bin/index.cgi>; mouse: http://www.Informatics.jax.org/menus/expression_menu.shtml; mouse gene expression pattern database: www.genepaint.org/; complexity of gene expression: <http://www.bioinf.med.uni-goettingen.de/services/deep/>.

Gene Expression Maps: They combine topological information on expression, co-expression and correlation of gene expression with all possible intrinsic (e.g., developmental) and extrinsic (e.g., heat shock) factors. These maps then allow predictions on biological processes, functions and phenotypes. ►protein mapping; Kim SK et al 2001 Science 293:2087; Ihmel J et al 2002 Nature Genet 31:370.

Gene Expression Omnibus: The gene expression/molecular abundance repository supporting MIAME compliant data submissions, and a curated, online resource for gene expression data browsing, query and retrieval. ►MIAME, <http://www.ncbi.nlm.nih.gov/projects/geo/>; <http://www.ncbi.nlm.nih.gov/geo/>.

Gene Family: The number of genes (paralogous loci) closely related by structure and generally also by function. They probably originated through duplications, domain shuffling, splicing and fusion (and some divergence) during evolution. The members of these gene families are frequently (closely) linked but may also be dispersed in the genome. The complete genome sequences can now reveal the relationships impossible to detect by earlier methods. Amino acid sequence comparison for 25, 193 human proteins indicate that on average that the vast majority of them involve relationship to ~ 26 other proteins. The average number of related amino acids is 36.5 for the majority that are related (Britten RJ 2005 Proc Natl Acad Sci USA 102:5466). ▶orthologous loci, ▶paralogous loci, ▶duplication, ▶deletion, ▶exon shuffling, ▶paranome, ▶lateral transmission, ▶homoeologous chromosomes, ▶homoeologous alleles, ▶evolution of proteins, ▶protein families, ▶immunoglobulins, ▶protein isomorphs; Thornston JW, De Salle R 2000 Annu Rev Hum Genet 1:41.

Gene Farming: Cloning, transformation and propagation of genes in another species.

Gene Fission: May occur during evolution by splitting one gene into two parts. This process has taken place most frequently in thermophilic archaea. ▶gene fusion

Gene Flow: The spread of genes in a population by migration of individuals and cross-fertilization. Gene flow, depending on its intensity, may rapidly alter gene frequencies in a population. Gene flow may be hindered or prevented by geographic isolation, physiological factors (differences in sexual maturity and breeding seasons), genetically (by chromosomal rearrangements causing hybrid sterility, incompatibility alleles and differences in chromosome number [polyploidy]). In neighboring populations, at the overlapping borders, repeated backcrosses may occur resulting in *introgressive hybridization* and permanent inclusion of new alleles into the gene pool in one or more populations. The availability of transformation techniques may overcome the natural gene flow and transfect genes among taxonomic groups that were earlier unable to exchange genetic information because of complete sexual isolation. The wave of advance of an advantageous gene was calculated by RA Fisher: $r = \sqrt{2gm}$ where g = the initial growth rate and m = the migration rate per time and space. Molecular markers greatly facilitate tracing of the path of genes in human and other populations. Analysis of the mitochondrial DNA, X and Y chromosomes are the most useful tools for this purpose. ▶migration, ▶introgressive hybridization, ▶Wahlund's principle, ▶transformation, ▶Y chromosome, ▶X chromosome, ▶Eve mitochondrial

foremother, ▶out-of Africa; Wells RS et al 2001 Proc Natl Acad Sci USA 98:10244; Oota H et al 2001 Nature Genet 29:20; Weale ME et al 2002 Mol Biol Evol 19:1008; Goldstein DB, Chikhi L 2002 Annu Rev Genomics Hum Genet 3:129; Cavalli-Sforza LL et al 1994 The History and Geography of Human Genes, Princeton University Press, Princeton, New Jersey.

Gene-For-Gene: The relationship between host and pathogen. ▶Flor's model, ▶host-pathogen relation, ▶co-evolution

Gene Frequency: The frequency of a certain allele relative to all alleles at a locus within a particular population ▶allelic frequencies, ▶Hardy-Weinberg theorem, ▶selection, ▶drift, ▶genetic equilibrium, ▶forensic genetics, ▶DNA fingerprinting, ▶ceiling principle

Gene Function: The typical action of the product of the gene. Relying on the sequenced genomes and the proteomic technology, the correlation between the transcriptome and the metabolome can be experimentally studied. ▶transcriptome, ▶metabolome; Hirai MK et al 2004 Proc Natl Acad Sci USA 101:10205; gene function network tool:

<http://whipple.cs.vt.edu:8080/virgo>, analysis of genes against any set of function: <http://genetrail.bioinf.uni-sb.de/>.

Gene Fusion: Attaching to a structural gene by in vitro genetic engineering, a selected promoter or other element(s), or a promoterless structural gene is transformed into a host cell and expressed only if it can trap in vivo an appropriate host promoter (enhancer). The procedure permits a study of the nature of the fused heterologous genetic element. If gene fusion occurs between coding regions of two genes, the translation product becomes a *fusion protein* that contains amino acid sequences from two structural genes. This process may modify the function of the fusion protein. During evolution, the fused chimeric genes develop amino acid substitutions that are rare or missing from the ancestral mutants (Jones CD, Begun DJ 2005 Proc Natl Acad Sci USA 102:11373). Fusing ablation factors, such as ricin or diphtheria toxin to site- or tissue-specific promoters may facilitate the study of differentiation and development because certain cell types can be eliminated during critical periods. Gene fusion may occur during evolution. Fused genes are frequently scattered in the evolutionary ranks, indicating that they did not evolve by vertical common descent (Yanai I et al 2002 Genome Biol 3(5):res0024.1). Metabolic enzymes of *E. coli* fuse three-fold more commonly than other proteins. Gene fusion may have pathological consequences; the fusion of the breakpoint cluster genes with that of Abelson murine

leukemia viral oncogene leads to leukemia (CML). Recurrent fusion of the androgen-responsive promoter element of TMPRSS2 (a transmembrane protease serine 2) with members of the ETS oncogene family leads to prostate cancer (Tomlins SA et al 2005 Science 310:6744). Several cases of cancers are caused by chromosomal rearrangement (translocations) and fusion of different genic elements. ►transcriptional gene fusion vectors, ►translational gene fusion vectors, ►trapping promoters, ►fusion protein, ►read-through proteins, ►intergenic transcript, ►ablation, ►diphtheria toxin, ►gene fission, ►leukemia, ►prostate cancer, ►chromosomal rearrangement; Casadaban MJ 1976 J Mol Biol 104:541; Silhavy TJ et al 1984 Experiments with Gene Fusions, Cold Spring Harbor Lab., Cold Spring Harbor, NY, USA; Lavasani LS, Hiasa H 2001 Biochemistry 40:8438; gene fusion and translocation breakpoints: <http://genome.ewha.ac.kr/ChimerDB/>.

G

Gene Gun: ►biolistic transformation

Gene Identification: This may be required after a particular DNA tract has been sequenced but its function is unknown. The simplest approach is checking the DNA databases for homologous sequences among genes with known function. Extensive amounts of redundant sequences may make the comparisons difficult but computer programs are available to identify repeats in human genes (pythia@anl.gov or <ftp://ncbi.nlm.nih.gov>) or BASTX for other organisms: <http://www.cshl.org/genomere/supplement/harris.htm>. BLAST, FASTA can search databases. ►databases, ►Blast, ►Fasta, ►BLOCKS; Fickett JW 1996 Trends Genet 12:316.

Gene Indexing: Organizing information on groups of genes according to sequences/ functions/EST using Unigene, STACK and HGI. ►Unigene, ►STACK, ►HGI, ►expressed-sequence tag; Haas SA et al 2000 Trends Genet 16:521; <http://genest.molgen.mpg.de/>; <http://www.tigr.org/tdb/tgi>.

Gene Interaction: A common misnomer; in most cases the products of the genes interact—with a few exceptions such as gene insertion, gene fusion, etc. ►gene product interaction, ►epistasis, ►modified Mendelian ratios, ►morphogenesis in *Drosophila*, ►networks

Gene Isolation: The first gene isolation was reported in 1969. The *Lac* gene of *E. coli* was inserted in reverse orientation in bacteriophages λ and $\phi 80$ by a modification of specialized transduction. The DNA of these phages was extracted, denatured and the heavy chain of λ was combined with the heavy chain of $\phi 80$. Since the base sequences of the two phage strands were not

complementary, only the *Lac* sequences annealed, and the phage DNA sequences remained single-stranded. S_1 nuclease degraded the single strands but the double-stranded *Lac* gene was preserved in pure form. Somewhat similarly, genes from F' plasmids could also be isolated. These ingenious methods did not have general applicability. A more general procedure was developed by isolation cDNA from mRNA. The problem was that a eukaryotic cell might contain over 40,000 mRNA molecules at a time. To be reasonably certain (say at 99% probability) that the desired molecule is included, a very large number of molecules had to be isolated in order that the desired one be included:

$$[1 - (1/40,000)]^n = 1 - P = 1 - 0.99 = 0.01$$

hence

$$n = \frac{\log 0.01}{\log[1 - (1/40,000)]} \cong 184,213$$

where n is the number of molecules to be screened to find at least 1 at P (=0.99) probability.

The desired mRNA may be enriched by “cascade hybridization.” The mRNAs can be extracted from cells at different developmental stages. Also, substrate induction, heat shock, drug, hormone or pathogen caused induction can be used for enrichment of the mRNA. If a *DNA library* is available and the gene can be probed by colony hybridization, the fragments containing the gene or parts of it can be identified by the use of DNA probes. The simplest method of isolation of genes uses *heterologous probes*. Such a probe contains a homologous sequence of the gene to be isolated. The probe is labeled by *nick translation* using either radioactive nucleotides or biotinylation or any other non-radioactive fluorochromes or immunoprobes. The probe permits the selective isolation of the DNA fragment annealed with the probe. If the amino acid sequence of at least part of the gene product is known, synthetic probes can also be generated.

Genes can be labeled also by transposon mutagenesis or by insertional inactivation using transformation (transfection). In case close genetic or physical mapping information is available, the gene may be isolated by the use of overlapping YAC clones and “chromosome walking” (*map-based gene isolation*). Linker scanning can identify essential regulatory elements of the gene. The identity of the gene generally requires confirmation by in vitro translation and testing the function of the protein so obtained. ►biotinylation, ►chromosome walking, ►cloning, ►colony hybridization, ►cosmids, ►DNA library, ►DNA probes, ►fluorochromes, ►heterologous probes, ►immunoprobes, ►insertional mutation, ►linker scanning, ►nick translation, ►plasmid rescue, ►radioactive labeling,

►synthetic probes, ►transfection, ►transformation, ►transposon mutagenesis, ►YAC vectors, ►functional cloning, ►positional cloning, ►candidate gene, ►EST; Nieuwlandt D 2000 Curr Issues Mol Biol 2:9; Bimstiel ML. 2002 Gene 300:3.

Gene Knockout: ►knockout, ►gene disruption, ►targeting genes, ►excision vector, ►Cre/loxP

Gene Library: A collection of cloned genes. ►cloning

Gene Locus: ►locus

Gene Manipulation: ►genetic engineering

Gene Mapping: ►mapping genetic, ►mapping function, ►physical mapping

Gene Marking: The insertion of a stable retroviral vector into some stem cells, blood cells or other tissue and detect its functional state or contamination with neoplastic cells or immunological reaction, etc. It may serve—besides diagnostic purposes—therapeutic goals for hereditary disorders, viral infections. It can be employed for the introduction of drug-resistance genes and test the therapeutic index (maximal, optimal or toxic dose of pharmaceuticals). ►retroviral vectors

Gene Mutation: Molecular alteration within a gene (base substitution or frameshift, point mutation, substitution mutation). ►mutation

Gene Neighbor Method: This method infers functional linkage of genes from the information of genetic linkage. It is applicable primarily to prokaryotes where operons are relatively common.

Gene Nomenclature: See <http://www.gene.ucl.ac.uk/nomenclature/> for human genes/ or <http://www.gene.ucl.ac.uk/cgi-bin/nomenclature/gdlw.pl>; ►gene symbols, ►databases

Gene Number: The number of genes per genome of an organism can be estimated on the basis of mRNA complexity, or by total sequencing of the genome. The estimates based on mRNA can be best determined when the entire genome is sequenced. By this method the single-stranded RNA phage, MS2 was found to have 4 genes. The gene number has been estimated also from mutation frequencies. If the overall induced mutation rate, for e.g., is 0.5 and the average mutation rate at selected loci is 1×10^{-5} then the number of genes is $0.5/(1 \times 10^{-5}) = 50,000$. Although this method has some errors, the estimates so obtained appear reasonable. On the basis of mutation frequency in *Arabidopsis* the total number of genes was estimated to be about 28,750 (Rédei GP et al 1984 in Mutation, Cancer, and Malformation, p. 306; Chu EHY & Generoso WM, (eds), Plenum). The number of protein-coding gene number of

Arabidopsis was estimated as 25,498 after sequencing the entire genome. The estimate after annotation has grown to 30,700 by June 2004 (TIGRE Annotation Database). By the late 1920s, John Belling counted 2,193 chromomeres in the pachytene chromosomes of *Lilium pardalinum* and assumed that this number corresponded to that of the genes.

In *Drosophila* ~17,000 genes were claimed on the basis of mRNA complexity. Based on the sequenced genome, the estimate was ~13,600. During the 1930s CB Bridges counted ~5,000 bands in the *Drosophila* salivary chromosomes and for many years it was assumed that each band represented a gene. Nucleotide sequencing of 69 salivary bands in the long arm of chromosome 2 of *Drosophila* pointed to the presence of 218 protein-coding genes, 11 tRNAs and 17 transposable element sequences within that ~2.9 Mb region. The shotgun sequencing of the *Drosophila* genome identified ~13,600 genes, encoding 14,113 transcripts because of alternate splicing. The number of protein-coding *Drosophila* genes was estimated to be ~14,000 (Yandell M et al 2005 Proc Natl Acad Sci USA 102:1566). In humans, 75,000–100,000 genes were expected on the basis of EST; of these about 4,000 may involve hereditary illness or cancer. The human gene number estimates in 2003 still varied from ~24,500 to ~45,00 (Pennisi E 2003 Science 301:1040). After the ‘completion’ of the sequencing the number was estimated between 28,000 to 35,000 yet the number of transcriptional units in humans appeared to be 65,000 to 75,000 (Wright FA et al 2001 Genome Biol 2(7):Research 0025). However, by 2004 the best estimate was 25,000–30,000. The finished euchromatic human genome seems to contain only about 20,000 to 25,000 genes (Nature [Lond] 431:931, 2004). Human chromosome 18 has the lowest gene density of 337 plus 171 pseudogenes (Nusbaum C et al 2005 Nature [Lond] 437:551). The ways of alternative splicing, the use of more than a single promoter (initiation codon) by the same DNA tract complicates the difficulties in estimation of functional units

In *Saccharomyces*, in the 5,885 open reading frames 140 genes encode rRNA, 40 snRNA and 270 tRNA (see also for revisions *Saccharomyces cerevisiae*). About 11% of the total protein produced by the yeast cells (proteome) has metabolic function, 3% each is involved in DNA replication and energy production, respectively; 7% is dedicated to transcription, 6% to translation and 3% (200) are different transcription factors. About 7% are concerned with transporting molecules and about 4% are structural proteins. Many proteins are involved with membranes.

In *Caenorhabditis* 19,099 protein-coding genes are predicted on the basis of sequencing of the genome.

The minimal essential gene number has also been estimated by comparing presumably identical genes in the smallest free-living cells *Mycoplasma genitalium* (482) and *Haemophilus influenzae* (1,749), both completely sequenced. In *Mycoplasma* 382 + 5 protein-coding genes are essential but 28% of the protein-coding genes have no known function (Glass JI et al 2006 Proc Natl Acad Sci USA 103:425). The minimal gene number among the ~4,000 in *Bacillus subtilis* appears to be 192 but another 79 are predicted to be essential (Kobayashi K et al 2003 Proc Natl Acad Sci USA 100:4678). Insertional inactivation mutagenesis indicated the minimal number to be ~265 to 300. Gene knockout indicates that some of the apparently minimally required genes of *Mycoplasma* are dispensable. Furthermore, only about 200 of the *Mycoplasma* genes are represented by orthologous genes in other organisms.

In *Caenorhabditis elegans* about 20 times more genes are indispensable for survival. In higher organisms, the number of open reading frames may be larger than the number of essential genes.

The gene number may not accurately reflect the functional complexity of a genome or organism because the combinatorial arrangement of proteins may generate great diversity and specificity. Many plants have about twice the number of genes of humans. ►gene, ►gene number in quantitative traits, ►transcriptome, ►genetic network, ►proteome, ►duplications, ►knockout, ►mtDNA; Cell 86:521 [1996]; Science 276:1962 [1997]; Adams MD et al 2000 Science 287:2185; Rubin GM et al 2000 Science 287:2204; Aparicio SAJR. 2000 Nature Genetics 25:129; Koonin EV 2000 Annu Rev Genomics Hum Genet 1:199; Akerley BJ et al 2002 Proc Natl Acad Sci USA 99:966; Moran NA 2002 Cell 108:583.

Gene Number in Quantitative Traits: It has been estimated by various complex statistical procedures (Mather, Jinks 1971 Biometrical Genetics, Chapman & Hall, London, UK) but none of the estimates are entirely reliable because the number of genes with minor contribution or greatly influenced by environmental effects, genetic linkage, etc. confound the picture. Perhaps the number of polygenes controlling one quantitative trait may not be more than five or six major genes rather than hundreds, postulated by some authors. Sewall Wright provided a very simple formula in 1913:

$$n = \frac{R^2}{8(s_1^2 - s_2^2)}$$

gene number (n) = where R is the difference between parental means, $[s_1]^2$ is the variance of the F_1 and $[s_2]^2$ is the variance of the F_2 generations.

An improved model of Zeng, considered linkage and variation in their effect where \bar{c} is the average recombination rate between loci and C is the coefficient of variation for the distribution. ►polygenes, ►QTL, ►gene number; Jones CD 2001 J Hered 92:274; Schliekelman P, Slatkin M 2002 Am J Hum Genet 71:1369.

$$\hat{n} = \frac{2\bar{c}\hat{n} + C2(\hat{n} - 1)}{1 - \hat{n}(1 - 2\bar{c})}$$

Gene Number Paradox: Although viruses and bacteria have fewer genes than eukaryotes, at first glance it appears unusual that the very simple nematode, *Caenorhabditis* has more (37%) genes than the much more complex *Drosophila*. The rice plant seems to show substantially more genes than humans, currently 37,544 seem to code for proteins. The cause appears to be in the difference of regulation, alternative splicing, and in a more elaborate array of transcription factor and transcriptional cofactors. The average human gene may be transcribed in three to four different ways. *Drosophila* seems to have about 1,000 transcription factors, whereas humans have more than 3,000. Ape's genomes are more than 99% identical to humans, although great deal of difference exists in the function of the nervous system, and in morphology. ►C value paradox; Levine M, Tjian R 2003 Nature [Lond] 424:147.

Gene Ontology (GO): A set of gene classification rules regarding their molecular function, biological role and cellular location. The same set of criteria is employed for the genomes of *Saccharomyces cerevisiae*, mouse, *Drosophila melanogaster*, *Arabidopsis*, etc. GOs include categories (and additional groups within the main entry) such as Nucleic Acid Binding Proteins, Cell Cycle Regulators, Chaperones, Motor Proteins, Actin Binding, Defense Proteins, Enzymes, Enzyme Activators, Enzyme Inhibitors, Apoptosis Proteins, Signal Transducers, Storage Proteins, Structural Proteins, Transporters, Ligands, Ubiquitin, Tumor Suppressors, Metabolism, Organelle Control, Developmental Regulators, Sensory Perception, Behavior, etc. ►genome projects, ►ontology; Ashburner M et al 2000 Nature Genet 25:215; Anonymous 2001 Genome Res 11:1425; WGS; <http://www.geneontology.org>; sequence ontology: <http://song.sourceforge.net/>; gene ontology annotation: <http://wego.genomics.org.cn/cgi-bin/wego/index.pl>; human and ten other organisms' gene partition: <http://bcl.med.harvard.edu/proteomics/proj/gopart/menu.php>; combination of information from 31 different species; converting between different database identifiers; finding orthologous genes from other species and searching a large body of public gene

Gene Order in the Chromosome: It can be determined by three-point or multipoint testcrosses in eukaryotes or by similar principles in prokaryotes. Conservation of the order permits evolutionary inferences among species. ▶mapping genetic, ▶bacterial recombination, ▶chromosome walking, ▶physical map

Gene Pool: The sum of alleles that can be shared by members of an interbreeding population. ▶population genetics

Gene Prediction: Computer analysis of DNA sequences for matching known genes. ▶Genie, ▶GENSCAN, ▶FGENE, ▶GRAIL, ▶Mzef, ▶GenomeScan, ▶TWINSCANM, ▶SGP-1, ▶SLAM, ▶GeneWise, ▶Gnotator, ▶HMMgene, ▶Ace.mbly, ▶EST_GENOME, ▶annotation of the genome; Mathé C et al 2002 Nucleic Acids Res 30:4103; Guigó R et al 2003 Proc Natl Acad Sci USA 100:1140.

Gene Product: The transcript(s) of a gene and by extension the processed transcripts and even the translated polypeptides or RNAs. ▶processing, ▶transcript, ▶polypeptide, ▶RNA

Gene Product Interaction: It is responsible for epistasis, additive, complementary and suppressor type of modifications of Mendelian segregation ratios. These are frequently called gene interactions but actually, the gene products interact. Interaction among gene products is quite extensive in yeast 250 sequence-specific regulators were found to affect the expression of ~6,000 genes. It appears that genes are co-regulated at the level of transcription. ▶modified Mendelian ratios, see examples under ▶morphogenesis in *Drosophila*, ▶protein-protein-interaction, ▶microarray hybridization, ▶two-hybrid method, ▶networks, ▶genetic networks, ▶phage display, ▶proteomics, ▶interactome, ▶epistasis, ▶protein complexes; Adamkewicz JI et al 2001 J Biol Chem 276:11883; Ito T et al 2001 Proc Natl Acad Sci USA 98:4569; Minton AP 2001 J Biol Chem 276:10577; von Mering C et al 2002 Nature [Lond] 417:399; <http://www.genome.ad.jp/brite/>; <http://dip.doe-mbi.ucla.edu>.

Gene Rearrangement: ▶immunoglobulins, ▶phase variation, ▶sex determination in yeast, ▶transposons, ▶chromosomal rearrangements, ▶gene replacement, ▶targeting genes

Gene Regulation: ▶regulation of, ▶gene activity

Gene Relic: Usually a member of a multigene family that does not have all the elements necessary for function; it is actually a pseudogene. Their existence

is explained by losses during evolution. ▶pseudo-gene, ▶processed pseudogene

Gene Replacement: Accomplished with the aid of genetic vectors that carry a different allele and the flanking sequences of a chromosomal locus (see Fig. G19). This constitution permits intimate homologous pairing in the area. If double crossing over or gene conversion takes place, the allele in the vector may replace the one in the chromosome. Because the frequency of such an event is very low, selectable markers (*URA3* in the diagram in this integrating vector) must be used to screen out the replacement in a large population. For the selection, one may use an antibiotic resistance gene with a defect in the upstream area and in the vector the same but with a defect downstream may restore antibiotic resistance and that can selectively be isolated on media containing the antibiotic. By the use of the LoxP-Cre system, larger than 100 kb mouse chromosomal segment can be replaced by homologous human DNA tracts and the procedure called recombinase-mediated genomic replacement (RMGR) can be used to model human genetic diseases in mouse (Wallace HAC et al. 2007 Cell 128:197). ▶targeting genes, ▶localized mutagenesis, ▶site-specific mutation, ▶transformation, ▶Cre/LoxP, ▶FLP/FRT, ▶knockout, ▶homologous recombination, ▶site-specific recombination, ▶RMCE; Richardson PD et al 2001 Curr Opin Mol Ther 3(4):327.

Gene Scanning: ▶linker scanning

Gene Sharing: An evolutionary process; a gene may acquire a new function without losing the original one, e.g., the crystalline protein gene $\delta 2$ in chickens

and ducks my have argininosuccinate lyase function as well as structural role in the eye lens (Piatigorsky J, Wistow G 1991 Science 252:1078).

Gene Silencing: ►silencer

Gene Size: It can be measured in different ways. If only the translated number of codons is considered, the smallest genes appear to be the 21 bp *mccA* coding for the antibiotic heptapeptide, microcin C7 (MW 1,177 Da) of *Enterobacteria* (Tenson T et al 1997 J Biol Chem 272:17425). Another is the pentapeptide encoded within the 23S ribosomal subunit by only 15 nucleotide pairs (González-Pastor JE et al 1994 Nature [Lond] 369:281). The largest mammalian genes, including introns and upstream and downstream regulatory sequences, may be in the range of hundreds of kbp. The human dystrophin gene with 2.34×10^6 bp includes 79 exons and it is probably the longest gene known (Tennnyson CN et al 1995 Nature Genet 9:184). Processed genes, reverse-transcribed from mRNA, are free of introns and other non-coding sequences are naturally shorter (Hollis et al 1982 Nature [Lond] 296:321). In human chromosome 7, the average gene length is 69,877 bp and it contains 10.1 exons with an average size of 261 bp. In human chromosome 10, the gene sizes vary from 1,776,209 bp (CTNNA3, CATENIN $\alpha 3$) to 859 bp (CLML5, CALMADULIN-LIKE 5). The longest exon is 9,763 bp (SH3MD1, SH3 multiple domain 1), the shortest is 3 bp (CDH23, CADHERIN 23). The “average” gene may have 400 codons and thus encode 46 to 48-kDa proteins. The 26,564 annotated human genes show an average of 8.8 exons and 7.8 introns. About 80% of the human exons are less than 200 bp. Less than 0.01% of the introns are less than 20 bp, and fewer than 10% are longer than 11,000 bp (Sakharkar MK et al 2004 In Silico Biol 4(2): 0032). The human genome of about 3×10^9 bp contains an estimated 25,000–30,000 genes. *Haemophilus influenzae* bacterium has 1,749 sequenced genes whereas budding yeast in its 1.8×10^7 genome encodes ~5,885 genes by 12,068-kb DNA; thus, its “average” gene is about 2,050 nucleotides long. By sequencing the genome of *Caenorhabditis* 1 gene was found per ~5-kb; the average intron number was found to be 5. In *Drosophila* upon completion of the sequencing of the “entire” genome, the average transcript size appeared to be ~3,058 bp with an average of ~4 exons. The intron sizes varied between 40 bp to > 70. The largest *Drosophila* protein, the cytoskeletal linker, Kakapo contains 5201 amino acids and the smallest is the 21-amino acid L38 ribosomal protein. The smallest gene numbers, four, are found in some viruses. ►introns, ►exons, ►genomic DNA, ►Enterobacteria, ►Mbp, ►dystrophin, ►ribosomal RNA, ►Haemophilus

influenzae, ►Saccharomyces cerevisiae, ►Aspergillus, ►exon, ►intron, ►gene

Gene Space: Regions of high gene density in the genome; generally it is rich in GC content. ►FANTOM, ►desert, ►jungle

Gene Substitution: The replacing of an old allele by a new one in a population, and chromosome substitution.

Gene Switching: It uses various ligands (tetracycline, rapamycin, estrogen analogs) that may down or regulate gene expression without turning it off. ►gene switch, ►tetracycline, ►rapamycin, ►estrogen

Gene Symbols: The abbreviated representation of the function of the genes or it designates it in a unique manner using a single or more letters. Very frequently, the allele that fails to carry out the normal function provides the name for the locus, e.g., the white eye locus in *Drosophila* is symbolized as *w* although the normal color of the eye is red. The symbols used vary in different organisms. Generally, the symbols begin with the first letter of the name and it is usually italicized. The recessive alleles in eukaryotes are symbolized with lower case letters whereas the wild type alleles either begin with a capital letter or all the letters are capitalized. Symbols of genes in the same chromosome strand are usually separated by a space in between them. Genes in the homologous strands customarily have a slash in between them (*a/b*). A semi-colon separates genes in non-homologous chromosomes and one space (*a; d*). Multiple alleles in *Drosophila* are designated by the same letter(s) representing the locus and further identified by superscripts, e.g., *w^a*, *w^{a2}*, *w^{aM}*, *w^{a79i}* or other additional distinctive signs. Recessive or dominant alleles in a series of mutant alleles are frequently symbolized as *a^R* or *a^D*, respectively. The common dominant allele may be designated also as *a⁺* or *A⁺*. Absence of a gene or lack of its function may be symbolized by a lower case letter such as *a⁻*.

Isoenzyme determining alleles may be designated as *Adh^F*, *Adh^S*, and the superscript indicating fast or slow run in the electrophoretic field. *Aⁿ* means null allele, *a^l* may be used for a lethal allele, if necessary with additional specifications. Non-allelic loci with similar phenotypes may be symbolized with the same letter(s) and subscripts: *a₁* and *a₂*. Also, non-allelic loci with similar phenotypes (mimics) may be symbolized as *tu-1a*, *tu-1b*, *tu-2*. Different loci encoding similar proteins may be designated with the same letters but attaching to the letters different numbers or by the addition of an abbreviated form of the molecular weight of the protein (*Hsp68*, *Hsp83*). Transpositions are symbolized with the designation of the original symbol followed in parenthesis the

new location: [*ry*⁺](*sd*), indicating that the *rosy* gene was moved from chromosome 3–52 location to the *scalloped* locus in chromosome 1–51.5. The designation of transformants follows that of transpositions. Modifier genes, such as suppressors may be designated as the symbol of the modifier, followed in parenthesis the gene modified: *su(lz*³⁴). Some symbols may carry also the name of the discoverer or the location of discovery of the mutation or the mutagenic agent used. Rv may indicate reversion in superscript. Capital letters and additional specifications designate chromosomal aberrations. Translocations (reciprocal interchanges between/among non-homologous chromosomes) are represented as *T(1;Y;3)* indicating that chromosomes 1 (X-chromosome), Y and 3 are involved. Each chromosome may be further specified using a capital letter superscript indicating the approximate position of the break point as P (proximal to the centromere), D (distal), or M (median). An X-chromosomal ring (of *Drosophila*) may be symbolized as *R(1)1*. Paracentric inversions are represented as *In(2L)* or *In(2R)*, depending whether the left or right arm of chromosome 2 is involved. *In(2L,R)* indicates pericentric inversion of chromosome 2. To this symbol, genes closest to the break points may be attached. For transposition (non-reciprocal transfer of chromosomal segments) the symbol is *Tn* and in parenthesis first the donor, followed by the recipient chromosome, e.g., *Tn(2;3)*. Again, the gene(s) involved may be included in the symbols. Deficiencies are symbolized by *Df* followed by the indication of the chromosome (arm) and locus involved: *Def(2R)vg*. Duplications are symbolized with *Dp* such as *Dp(3;1)* indicating that duplicated segment of chromosome 3 is located in the X-chromosome. When the duplicated segment has a centromere and it is a free element, it is symbolized with a letter *f*, e.g., *Dp(1;f)*. In case there are multiple repeats: *Dp(1;1;1)*. When a combination of multiple chromosomal rearrangements occur, they are indicated one after the other with a “+” sign between them. The location of break points may be designated by the euchromatic (1 to 102) or heterochromatic (h1 to h61) segment numbers. The older symbols in plants followed the customs in *Drosophila*. Recently, largely for convenience of typing or printing, the subscripts are substituted with a number written together with the gene symbol and the allelic number is attached hyphenated: *a2-5* the second *a* locus and allele 5 (rather than superscript 5). Mouse geneticists identify loci with three or four italicized letters, the first is capitalized. Human geneticists also use three or four (commonly not italicized) all-capital letter symbols with additional numbers. In Yeast and *Arabidopsis*, the new gene symbols use three italicized capital letters for the wild

type and three italicized lower case letters for the recessive alleles. In the majority of fungi the wild type alleles are designated with a superscript “+”. Allelic designation frequently follows the locus designation in parenthesis: *ilv(STL6)* or *pyr-3(KS43)*. Suppressor mutation symbols may include also the gene they modify: *su(met-7)-1*. The symbol *ssp* means super-suppressors. Mitochondrial mutations are designated as *mi*, and additional numbers. RFLP fragments are identified with an italicized three-letter symbol of the laboratory and a serial number. Transposable elements are symbolized similarly to the genes. In human genetics only capital letter symbols (no more than 4–5 letters) are used without sub- or superscripts. Hyphens or punctuations in the symbols are exceptional. Different loci by the same symbol are numbered, e.g., BPAG1, BPAG2. Alleles may be indicated by an asterisk after the symbol and followed by other designation e.g., ACY1*2. A slash between two symbols stands for the diploid genotype, hetero- or homozygous. Lack of synteny is indicated by semicolons(s) between the symbols. If linkage is unknown comma is used. Gene order is usually started from the short arm down.

Bacterial geneticists designate the loci with italicized three lower case letters followed by a capital letter: *lacI*, *lacZ*, *lacZ* indicating the lactose utilization operon regulatory (inhibitor), operator and the β -galactosidase genes, respectively. The letters *p*, *o*, *a*, stand for promoter, operator and attenuator, respectively.

Protein products of the genes are generally symbolized with the abbreviations of the genes but they are all in capitals or in yeast, the first letter is capital and the rest are lower case and not italicized.

Arabic numerals and chromosomes generally designate linkage groups by Roman numerals. In some publications, the linkage groups may not be correctly identified with particular chromosomes.

Gene symbols have been periodically revised in some organisms and this may make reading the older literature difficult. Creating new symbols is a cheap attempt to gain citations. If new symbolism is warranted that should not be used retroactively to published and used symbols. It is quite unfortunate that many genes have multiple synonyms and symbols. ▶*Drosophila*, ▶databases [plants–Mendel], gene nomenclature assistance; for *Caenorhabditis*, Horvitz HR et al 1979 Mol Gen Genet 175:129; mouse, Maltais LJ et al 2002 Genomics 79:471; humans, Wain HM et al 2002 Genomics 79:64; <http://www.gene.ucl.ac.uk/nomenclature>; www.flynome.com.

Gene Synthesis: The generation of nucleotide sequences by the methods of organic chemistry. These sequences—and their variations—can then be tested

for function after transformation into suitable host cells (see Fig. G20). The first entirely synthetic genes coded for tRNAs. Gene may be carried out also in a different and much simpler way. Sometimes an investigator wishes to remove or add a restriction enzyme recognition site or alter the coding properties so a different amino acid would be inserted into the protein. The desired sequence can be synthesized by using pairs of 10–15mer oligonucleotides and anneal them at the 3′-ends of long oligonucleotides as templates and primers. At the same time, several sequences can be generated each up to 400 nucleotides and then ligated before transforming them into a vector. The simplest diagrammatic representation is as follows:

Figure G20. Gene synthesis. Annealed, then use T7 DNA Polymerase and proceed with synthesis

On programmable microchips, multiple genes (21) can be synthesized (Tian J et al 2004 Nature [Lond] 432:1050). ▶genes synthetic, ▶synthetic genes, ▶DNA chips, ▶microfluidic; Uhlmann E 1988 Gene 71:29.

Gene Tagging: Gene tagging places an insertion or transposable element or any other DNA sequence into a gene with the aid of genetic transformation (transfection). When the inserted sequence is known and can be probed by molecular hybridization and/or genetical inactivation or altering the function (insertional mutation), it can identify the target gene. Some insertions going into intergenic or untranslated (intron) regions may not affect the expression of the gene involved. ▶labeling, ▶probe, ▶insertional mutation, ▶targeting genes, ▶biolistic transformation, ▶transformation genetic, ▶transposons; Johnson GC et al 2001 Nature Genet 29:233.

Gene Targeting: A method of transformation using cell-specific promoter attached to the prospective transgene in the vector. The goal is to localize the transgene expression to only one type of cells. ▶promoter, ▶transformation genetic, ▶gene replacement, ▶targeting genes, ▶targeted gene transfers, ▶knockout, ▶localized mutagenesis, ▶excision vector, ▶Cre/loxP, ▶FLP/FRT; Reynolds PN et al 2001 Nature Biotechnol 19:838.

Gene Therapy: The insertion of a functional gene into an organism for the purpose of correcting or compensating for genetic defect or combat or prevent infection. In contrast to biochemical compensation for

a genetic defect (e.g., use of insulin), gene therapy may provide a dynamic supply of the missing or deficient metabolite rather than in discrete shots. The vector RetroTet-Art was designed to modulate the expression of the transgene by employing the tetracycline inducible system as well as the p16 growth arrest protein (Rossi FM et al 1998 Nature Genet 20:389). The most important requisite of gene therapy is the correct identification of the genotype responsible for the phenotype determined by clinical means. It can be carried out either in somatic cells or in the germline (gametes, zygotes). Germline gene therapy may be risky because of various chromosomal rearrangements may be caused in the transgenic cells. There is, however, a possibility to achieve some of the goals of introducing into the gametes or zygotes genetically engineered DNA. In vitro fertilization followed by screening of the 8-cell stage embryos for some of the defects present in the heterozygous families may permit the transfer into the uterus only those embryos, which are free from the genetic defect. This procedure avoids most of the risks of directly manipulating the genome, and it is the technology used by natural selection during evolution. The methods potentially available are microinjection of (foreign) DNA or transformation with retroviral or adenovirus vectors, liposomes (see transformation of animals; human gene transfer) and gene replacement by homologous recombination. Another possibility is “knockout” when the function of a deleterious gene is eliminated by insertional inactivation or deletion. The technology is available for transformation or in vitro mutation that can be followed by injecting embryonic stem cells into blastocytes that are introduced into the uterus of a female to develop genetically modified embryos and eventually viable offspring. Recently introduction of —into mice with induced tyrosinemia—hepatic cells that could proliferate in the defective liver was successful in the laboratory with a model organism. The transformation technology needs refinements before it can be widely applied to humans. Polyelectrolyte films such as poly(L-glutamic acid/PLG) and poly(L-lysine/PLL) in the presence of charged cyclodextrin seem to be effective delivery vehicles for DNA. Such construct may be maintained at elevated level in the specific target environment and facilitate internalization of the DNA into the nucleus (Jessel N et al 2006 Proc Natl Acad Sci USA 103:8618).

The current gene therapy protocols (several hundreds available) involve altering the somatic cells. The techniques of embryo implantation are widely used to overcome female inability of conceive without surgical assistance. Before implantation, these fertilized embryos may be then tested for

expression of transferred remedial genes. These procedures may become potentially useful for preventing the expression of genetic diseases under the control of single genes such as the Lesch-Nyhan syndrome, Tay-Sachs disease, cystic fibrosis, muscular dystrophy, Gaucher's disease, β -thalassemia, ADA, melanoma, neuroblastoma, multiple myeloma, lymphoma, breast cancer, colorectal cancer and several others. An ADA patient treated by gene therapy appeared relatively well and survived more than ten years after the use of retroviral transformation although her immune system was below normal. Autologous CD34⁺ and functional ADA gene transplantation by umbilical cord blood resulted in low frequency (1–10%) of ADA expressing T lymphocytes, too low to be effective for a cure. Polyethylene-glycol-conjugated ADA enzyme treatment was much more effective yet not without undesirable effects. Liposomal vectors carrying the human leukocyte antigen (HLA)-B7 and the β_2 microglobulin cDNA to tumors can express these genes (see Fig. G21). One lentiviral vector contains an antibody for special cell recognition and a mutant viral glycoprotein, which is inactivated in binding ability to its receptor but retains its ability to trigger pH-dependent membrane fusion. Such a vector recognizes the target cell membrane and attaches to it. The antibody induces endocytosis. There the fusogenic molecule of the vector responds to the low pH and triggers membrane fusion and virus can enter the cytosol. After reverse transcription and migration to the nucleus the vector can integrate into the host genome and the transgene can be inherited (Yang L et al 2006 Proc Natl Acad Sci USA 103:11479).

Figure G21. β Cyclodextrin

SCID-X1 patients were transfused by hematopoietic stem cells, expressing the CD34 surface marker and transfected by a defective Moloney retroviral vector carrying the γ c cDNA of the SCID-X1 human gene (Cavazzana-Calvo M et al 2000 Science 299:669). The CD34 cells are capable of differentiating into all types of blood cells. The SCID-X1 gene is a cytokine receptor. The patients so treated displayed normal lymphocytes and immune reactions

ten months after the treatment. Actually, in three months they were able to leave the complete isolation of the hospital. The apparent success of this treatment—compared to the earlier attempts described above—was due to improvements in the cell culture techniques (using Flt3 protein). Flt3 is a natural embryo cell growth factor. The new method avoided the administration of polyethylene glycol-conjugated ADA enzyme that exerted earlier a toxic effect by deoxyadenosine. Another important technical improvement was the use of transfected stem cells rather than mature transgenic T cells. More recently, highly efficient endogenous human gene correction (SCID) has been reported by the use zinc finger nucleases. Library of zinc finger proteins have been engineered for the recognition of unique chromosomal sites and fused to a nuclease domain. Such a construct can bring about double-strand breaks in the DNA required for homologous recombination. A plasmid-carried corrective DNA can thus replace the defective gene. Actually, 7% of IL2R γ genes, responsible for SCID, were corrected in both X chromosomes and expressed the right mRNA and protein (Urnov FD et al 2005 Nature [Lond] 435:646).

In 2002, acute lymphoblastic leukemia was observed in some of the children so treated (Science 298:34). The leukemia was caused in two cases by insertional mutation affecting the Lmo12 oncogene and in two instances into the IL-2rg gene. In one case, integration took place at both of these sites. It seems these cytokine receptors enhance leukemia (leukemogenesis). Davé UP et al 2004 (Science 303:333) are optimistic regarding the use of this type of therapy because the frequency of harmful insertions is relatively low. Clinical trials in the USA continue with careful consideration given to each case. In several European countries, temporary bans have been lifted or new rulings were suggested in 2004. Unfortunately, since then additional leukemia cases have been reported. Adverse effect of the gamma c gene subunit of the T cell antigen receptor (7p15-p14)—contained by the vaccine—has been suspected in the leukemogenic effects in some case. These adverse experiences cause a halt in this type of gene therapy and limit its application to cases where other approaches failed.

Using adenovirus vector with the human cystic fibrosis transmembrane conductance regulator (CFTR) resulted in expression of the gene for nine days in the nasal or bronchial membranes. With retroviral vector the low-density lipoprotein (LDL) receptor, important for familial hypercholesterolemia, has been successfully transformed and functioned. Promising initiatives were made by treatment of patients with retroviral vectors carrying interleukin-4 (IL-4) to fibroblasts resulting in infiltration

of the tumor with CD3⁺ and CD4⁺ T cells and cell adhesion molecules. The treatment resulted in some trials in the increase of CD8⁺ tumor-specific cytotoxic T lymphocytes (CTL) and eosinophils as well as CD16⁺ killer cells. Another approach is using intrabodies. As a treatment of the HIV-1 virus infection, intrabodies are directed to the lumen of the endoplasmic reticulum of the cells where they prevent the secretion of the gp160 glucoprotein precursor (a viral envelope protein) and its transport to the cell surface. Using anti-gp120 intrabodies the gp120-gp160 envelope proteins of the virus may be neutralized. Anti-tat antibody fragments introduced into the cells may prevent the activation of transcription by the viral TAT and the cellular NF- κ B proteins. Intrabodies against the Rev splicing element may also reduce the replication of the virus. Intrabodies against fusin may hinder HIV entry into the cells. The somatic cell genetic therapy may target cancer cells with interleukins, tumor necrosis factor, granulocyte macrophage colony stimulating factor to reinforce the immune system or use monoclonal antibodies against cancer cells equipped with toxins or sources of radiation (see lymphocytes; magic bullet). Some of the genes that are suitable for germline modification may be targeted to specific organs for alleviating or to overcome the symptoms of the disease. In some cases, e.g., neurological disorders, *ex vivo* methods have been sought of for the restoration of the normal function (in Alzheimer disease) of nerve growth factor (NGF) or transplanting dopamine-producing tissue (in Parkinson disease). Bone marrow transplantation may alleviate or reverse the course of lysosomal storage diseases. In the future, targeting the medication to specific cells, tissue or organs may gain increased significance because it will permit greater effectiveness and higher dosage without side effects. Purified genetically engineered myoblasts and myofibers can be propagated *ex vivo* and re-injected into the body. The multinucleate muscle cells may make possible the delivery of two or more different small vectors (e.g., AAV), which may be simultaneously expressed within the same cell and their product(s) released into the circulatory system to treat not only muscle but also other problems (Ozawa CR et al 2004 J Clin Invest 113:516).

One problem of gene therapy is that the cell defense mechanism may inactivate the introduced gene by methylating their promoters or immunologically neutralize the foreign proteins. Integration of the vector into tumor suppressor genes results very rarely in cancerous transformation. Other problems arise by unexpected reconstitution of the retroviral pathogenicity through recombination of the vector and endogenous human viruses. These latter problems are reduced by the use of DNA (rather than retroviral) vectors.

Some of the adenoviral vectors contain a much-truncated DNA to prevent viral replication and reduced immunological response against the vector but other adenoviral proteins are actually immunosuppressors and their deletion may cause the elimination of the vector by the host cells. Currently the adeno-associated and the lentiviral vectors may be most promising.

Somatic gene therapy involves apparently smaller risks. The possible harmful consequences of germline alterations are much more difficult to assess. Some gene therapy protocols combine the procedure with chemical treatment. Introduced into a cancerous brain, by a viral vector, working only with dividing cells, the herpes simplex virus thymidine kinase (HSTK) gene, it is assured that the vector lands only in the tumor cells because the normal cells do not divide. After the establishment of the transgene the patients are treated with ganciclovir. This drug after phosphorylation by HSTK can be incorporated into the DNA but it prevents then DNA replication resulting in the selective death of the cancer cells. Recombinant proteins may be used to remedy diverse metabolic defects. Ideally, the protein supply should be as under natural conditions, i.e., the amount would be variable in response to the need. For success of such treatments it is usually important that the protein would be rapidly secreted in response to orally administered drugs and the secretion would be rapidly stopped after discontinuation of the drug. Moreover, the protein must not incite an immunologically adverse reaction. Enzyme replacement or enhancement may be effective for lysosomal storage diseases (Desnick RG, Schuman EH 2002 Nature Rev Genet 3:954).

Recently, in utero treatments of fetuses afflicted by α -thalassemia or severe combined immuno deficiency (SCID), which may harm the developing embryo before or immediately after birth, respectively, have been considered. Such treatments may have still unknown side effects both on the fetus and mother. Some defects involving differentiation of limbs or brain (e.g., Greig's syndrome) occur early during pregnancy and may not be obvious until it is too late to apply any treatment. The α -Antitrypsin deficiency is manifested in adult stage and then oral administration of 4-phenylbutyric acid facilitates the release of antitrypsin from the endoplasmic reticulum and as a "chemical chaperone" may prevent the injuries resulting from AAT deficiency.

Human neural progenitor cells can be modified to release glial cell derived neurotrophic factor (GDNF) under an inducible promoter. After partial lesion of the dopamine system of rats, the engineered cells were transplanted into the brain of rats. Two weeks after implantation the engineered cells migrated within the striatum and released physiologically

relevant level of GDNF and facilitated survival of the neurons, and after eight weeks it even migrated to the substantia nigra. Loss of dopaminergic neurons in the substantia nigra is usually associated with Parkinson disease. The same type of cells survived for three months in the brain of aged monkeys and released GDNF. This technology shows promise to eventual cure of Parkinson disease currently largely incurable (Behrstock S et al 2006 *Gene Therapy* 13:379).

Some people oppose gene therapy on biological and/or ethical grounds. The arguments against gene therapy stem from the fears of unforeseeable damage to the human gene pool and the possibility of using these procedures for “genetic enhancement”. Genetic enhancement would have similar goals as eugenics and eventually may be exploited to create “super-soldiers” or other antisocial individuals with “uniform” genetic makeup. These fears are frequently fanned by political agenda or by unfounded speculations. The argument in favor of gene therapy is that it provides means to prevent the perpetuation of “disease genes” by specifically targeting the single defects. It may result not only in elimination of suffering but may also reduce health maintenance cost on the long run. In case of somatic gene therapy, unintended insertions into the germline may happen rarely. The US Federal Drug Administration proposed that such insertion should be limited to less than 50 per μg of DNA employed and genetically this may mean less than 1 insertion/6,000 sperm. It is true that not all possible consequences of gene therapy have been seen in an evolutionary history. The same criticism may also apply to several drugs that are part of current medical practice. Many of the medicines have physiological and genetic side effects (e.g., diagnostic and therapeutic X-rays, several antibiotics, anticancer drugs, etc.) yet the benefits are supposed to outweigh their risks. In human gene transfer, there are some potential risks of new constructs to develop by recombination with the viral vector. In some cases, the decision is very difficult, e.g., human dwarfism can be cured by the application of growth hormones or by functional growth hormone genes. Dwarfism is not an acute life-threatening anomaly yet it interferes in many ways with the normal fulfillment of life. The question arises then how far social philosophy should be permitted to affect the life of an individual. Animal models can be successfully applied for the testing of the physiological and biochemical consequences of gene therapy but it may not detect all the consequences for human behavior and mental abilities. One possibility appears the repair of disease genes at the site of the defect. Single-stranded DNAs, double-stranded DNA, DNA-RNA hybrid constructs, artificial chromosomes have been designed that may repair the defective nucleotides through site-specific

recombination. Although the numerous repair attempts are promising and some initial successes have been reported, the efficiency of the system is not sufficient for clinical applications (Liu L et al 2003 *Nature Rev Genet* 4:679). Thus, gene therapy still has to face not just biological, technical problems but ethical ones as well. The public often mistrusts new technologies, especially when the application suffers initial mishaps. The freedom of scientific inquiry and the innate human striving for knowledge should not be prevented, however, for any reason. Although the same caution may be necessary as it was applied with the techniques of “recombinant DNA”. Some of the problems to be solved include the development of more effective vectors and extrapolating successfully from animal models to humans. Sporadic tragic misfortunes (Teichler Zallen D 2000 *Trends Genet* 16:272) with the application of this technology cannot be a rational cause for opposing these innovative and promising medical research efforts. By July 2002, there were no US Government-approved gene therapy product on the market (Cimons M 2002 *Nature Med* 8:646), and none by 2008. The approximate share of the various genetic vectors in gene therapy experiments: retroviruses 40%, adenovirus 26%, liposomes 14%, plasmids 9%, vaccinia virus 5%, adeno-associated virus 2%, fowlpox virus 2%, canarypox virus 1%, RNA 1%, herpes simplex virus 0.3%. Gene therapy has potential applicability not only to hereditary diseases but also for a wide variety of acquired illnesses. (See diseases and terms under specific entries; ►hemo-

Gene Therapy for Infectious Diseases: Gene therapy is most commonly directed against hereditary diseases or other acquired conditions for what drugs are not sufficiently effective. Gene therapy may be designed against pathogenic microorganisms too. The available or potentially working approaches to be considered are: transformation by resistance genes, DNA vaccination, suicide genes, use of lytic phage, antibody genes, increase the production of metabolites that interfere with the development of the disease, use of antisense technology, RNAi, transgenesis for antimicrobial peptides, ribozyme-mediated cleavage of RNA, activation of antimicrobial defense genes, increase the dosage of antimicrobial genes, inactivate receptors required for infection, recruit antagonists of parasites, etc. A great variety of possible strategies may be developed. (See terms listed in separate entries in this book; Kaslow DC 2004 Trans R Soc Trop Med Hyg 98:593).

Gene Titration: Determining the quantitative expression of gene(s) as a function of dosage. ▶dosage effect, ▶titration; Yinduo J et al 2001 Science 293:2266; Shiao AL et al 2005 J Virol 79:193.

Gene Transfer: ▶transformation, ▶human gene transfer, ▶gene transfer lateral

Gene Transfer by Microinjection: It was the principal means of transformation of animals in the 1980s. Today gene targeting and other procedures are preferred (see Fig. G22). (See diagram, ▶transformation genetic [animals], ▶gene replacement, ▶targeting genes

Gene Transfer, Lateral: The transmission of genes and genetic elements by infection, plasmids, transposable elements and the acquisition of mitochondria and chloroplasts during evolution. ▶infectious heredity, ▶plasmids, ▶organelle sequence transfer, ▶evolution

Gene Trap Vectors (entrapment vector): These are equipped with a reporter gene that can insert at a splice acceptor site. The resulting gene fusion may facilitate the transcription of the reporter gene. It may be used with (mouse) embryonic stem cells to detect genes expressed during early development (Hansen J et al 2003 Proc Natl Acad Sci USA 100:9918). Actually, this procedure can tag any gene even if it is not expressed. ▶ES, ▶gene fusion, ▶insertional mutation, ▶reporter gene, ▶OMNIBANK; Medico E et al 2001 Nature Biotechnol.19:579; Stanford WL et al 2001 Nature Rev. Genet 2:756; Lai Z et al 2002 Proc Natl Acad Sci USA 99:3651.

Gene Trapping: A vector cassette consisting of a promoterless reporter gene and/or a selectable marker

Figure G22. Gene transfer by microinjection

flanked by an upstream splice acceptor site and a downstream transcriptional termination sequence is used. When inserted into an intron of a target gene, the cassette is expressed from the host promoter fused to and easily recognized by the expression of the reporter. Since it contains a termination signal (such as for polyadenylation), the protein product is truncated. The insertion represents a tag on the disrupted target gene. Such a system permits tagging of a large number of genes across the entire genome of an organism. In plants, any somatic cell can be regenerated into intact seedlings. In animals, the targeting may use site-specific recombination system limited to somatic cells to avoid germline mutations. In self-fertilizing plants, the transferred gene or the knockout can become homozygous in the following generation of selfing. In mice, it is commonly used for knocking out genes. In bisexual animals, homozygosity can be achieved by mating of individuals that are heterozygous for the mutation. In mouse, embryonic stem cells can be genetically manipulated in vitro and offspring can be obtained by injecting the stem cells into early embryos. ▶[splicing](#), ▶[promoter](#), ▶[trapping promoters](#), ▶[targeting genes](#), ▶[knock-out](#); Schnütgen F et al 2005 Proc Natl Acad Sci USA 102:7221.

Gene Tree: It reveals when a population was divided into two subgroups on the basis that one of the subgroups has a particular mutation(s) and the other does not. Such an analysis can be continued for any number of genes. ▶[evolutionary tree](#), ▶[population tree](#)

Genealogy: The list and description of successive ancestors in a family. An extensive study of Icelandic populations of the last 300 years indicates a faster evolutionary rate for the matrilinear than the patrilinear descendants based on mtDNA and Y chromosome haplotype data. ▶[pedigree](#), ▶[coalescent](#); Helgason A et al 2003 Am J Hum Genet 72:1370.

GeneCards: ▶[GeneNote](#), ▶[EST](#), <http://genecards.weizmann.ac.il/genetide-bin/tide.cgi>.

GeneChip: ▶[microarray hybridization](#)

GeneDB: The sequences and annotations by the Sanger Institute Pathogen Sequencing Unit (PSU). (<http://www.genedb.org/>).

GeneEMAC: A computerized method for the monitoring of gene expression during development by external marker-based automatic congruencing (EMAC). (See Streicher J et al 2000 Nature Genet 25:147).

Genefinder: A computer program for finding genes within DNA sequences on the basis of identifying likely splicing sites, translation starts, coding potential, intron sizes, etc., by statistical criteria based on log likelihood ratios. The prokaryotic gene

finder GISMO combines searches for protein family domains with composition-based classification based on a support vector machine. GISMO is highly accurate and highly sensitivity and specific. It performs well for complete prokaryotic chromosomes, irrespective of their GC content, and also for plasmids as short as 10 kb, short genes and for genes with atypical sequence composition (Krause L et al 2007 Nucleic Acids Res 35:540). ▶[lod score](#), ▶[support vector machine](#); Rogic S et al 2001 Genome Res.11:817.

Genelet: ▶[SVD](#)

Geneology: The recorded or inferred steps of descent from ancestors, a family history ▶[pedigree analysis](#), ▶[evolutionary tree](#)

GeneNote: A database of human gene expression in normal tissues. ▶[GeneCard](#), ▶[Recon](#); <http://bioinfo.weizmann.ac.il/genecards>.

General Acid-Base Catalysis: The proton transfer from and to a molecule, water excepted.

General Recombination: The recombination between homologous sequences. ▶[illegitimate recombination](#), ▶[recombination genetic](#), ▶[gene conversion](#)

General Transcription Factors: ▶[transcription factors](#)

Generalized Transduction: It can be mediated by either temperate or virulent bacteriophages. The phage infects a donor bacterium (step 1) carrying the wild type allele (a^+) and then lyses it (step 2). Some phage shells scoop up *at random* only or almost only *any* bacterial DNA fragment rather than phage DNA (see Fig. G23). When these unusual phages infect a recipient cell, they can transfer the donor bacterial gene into the recipient (step 3). The transduced DNA and the indigent DNA can synaps (step 4) if they are homologous and by a double exchange replace the recipient's gene with that of the donor. This step then completes the generalized transduction. In case the donor DNA carries alleles $\underline{a}^+ \underline{b}^+$ and the constitution of the recipient is $\underline{a} \underline{b}$ recombination frequencies can be calculated as shown by the formula:

$$\frac{(a + b)(ab^+)}{(a^+b) + (ab^+) + (a^+b^+)}$$

With generalized transduction recombination can be estimated only within very short intervals, e.g., within genes. ▶[marker effect](#), ▶[pac sites](#), also ▶[specialized transduction](#), ▶[abortive transduction](#), ▶[bacterial](#), ▶[recombination frequency](#); Lederberg J et al 1952 Cold Spring Harbor Symp Quant Biol 16:413; Burke J et al 2001 Proc Natl Acad Sci USA 98:6289.

Generation Time: The time required for a cell division in continuous culture or the period from birth of an

Figure G23. Generalized transduction

individual to the birth of its offspring (reproductive cycle).

GeneReviews: ►genetic testing

Genes, Good: They do not affect health adversely. Also, genes, which are transmitted and expressed in simple Mendelian fashion are called “good.” ►expressivity, ►penetrance, ►polygenic inheritance, ►QTL

Genes, Split: They contain introns; the vast majority of eukaryotic genes are therefore split into segments of exons. ►introns, ►exon

Genes, Synthetic: These have been produced since the 1970s. In 1976, Khorana synthesized the tyrosine suppressor tRNA genes of *E. coli* by classical methods or organic chemistry. In vitro synthesis of 26 oligonucleotide tracts were ligated into a 207 bp DNA containing the 86 nucleotide sequence of the gene plus leader, promoter and the terminator sequence. This gene turned out to be biologically

active and suppressed an amber mutation when transformed into bacterial cells. ►tRNA, ►suppressor tRNA, ►synthetic genes [for a diagram]; Ryan MJ et al 1979 J Biol Chem 254: 10803.

GENESCAN: A computer program for the detection of gene structure, transcriptional and translational splicing signals, exons, introns and intergenic regions of the mammalian genome on probabilistic basis. Multiple sequences are identified (Burge C, Karlin S 1997 J Mol Biol 268:78).

GeneScape: A computer program that seeks out miniset clones, DNA sequences, gene alignments to restriction maps and allows zooming from a display to the entire map of *E. coli*.

Gene-Scribe: A commercial transcriptional kit with a T7 phage RNA polymerase. It can be used to transcribe cloned genes without subcloning. ►EMBL3, ►λDASH, ►λFIX

Genesis: Used with several meanings such as inception, origin, the process of differentiation and development; also in composite words such as embryogenesis, morphogenesis, neurogenesis, etc.

Gene-Specific Repair Assay: Detects the presence of functional repair enzymes acting at a specific gene. The procedure: (i) expose cells (DNA) to mutagen/carcinogen, (ii) withdraw DNA after specific time periods, (iii) separate replicated and unreplicated DNAs on cesium chloride gradient ultracentrifugation, (iv) restriction enzyme digestion, (v) employ repair enzymes (uvrABC, T4 endonuclease, Fpg, endonuclease III), (vi) electrophorese DNA and on Southern blots probe the gene of interest, (vii) on the autoradiographed gel compare band intensities after allowed for repair as in (v). In the absence of repair, the intensity of the critical band in the gel is independent from the time allowed for repair whereas if repair is working the intensity of the band increases by the length of the period of incubation. ▶DNA repair, ▶uvrABC, ▶endonuclease, ▶Fpy, ▶density gradient centrifugation, ▶autoradiography; Anson RM, Bohr VA 1999 *Methods Mol Biol* 113:257; Ayala-Torres S et al 2000 *Methods* 22:135.

Gene-Switch Cassette: A construct facilitating turning genes on and off in a controllable manner. It encodes the DNA-binding domain of GALA4, the human progesterone receptor-ligand-binding domain and the activation domain of the human p65 protein gene. In the presence of the antiprogestin mifepristone (RU486) the chimeric molecule binds to the upstream activating domain (UAS) and in a ligand-dependent manner transactivates the appropriate downstream genes. The construct can be inserted into *Drosophila* by adenoviral or P vectors. A toggle switch system has been constructed in bacteria by the use of two repressible promoters arranged in a mutually inhibitory network. By chemical or temperature treatment, the system can be flipped between two stable states. Such system has potential application in biotechnology, gene therapy and biocomputing (Gardner TS et al 2000 *Nature [Lond]* 403:339). ▶GALA4, ▶progesterone, ▶RU486, ▶UAS, ▶p65, ▶transactivator, ▶tetracycline, ▶hybrid dysgenesis, ▶gene circuit; Roman G et al 2001 *Proc Natl Acad Sci USA* 98:12602; Osterwalder T et al 2001 *Proc Natl Acad Sci USA* 98:12596; Galimi F et al 2005 *Mol Ther* 11:142.

Genet: Genetically identical ramets that are clonal progeny of a single individual. ▶ramet

GeneTest: A publicly funded medical genetics information resource developed for physicians, other healthcare

providers, and researchers, available at no cost to all interested persons. According to GeneTest, in 2007 there have been 1,054 clinical tests and 297 research tests for 1,351 diseases. (See: <http://www.genetests.org/>; http://www.fnih.org/GAIN/GAIN_home.shtml).

Genethics: ▶ethics

Genetic Accommodation: Mutation or environmental effects cause the appearance of a novel adaptive phenotype through quantitative genetic changes. It is similar to genetic assimilation but unlike genetic assimilation, genetic accommodation results in increased environmental sensitivity of a plastic phenotype (Suzuki Y, Nijhout HF 2006 *Science* 311:650). ▶genetic assimilation, ▶polypheny

Genetic Assimilation: An adaptive mechanism in a population to fix genes as permanent parts of the genome by selection. An initially epigenetic (acquired-phenotypic) modification becomes fixed by heredity. ▶adaptation, ▶genetic accommodation, ▶assimilation, ▶fixation, ▶fixation index, ▶canalization, ▶epigenetic, ▶reaction norm, ▶plasticity, ▶fitness, ▶Baldwin effect; Palmer AR 2004 *Science* 306:828; Waddington CH 1953 *Evolution* 7:118.

Genetic Association: The correlation between the presence of a genetic marker and a certain type of multifactorial disease. For the trustworthiness of the conclusions large populations and high statistical probability are required (Dahlman I et al 2002 *Nature Genet* 30:149; Xiong M et al 2002 *Am J Hum Genet* 70:1257). ▶GAIN

Genetic Association Information Network (GAIN): GAIN is a public-private partnership of the Foundation for the National Institutes of Health, Inc., which includes corporations, private foundations, advocacy groups, concerned individuals, and the National Institutes of Health. This initiative will take the next step in the search to understand the genetic factors influencing risk for complex diseases. Through a series of whole genome association studies, using samples from existing case-control studies of patients with common diseases, the project will contribute to the identification of genetic pathways that make us more susceptible to these diseases and thus facilitate discovery of new molecular targets for prevention, diagnosis, and treatment. (See: http://www.fnih.org/GAIN/GAIN_home.shtml).

Genetic Background: All residual genes, besides the one(s) of special interest. It may be critical for

analysis because the background may affect (+/–) the expression of particular genes. Therefore, failure of identifying the background may make confirmation of the results impossible. It is improper in a scientific paper to state only that the material was purchased in a certain store.

Genetic Balance: ▶balance of alleles, ▶balanced lethals, ▶balanced polymorphism

Genetic Bar-Code: ▶DNA chip, ▶bar code

Genetic Block: Mutation in a gene may prevent or slow down the flow of a metabolic pathway. ▶null allele, ▶leaky mutant

G

Genetic Burden: Same as genetic load.

Genetic Cascade: Genes of a developmental pathway are activated in successive waves; the expression of “earlier” genes activates the next ones.

Genetic Circuits: ▶gene circuits

Genetic Circularity: A consequence of circular DNA genetic material, i.e., the genetic map has no ends

although one point is generally designated as origin.
▶DNA circular

Genetic Code: It consists of 64 contiguous nucleotide triplets; 61 specify 20 amino acids and three serves as signals for termination of translation on the ribosomes (see Table G1). The number of triplet codons for a particular amino acid varies from one to six. In animals, the 21st encoded (UGA) amino acid is selenocysteine and in Archaea and Eubacteria UAG may encode the 22nd amino acid, pyrrolysine. In addition, programmable ribozymes may attach non-natural amino acid to RNAs and incorporate them into engineered proteins (Bessho Y et al 2002 Nature Biotechnol 20:723). In an engineered *E. coli* bacterium the amber codon my direct the incorporation of the non-natural amino acid p-aminophenylalanine into protein at high efficiency (Mehl RA et al 2003 J Am Chem Soc 125:935). More than a dozen unnatural amino acids can be incorporated into proteins. The number of triplet codons for a particular amino acid varies from 1 to 6. It is of theoretical and of practical importance to amplify the genetic code beyond the “magic number”. Chemically modified, unnatural amino acids may alter protein function if

Table G1 The genetic code in RNA triplets

| 5' Nucleotide | Second nucleotide | | | | 3' Nucleotide | |
|---------------|-------------------|-----|-------|------|---------------|-------------------------|
| | U | C | A | G | | |
| U | Phe | Ser | Tyr | Cys | U | Ala = alanine (4) |
| | Phe | Ser | Tyr | Cys | C | Arg = arginine (6) |
| | Leu | Ser | ochre | opal | A | Asp = aspartic acid (2) |
| | Leu | Ser | amber | Trp | G | Asn = asparagine (2) |
| C | Leu | Pro | His | Arg | U | Cys = cysteine (2) |
| | Leu | Pro | His | Arg | C | Glu = glutamic acid (2) |
| | Leu | Pro | Gln | Arg | A | Gln = glutamine (2) |
| | Leu | Pro | Gln | Arg | G | Gly = glycine (4) |
| A | Ile | Thr | Asn | Ser | U | His = histidine (2) |
| | Ile | Thr | Asn | Ser | C | Ile = isoleucine (3) |
| | Ile | Thr | Lys | Arg | A | Leu = leucine (6) |
| | Met | Thr | Lys | Arg | G | Lys = lysine (2) |
| G | Val | Ala | Asp | Gly | U | Met = methionine (1) |
| | Val | Ala | Asp | Gly | C | Phe = phenylalanine (2) |
| | Val | Ala | Glu | Gly | A | Pro = proline (4) |
| | Val | Ala | Glu | Gly | G | Ser = serine (6) |

Thr = threonine (4)
Trp = tryptophan (1)
Tyr = tyrosine (2)
Val = valine (4)

RNA codons represent the universal genetic code for amino acids. The table shows the three nonsense codons (chain-termination codon, boxed) and 61 sense codons coding for amino acids. The numbers after the amino acids (right-most column) indicates the number of synonymous codons for each amino acid. methionine and tryptophan each have only..... 1
asparagine, aspartic acid, cysteine, glutamic acid, glutamine, histidine, lysine, phenylalanine, tyrosine, each has.....2
isoleucine has..... 3
alanine, proline, threonine, and valine have..... 4
arginine, leucine, serine all have..... 6 codons.
The codon usage is not random; it varies among organisms and genes

Table G2. Exceptional codon meanings

| <i>Mycoplasma capricolum</i> | <i>Tetrahymena thermophila</i> | <i>Euplotes octacarinatus</i> | Mitochondria | | | |
|------------------------------|--------------------------------|-------------------------------|---------------|-------------------|--------------|-------------------|
| | | | <i>Mammal</i> | <i>Drosophila</i> | <i>Yeast</i> | <i>Neurospora</i> |
| UGA: Trp | UAA: Gln | UGA: Cys | AUA: Met | AUA: Met | AUA: Met | CUN: Thr |
| | CAG: Gln | UAA: stop | AUU: Met | AUU: Met | CUA: Thr | |
| | UAG: Gln | UAG: absent | AUG: Met | AUG: Met | CUC: Met | |
| | | | AUC: Met | | CUU: Met | |
| | | | UGA: Trp | UGA: Trp | CUG: Met | |
| | | | AGA: stop | AGA: Ser | | |
| | | | AGG: stop | | | |

The UGA “universal” stop codon means Trp in the mitochondria of vertebrates, insects, molluscs, echinoderms, nematodes, platyhelminthes, fungi and ciliates. Selenocysteine is also coded by UGA in *E. coli* and mammals.

G

incorporated in vivo in place of the natural ones. Modified special tRNAs and mutant aminoacyl tRNA synthetases may achieve incorporation. Mutations at the editing sites of *E. coli* tRNA^{Val} synthetase incorporated in higher than 29% aminobutyrate, a steric analog of cysteine into the site of cysteine (see Table G2).

Besides providing information for the primary sequence of amino acids in proteins, the genetic code includes parallel information for binding sequences for regulatory and structural proteins, signals for splicing, and RNA secondary structure. The universal genetic code can efficiently carry arbitrary parallel codes much better than the vast majority of other possible genetic codes. The ability to support parallel codes is strongly tied to the identity of the stop codons and to the minimization of the effects of frame-shift translation errors. Whereas many of the known regulatory codes reside in nontranslated regions of the genome, it seems that the protein-coding regions can readily carry abundant additional information (Itzkovitz S, Alani U 2007 Genome Res 17:405).

Genetic Code, Combinatorial: The transcription factor binding sites are assembled to form tissue-specific enhancer elements. ►enhancer, ►tissue-specificity, ►transcription factors

Genetic Code, Second: Determines the binding specificities of the transcription factors. ►aminoacyl-tRNA synthetase

Genetic Colonization: An infection of plants by *Agrobacteria* results in the expression of bacterial genes in the plant cells and the gene products, such as opines, and is utilized only by the bacteria. In population genetics, colonization means also the establishment of a breeding population in new habitat. ►*Agrobacterium*, ►transformation, ►opines; Harding RM, McVean G 2004 Curr Opin Genet Dev 14:667.

Genetic Complementation: ►complementary alleles, ►complementation groups, ►allelic complementation, ►complementation maps

Genetic Conflict Theory: The evolutionary conflict between maternal and paternal genes such as exists in imprinting. ►imprinting; Wilkins GF, Hasig D 2003 Nature Rev Genet 4:359.

Genetic Conservation: The preservation of species and subspecific genetic variations in protected areas, national parks, game reserves, botanical gardens,

zoos, seed depositories, culture corrections, sperm banks (Ryder OA 2005 Cytogenet Genome Res 108:6).

Genetic Correlation: Linked genes are expected to segregate together depending on the frequency of recombination. Members of the same family display correlation, and even assortative mating shows correlations although the latter may not be genetic. From the correlation between certain phenotypes the chromosomal location of genes can be predicted. The term genetic correlation in animal breeding is defined as a measure of the ratios of additive variances: $\text{Cov}(X,Y)/\sqrt{\text{Var}(X)\text{Var}(Y)}$. ▶correlation

Genetic Counseling: Provides information, medical diagnosis on hereditary bases, recurrence risk, family history, and possible management of genetic anomalies for the benefit of the family. It has no eugenic purpose and it does not make recommendations for decision; it merely informs the concerned individual(s). ▶counseling genetic, ▶risk, ▶recurrence risk, ▶utility index for genetic counseling; Mahowald MB et al 1998 Annu Rev Genet 32:547; Thornburn DR, Dahl HH 2001 Am J Med Genet 106:102; GENETests: http://www.ornl.gov/sci/techresources/Human_Genome/medicine/genecounseling.shtml; <http://www.nlm.nih.gov/medlineplus/geneticcounseling.html>; <http://www.genetest.org/>.

Genetic Death: Genetic death occurs if an organism leaves no offspring or a gene is not transmitted to subsequent generations. ▶mutation beneficial, ▶mutation neutral, ▶fitness, ▶selection coefficient, ▶selection conditions, ▶transmission, ▶apoptosis; Hay BA et al 2004 Nature Rev Genet 5:911.

Genetic Determination (g^2): Similar to heritability in the broad sense (measured by intraclass correlation) where MS_b and MS_w stand for between and within strain mean squares, respectively. The $2n-1$ in the denominator is used in testing inbred strains to compensate for the increase of additive genetic variances during inbreeding. ▶intraclass correlation, ▶heritability, ▶variance

$$\frac{MS_b - MS_w}{MS_b + (2n - 1)MS_w} = g^2$$

Genetic Discrimination: Prejudicial treatment on the basis of phenotypic or genotypic constitution by employers, insurance companies or any other person or institution. ▶genetics and privacy, ▶bioethics; Nowlan W 2002 Science 297:195; Rothenberg KH, Terry SF 2002 Science 297:196; Wright Clayton E 2003 New Engl J Med 349:562). Genetic discrimination is also for the detection of differences in the

genetic material of cells, e.g., normal and cancer cells (Huang J et al 2004 Human Genomics 1:287).

Genetic Diseases: An estimated 4,000 human genes are directly or indirectly involved in the determination of human malformations and physical and mental disabilities. According to some estimates 15 to 20% of newborns are afflicted by some hereditary problems and a large fraction of the abortions are caused by chromosomal anomalies and/or recessive or dominant lethal genes. Approximately 25% of the hospitalizations are due to maladies with a genetic component. One study found that ~71% of the 4,224 children admitted to a hospital a significant genetic component of the illness they were treated for (McCandless SE et al 2004 Am J Hum Genet 74:121). After birth, defective enzymes have the largest share in the disorders. Anomalous genetic regulation accounts for the majority of the developmental defects. Amino acid replacement mutations (based on six human diseases) indicate that evolutionarily conserved sites are most common in human disease. From the degree of physicochemical alterations in the protein caused by missense mutation the grade of the disease or the likelihood of developing cancer can be predicted (Stone EA, Sidow A 2005 Genome Res 15:978). Polymorphic replacement mutations and silent mutations appear, however, randomly distributed. In several countries, population databases are being established with purpose to gain information on the interplay among genes and environmental factors and eventually to facilitate individualized medical treatment. Epidemiological observations indicate adulthood diseases are affected not only by genetic causes but also by early environmental factors such as conditions at the time of conception, fetal and infant environment as well as by adult life style (Gluckman PD, Hanson MA 2004 Science 305:1733). Very often genes are not the absolute cause of the disease because many of them can be prevented by proper life-style and preventive medication if disposition exists. The occurrence of genetic disease sometimes can be avoided or the risks reduced by proper education, premarital genetic counseling. During gestation, transcription factor and enzyme defects are the most prevalent fraction of diseases of the fetus. ▶eugenics, ▶gene therapy, ▶readthrough, ▶selection coefficient, ▶inbreeding, ▶consanguinity, ▶risk, ▶recurrence risk, ▶DALY, ▶prevalence, ▶genetics and privacy, ▶OMIM, ▶genetic screening; Miller MP, Kumar S 2001 Hum Mol Genet 10:2319; Perez-Iratxeta C et al 2002 Nature Genet 312:316; Dean M et al 2002 Annu Rev Genomics Hum Genet 3:203; Homophila; statistical tests for genome-wide identification

of disease genes: Marchini J et al 2005 Nature Genet 37:41; frequencies: <http://archive.uwcm.ac.uk/uwcm/mg/fidd/>; candidate disease genes:

[dhttp://disease.bork.embl-heidelberg.de/g2d/](http://disease.bork.embl-heidelberg.de/g2d/); disease genes: <http://dgcst.ceinge.unina.it/>.

Genetic Disorder: In the manifestation of the anomaly (disease) hereditary factors play major role. Single genes determine primarily some of the diseases; others are under the control of several genes. In either case, environmental factors can modify the expression of the disorder. ▶ [monofactorial inheritance](#), ▶ [polygenic inheritance](#), ▶ [QTL](#), ▶ [mitochondrial diseases in humans](#)

Genetic Dissection: Analyzes the mechanism(s) of genetic determination and control of biological traits, morphogenesis and/or other function(s) by the techniques of mutation, recombination and pattern of inheritance in pedigrees or populations. ▶ [one gene—one enzyme theorem](#), ▶ [morphogenesis in *Drosophila*](#), ▶ [metabolic pathways](#)

Genetic Distance: Genetic distance (d) can be measured by different procedures. One simplification is based on a geometric model is $d^2 = 1 - \sqrt{p_1 p_2} - \sqrt{q_1 q_2}$ where p and q represent the frequencies of the two alleles of a locus in populations 1 and 2, respectively. For actual determination of the distance between two populations more than one allelic pair must be considered. Genetic distance, F_{ST} is calculated also as $V_p / \bar{p}(1 - p)$ where V_p is the variance between gene frequencies in a set of n populations and \bar{p} = their average gene frequencies. ▶ [evolutionary distance](#), ▶ [evolutionary tree](#); Nei M 1972 Am Nat 106:283; molecular distances among some animals: <http://warta.bio.psu.edu/DED>.

Genetic Divergence: ▶ [divergence](#)

Genetic Diversity: The variations in the gene pool of a population or the genetic variations in the populations. ▶ [gene pool](#), ▶ [genetic variation](#), ▶ [genetic conservation](#), ▶ [diversity](#)

Genetic Drift: A change in gene frequencies by sampling error(s) of the gametic array so the genes are not maintained on the basis of their fitness or selective advantage they may convey but the selection is the outcome of chance. In case of two alleles, selection by chance alone is determined by the frequency of the alleles, the binomial distribution and population size. Thus, if the frequency of allele A is p and that of a is q the frequency of alleles by chance alone will follow the binomial distribution of $(p + q)^n$ where n = the number of individuals that leave offspring surviving

to the reproductive age; e.g., in case the allelic frequencies are equal and four individuals survive, the probability that all 4 will be homozygous recessives is 0.0625. ▶ [effective population size](#), ▶ [founder principle](#), ▶ [binomial distribution](#), ▶ [Pascal triangle](#), ▶ [Eve foremother](#); Cavalli-Sforza LL, Bodmer WF 1971 The Genetics of Human Populations, Freeman, San Francisco, California.

Genetic Endpoint: Classification of the types of genetic lesions such as mutation, chromosomal aberration, unscheduled DNA synthesis, etc. that are detected in mutagen testing. ▶ [bioassays in genetic toxicology](#)

Genetic Engineering: Construction of special chromosomes by cytogenetic manipulations, somatic cell fusions, or introduction of organelles into cells by mechanical means (genetic microsurgery). Isolation and propagation of DNA molecules in suitable hosts, molecular modification of genes and regulatory elements for special purposes, and transfer genes among diverse organism by bypassing the constraints of sexual reproduction and manipulate them for medical, industrial and agricultural use. ▶ [transformation](#), ▶ [cloning vectors](#), ▶ [homologous recombination](#), ▶ [chromosome substitution](#), ▶ [alien addition](#), ▶ [alien substitution](#), ▶ [alien transfer lines](#), ▶ [metabolite engineering](#), ▶ [protein engineering](#), ▶ [pathogen identification](#), ▶ [intercellular immunization](#), ▶ [intracellular immunization](#), ▶ [input trait](#), ▶ [gene therapy](#), ▶ [cancer gene therapy](#), ▶ [transgenic](#), ▶ [genomics](#), ▶ [biotechnology](#), ▶ [monoclonal antibody](#), ▶ [intein](#), ▶ [monoclonal antibody therapies](#), ▶ [targeting genes](#), ▶ [nuclear transplantation](#), ▶ [terminator technology](#), ▶ [scaffold](#), ▶ [GMO](#), ▶ [stem cells](#), ▶ [tissue engineering](#), ▶ [stem cells](#), ▶ [RAC](#), ▶ [synthetic biology](#)

Genetic Enhancement: ▶ [gene therapy](#), ▶ [plant breeding](#), ▶ [animal breeding](#), ▶ [eugenics](#)

Genetic Equilibrium: Exists when gene frequencies are stable for generations. (See also ▶ [mutations and genetic equilibrium](#)). In a panmictic diploid equilibrium population, the frequency of heterozygotes is twice the square root of the product of the frequencies of the two homozygous classes: $2 = H / \sqrt{D \times R}$ where H , D , R and stand for heterozygotes, homozygous dominants, and homozygous recessives, respectively (see Table G3). This is derived from the middle term of the Hardy-Weinberg formula, $2pq = h = 2\sqrt{p^2 q^2} = 2 \times \sqrt{D \times R}$ and hence $2 = H / \sqrt{D \times R}$.

This principle can graphically be represented (see Fig. G24). In an equilibrium population the frequency of heterozygotes is represented by a parabola as the proportion of the alleles vary from 0 to 1 to 0 as long the as three genotypes have equal fitness. With respect to an individual locus, equilibrium is attained

Table G3. Genotypic frequencies

The four populations represented in the body of the table below all have identical gene frequencies, $p = 0.8$, $q = 0.2$ yet the genotypic proportions are quite different. According to the definition in the text only population 4 is in equilibrium.

| Populations | Genotypic Frequencies | | |
|-------------|-----------------------|------|------|
| | AA | Aa | aa |
| 1 | 0.80 | 0.00 | 0.20 |
| 2 | 0.70 | 0.20 | 0.10 |
| 3 | 0.60 | 0.45 | 0.00 |
| 4 | 0.64 | 0.32 | 0.04 |

Figure G24. Genetic equilibria.

within one generation of random mating. As long as random mating prevails and there is no selection; gene and genotypic frequencies do not change and the Hardy-Weinberg principle prevails. Multiple loci require more generations to attain equilibrium. Also, equilibrium depends on the intensity of linkage among the loci. Progress toward equilibrium is delayed if the genes are sex-linked. If in the original mating the homogametic sex is homozygous for a recessive allele (X^aX^a) and the heterogametic sex carries the other allele (X^AY), the allelic frequencies in the two sexes will follow an oscillatory path during the generations because of the zigzag pattern of inheritance of the X chromosome. In equilibrium, the allelic proportions in the two sexes will be represented by the proportions of the X chromosomes.

Figure G25. Progress toward genetic equilibrium in case two genes are linked in repulsion at zero generation time. At equilibrium the repulsion and the coupling phases are equal. Four of the curves (0.05 to 0.3) represent the courses to equilibria at various intensities of recombination; 0.5 indicates independent segregation. (Modified after Falconer, D.S. Introduction to Quantitative Genetics. Longman, London, UK)

Somewhat similar situation exists in hermaphrodites carrying self-sterility alleles (S) (see Fig. G25). The mating of plants self-incompatibility alleles (S) produce the offspring shown in the table (See Table G4) below.

Table G4. Self-sterility progenies

| Female | Male | Offspring |
|----------|-----------------------------|---|
| S_1S_2 | Either S_1S_3 or S_2S_3 | $\frac{1}{2} S_1S_3 + \frac{1}{2} S_2S_3$ |
| S_1S_3 | Either S_1S_2 or S_2S_3 | $\frac{1}{2} S_1S_2 + \frac{1}{2} S_2S_3$ |
| S_2S_3 | Either S_1S_2 or S_1S_3 | $\frac{1}{2} S_1S_2 + \frac{1}{2} S_1S_3$ |

Half of the progeny is the same as the male whereas the other half has a different constitution. The genetic constitution of the females does not reappear in the immediate progeny because of the self-sterility. Therefore, if the frequencies of the alleles are not identical, the genotypes most common among the parents will be the least frequent among their offspring although will reappear in advanced generations. Equilibrium is reached however if the frequencies of the alleles are equal.

In polyploids the progress toward equilibrium is quite complicated and can be determined according to

CC Li (First Course in Population Genetics, Boxwood Press, California). If the gametic output of an autotetraploid population is $G_0 \equiv x(AA) + 2y(Aa) + z(aa) = 1$, the frequency (p) of $A = x + y$ and the frequency (q) of $a = y + z$. The gametic proportions in the course of generations (n) is expressed as $d = (y^2 - xz) = y^2 - (p - y)(q - y) = y - pq$, and d is the index of divergence from the equilibrium condition. This index is reduced by $2/3$ during each generation of random mating. The gametic proportions and gene frequencies can thus be obtained as:

$$\begin{aligned} yn &= pq + dn = pq + \left(\frac{1}{3}\right)nd \rightarrow pq, \\ xn &= p - yn = p^2 - \left(\frac{1}{3}\right)nd \rightarrow p^2, \\ zn &= q - yn = q^2 - \left(\frac{1}{3}\right)nd \rightarrow q^2 \end{aligned}$$

►Hardy-Weinberg, ►linkage disequilibrium, ►autopolyploidy, ►sex-linkage, ►self-sterility, ►Wahlund's principle

Genetic Essentialism: A criticism of modern genetics for "equating" human (and other) beings with a molecular entity (DNA), including social, historical and moral complexities and responsibilities. In contrast, some physicians and ethicists emphasize the holistic approaches, which integrate also human consciousness. ►vitalism

Genetic Fine Structure: Analysis involves recombination within the boundaries of individual genes.

Genetic Fingerprinting: ►DNA fingerprinting

Genetic Hazards: ►risk, ►genetic risk, ► λ_s , ►recurrence risk, ►empirical risk, ►genotypic risk ratio, ►radiation hazard assessment, ►radiation effects, ►environmental mutagens, ►Kaplan-Meier estimator of survival, ►GMO

Genetic Homeostasis: The property of a population to maintain its genetic composition and resist changes in gene frequencies by phenotypic regulation under variable environmental conditions. ►homeostasis, ►canalization, ►artificial selection; Lerner IM 1954 Genetic Homeostasis, Wiley, New York.

Genetic Homology: The degree of similarity in the base sequences of DNA and RNA or the amino acid sequences in the proteins. ►DNA sequencing, ►RNA sequencing, ►protein structure, ►amino acid sequencing, ►homology, ►databases

Genetic Information: Instructions in the nucleic acids for the cellular machinery.

Genetic Instability: ►instability genetic

Genetic Interaction: Genetic interaction is becoming increasingly interesting in modern biology and needs new (bioinformatics) approaches for its genome-wide use. The global performance of four existing classes of inference algorithms using 445 *Escherichia coli* Affymetrix arrays and 3,216 known *E. coli* regulatory interactions from RegulonDB have been tested. The context likelihood of relatedness (CLR) algorithm can also be applied as a novel extension of the relevance networks class of algorithms. CLR demonstrates an average precision gain of 36% relative to the next-best performing algorithm. At a 60% true positive rate, CLR identified 1,079 regulatory interactions, of which 338 were in the previously known network and 741 were novel predictions (Faith JJ et al 2007 PloS Biol 5(1)e8). ►epistasis, ►gene product interaction, ►QTL, ►genetic networks, ►systems biology

Genetic Isolation: The lack of ability to interbreed (incompatibility) and/or hybrid inviability or sterility between/among different taxonomic groups. ►isolation genetic, ►speciation

Genetic Load: Sum of deleterious genes in the genome. Recessive alleles cannot generally be detected in the heterozygotes. These heterozygotes may continuously contribute homozygotes to the population and if the recessives are deleterious, they may adversely affect the fitness of the population; thus constituting a genetic load. The amount of hidden genetic variation is revealed by the coefficient of inbreeding. In F_1 , 100% of the population is heterozygous. In successive generations of selfing, the heterozygosity decreases by $(0.5)^n$ where n = the number of selfed generations (e.g., by F_5 there are four selfings). Thus, the sum of the heterozygotes = $1 - (0.5)^n$. The coefficient of inbreeding F , in the offspring of first cousins, is 0.0625 whereas among unrelated individuals it is presumed to be 0. Thus, if the mortality range in a certain age group is, say, 11% in the general population, and 16% among the children of first cousins, the difference is 5%. Therefore, $16 \times 0.05 = 0.80$, and 80% would be the average mortality if the coefficient of inbreeding would reach 100%. Recessive zygotic lethality requires homozygosity at the same locus (present in both parental gametes). According to the Hardy-Weinberg theorem, the frequency of the double recessive genotypes is expected to be q^2 , and the frequency of at least one lethal equivalent gene is then $\sqrt{0.80} \approx 0.89$. This indicates that almost 90% of the gametes carried a lethal gene or a combination of genes that cause lethality at homozygosity. On this basis, the genetic load of this population is close to one lethal equivalent factor per gamete. Other investigations estimated the genetic load to be twice as high in some

The frequency of deleterious alleles is proportional to the mutation rate and selection coefficient: $\hat{q}^2 = u/s$. By rewriting the formula, the mutational load of recessive alleles becomes $u = s\hat{q}^2$, and $\hat{q} = \sqrt{u/s}$.

The mutational load of dominant genes is $2u$. In the absence of dominance in a random-mating population, the mutational load is $L = 2u/(1 + u)$. The mutational load in the most common cases is proportional to the rate of mutation and not to the severity of the affliction.

G

populations. The amount of the genetic load may vary. It is affected by exposure to environmental mutagens, drugs, exposure to chemicals in the food chain (natural toxins or insecticides, pesticides) or in industrial pollutants, occupational hazards, presence of mutator genes (transposable elements), and natural or other types of radiations (X-rays, UV, etc.). Completely dominant lethal mutations do not contribute to the genetic load because they may eliminate the carriers of the genetic defect and thus no load is passed on to successive generations. Of course, some mutations may show intermediate types or conditional expression and may or may not contribute to the load. Some deleterious genes are closely linked to advantageous genes and thus transmitted beyond their merit by this "hitchhiking" effect. In such a situation, a recombinational load may exist. Environmental load is generated in highly variable environments where under certain conditions genes are selected that normally convey inferior fitness. Incompatibility load arises in cases of deleterious maternal—fetal interactions, such as those that may arise if the mother is Rh negative for this blood antigen and the fetus is positive or if the mother expresses phenylketonuria but the fetus is heterozygous (maternal epistasis). ▶allelic frequencies, ▶Hardy–Weinberg theorem, ▶mutation neutral, ▶mutation beneficial, ▶recombinational load, ▶selection coefficient, ▶fitness, ▶coefficient of inbreeding, ▶consanguinity, ▶incest, ▶genetic risk, ▶lethal equivalent, ▶Muller's ratchet, ▶incompatibility, ▶epistasis, ▶mutation in human populations, ▶death, ▶truncation; Cavalli-Sforza LL, Bodmer WF 1971 The genetics of human populations, Freeman, San Francisco; Muller HJ 1950 Am J Hum Genet 2:111; Drake JW et al 1998 Genetics 148:1667; Szafraniec K et al 2001 Proc Natl Acad Sci USA 98:1107; Kondrashov AS et al 2002 Proc Natl Acad Sci USA 99:14878.

Genetic Lottery: (Journalistic) chance of individuals to inherit certain genes in a population.

Genetic Manipulation: Application of genetic, cytological, or molecular techniques for constructing altered organisms. ▶genetic engineering, ▶chromosome engineering

Genetic Map: The relative position of genes or other chromosomal markers represented in a linear manner on the basis of recombination frequencies. ▶mapping genetic, ▶physical map, ▶mapping function, ▶deletion maps, ▶linkage group

Genetic Markers: Genetic markers help identify nuclear chromosomes, cytoplasmic organelles, and isolated cells on the basis of their inherited behavior and facilitate the identification of the genetic mechanisms involved in special phenomena, such as recombination, gene conversion, mutation, chromosomal rearrangements, genetic transformation, cell fusion, selection, etc.

Genetic Material: Either DNA (in eukaryotes and the majority of prokaryotes) or RNA (in some viruses). These nucleic acids can occur in either double or single-stranded forms. ▶RNA, ▶mtDNA, ▶ctDNA, ▶prion, ▶Watson and Crick model

Genetic Medicine: Genetic medicine aims to correct diseases by the use of DNA, RNA, or proteins. Inborn errors of metabolism were recognized since the beginning of the twentieth century and metabolic corrections or alleviations of the defect has been used by modified defect. Phenylketonuric patients were placed on phenylalanine-restricted diet, or in case of fructose intolerance, fructose-rich food was proscribed. Low-cholesterol diet and the use hydroxymethylglutaryl co-enzyme A (HMG CoA) inhibitor statins alleviate hypercholesterolemia. To avoid iron overload caused by the frequent blood transfusions in thalassemia, the iron chelating desferrioxamine proved useful. In several diseases, *protein augmentation* therapy corrected for the low level of a protein in the extracellular compartment; purified proteins were introduced into the body in case of endocrine disorders, immunoglobulin deficiencies, lysosomal storage diseases, and others. This approach was successful only when the administration was effective and simple, allergic or immunological reactions were not prohibitive, and the supply was adequate at reasonable cost. This type of therapy is applicable (at least in principle) to the approximately 1,800 human diseases involving a single major gene. The complex, multigenic quantitative diseases and chromosomal aberrations are generally not amenable to this type of corrections. Some of the disease sites are difficult to reach directly (e.g., in the brain in utero). Others, e.g., α -antitrypsin (ATT) deficiency is manifested in adult stage and then, oral administration of 4-phenylbutyric acid facilitates the release of antitrypsin from the endoplasmic

reticulum. Antitrypsin, as a “chemical chaperone”, may prevent the injuries resulting from AAT deficiency. Some injuries of the brain or spinal cord, or tissue degeneration (e.g., prion diseases, Parkinson disease, cardiac muscle defects, hematological anomalies, etc.) can eventually be remedied in humans, also by the use of embryonic or somatic stem cells. Gene therapy and stem cell mediated cures are generally expected to be effective for all variations within a specific monogenic disease. MicroRNA or RNAi technology must target specific sites (corresponding to that RNA) to be effective. ▶antisense technology, ▶microRNA, ▶RNAi, ▶gene therapy, ▶readthrough, ▶cancer gene therapy, ▶stem cell, ▶biomarker, ▶drug development, ▶SADR; O'Connor TP, Crystal RG 2006 Nature Rev Genet 7:261.

Genetic Milieu: ▶genetic background

Genetic Module: ▶module, ▶genetic network

Genetic Mosaic: An individual with cell patches of different genetic constitutions. It may come about by somatic mutation, movement of insertion- or transposable elements, somatic recombination, nondisjunction, deletion, etc. ▶individual entries, ▶chimera, ▶codominance

Genetic Network: The connections between DNA, RNA, protein, cis- and transacting regulators, operons, epistasis, signals and the signal transducing systems, and feedback, involving a large number of genetic and environmental inputs (see Fig. G26). M.

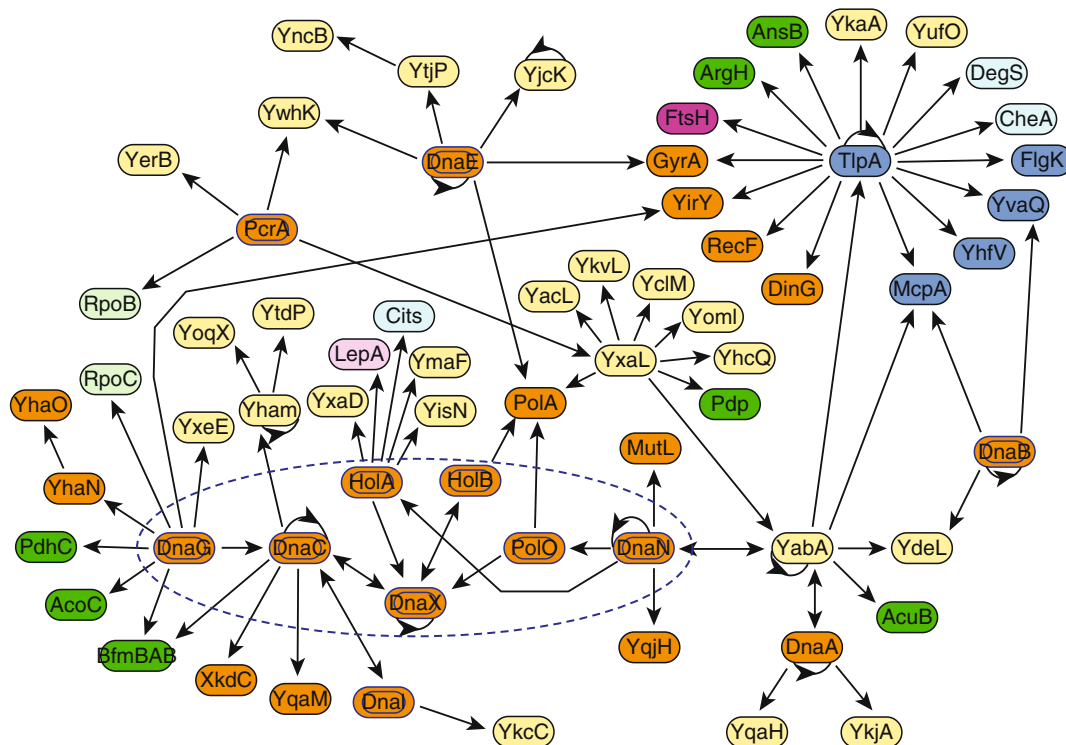

Figure G26. A network of 69 proteins involved in 91 specific interactions centered on the replication machinery of *Bacillus subtilis*. It shows the relations of DNA replication with recombination and repair, membrane-bound protein complexes, and signal transduction. The names, basic function, and location in the physical map of most of the specific proteins can be found in Kunst F et al 1997 Nature [Lond] 390:249, reporting the complete genome sequence of this prokaryotic genome. Two-hybrid tests were used to determine the interacting components. The arrows are oriented from bait to prey. Double blue lines designate the primary baits (with the exception of PriA and DnaD). The dashed black oval outlines the replisome. The number of the interacting components varies from 17 to 1. Details can be accessed by <http://www-mig.versailles.inra.fr/bdsi/SpiD>. The color code identifies functional categories. Orange: DNA replication/ recombination/ repair. Dark blue: mobility and chemotaxis. Light blue: signal transduction. Light green: transcription. Pink: protein synthesis. Dark green: metabolism of carbohydrates and amino acids. Purple: cell division. Yellow: unidentified functions. (From Marie-Françoise Noirot-Gros, Etienne Dervyn, Ling Juan Wu, Peggy Mervelet, Jeffery Errington, S. Dusko Ehrlich and Philippe Noirot 2002 Proc Natl Acad Sci USA 99:8342–8347. Courtesy of Dr. M.-F. Noirot-Gros, I.N.R.A., France. Copyright 1992 National Academy of Sciences, U.S.A.).

Demerec in 1933 said (J. Hered. 24: 369) “We know today, however, that no single gene has the sole responsibility for the appearance of any one character. The final effect is produced through the interaction of the whole complement of genes, although certain genes may have greater influence on the expression of certain characteristics than some other genes have.”

Genes involved in common processes tend to be expressed in detectable hierarchical waves. Exposure of yeast cells to Cd^{2+} induced 54 proteins, the majority of the sulfur assimilated by the cells was utilized for the formation of glutathione, and this reduced the production of other sulfur-rich proteins. The regulation takes place at the mRNA level. Glutathione is required for detoxification (Fauchon M et al 2002 Mol Cell 9:713). Interacting proteins may be identified experimentally by the two-hybrid system, TAP, three-dimensional structures, or by mass spectrometry.

Computational methods exist that reveal the co-inheritance of functional linkages across phylogenetic boundaries. By such procedures in yeast 3,875 linkages of 804 proteins have been revealed (Date AV, Marcotte EM. 2003 Nature Biotechnol 21:1055). In yeast, 4681 genes, i.e., ~81% of the genome, displayed ~34,000 probabilistic linkages (Lee I et al 2004 Science 306:1555). In *E. coli*, 74% of the known metabolic enzymes seem to be clustered in modules with an average pathway specificity of 84% (von Mering C et al 2003 Proc Natl Acad Sci USA 100:15428). On the basis of experimental data available or perturbation of the systems as the result of the recent molecular techniques, mathematics-aided models can be developed that may be applied to medical and biotechnological problems (Tegnér J et al 2003 Proc Natl Acad Sci USA 100:5944). Highly connected topological modules are combined into larger, less cohesive units and display similarities across different organisms. During development, multigenic feedback loops and spatial repressive control systems operate both periodically and constitutively in a dynamic manner (de Lichtenberg U et al 2005 Science 307:724). Behavioral traits of *Drosophila* displayed dramatically different interactions depending on the genetic background (van Swinderen B, Greenspan RJ 2005 Genetics 169:2151). The protein interaction networks are conserved in even unrelated species (Sharan R et al 2005 Proc Natl Acad Sci USA 102:1974). In 17 fungal genomes, cis-regulatory elements are conserved for several interacting modules. However in the ribosomal modules for dozens of promoters, new cis elements have emerged and switched on while retaining the functionality of the modules and shedding light on the evolution of regulatory

networks (Tanay A et al 2005 Proc Natl Acad Sci USA 102:7203). In some fungal species, the transcriptional network is altered by the loss of cis-regulatory functions (Ihmels J et al 2005 Science 309:938). A model of oscillatory signals may offer greater quantitative precision (Lipan O, Wong WH 2005 Proc Natl Acad Sci USA 102:7063). Herpes virus (Kaposi sarcoma-associated herpesvirus and varicella-zoster virus) proteins interact within their proteomes and with the human proteome (Uetz P et al 2006 Science 311:239).

Some network designs may require revisions when additional knockout(s) indicate no significant downstream consequence of the gene loss. In yeast, however, in some cases 4,000 double knockouts lead only to synthetic lethality (see Fig. G27) (Yeang C-H et al 2005 Genome Biol 6:R62).

The protein–protein interaction networks can facilitate understanding the pathogenic mechanisms involved in disease. In hereditary human ataxias and neural degenerations, Purkinje cell defects are

Figure G27. Genetic network of yeast nuclear proteins displaying 318 interactions of 329 proteins. Note the reduced links between highly connected proteins and the preference between highly connected and low-connected pairs of proteins. Green nodes correspond to viable null-mutations. Red nodes represent indispensable functions and their mutation is lethal. The map was constructed on the basis of two-hybrid data and the statistical properties of the interactions are discussed by Maslov S, Sneppen K 2002 Science 296:910. (Courtesy of Dr. Sergei Maslov)

G

Figure G28. *Caenorhabditis elegans* interactive network (interactome) displaying approximately 5,500 interactions. The experiment involved the use of yeast two-hybrid method. The nodes (circles) of proteins are colored according to phylogenetic class. Red: ancient, yellow: multicellular and blue: worm specific sets. See for details Li, S. *et al.* 2004 Science 303:540; the illustration is the courtesy of Drs. Marc Vidal and Nicolas Bertin

involved. A study of 54 proteins of 23 genetically determined ataxias revealed 770 protein–protein interactions by stringent yeast two-hybrid system; 83% of the interaction could be verified also in mammalian cells (Lim J *et al* 2006 Cell 125:801 (see Fig. G28)). In *Caenorhabditis*, using RNAi interference of gene expression by simply feeding RNAi containing bacteria revealed that a few “hub” genes affected several others, including homologs of genes involved in hereditary diseases. The data indicated that these genes modify the state of the chromatin and can affect the expression of many functionally unrelated genes and provide new information on the complexity of human disease (Lehner B *et al* 2006 Nature Genet 328:896).

Regulatory interactions affect the evolution of proteins that can be different in coding properties (see Fig. G29).

Evolution of genetic networks may be based either on the *link dynamics* or on *node dynamics*. Comparison of genetic networks may be relatively

simple if the species are closely related, and it can be measured by sequence comparisons (see Fig. G30). In case the species are less closely related, unrelated sequences may assume similar function within the network. These problems of evolutionary analyses can be resolved by a Bayesian parameter inference. Correlation coefficients of gene expression measured on RNA microarrays can be used to assess quantitatively the divergence between humans and mice, even when there is loss or gain of genes (Berg J, Lässig M 2006 Proc Natl Acad Sci USA 103:10967).

A probabilistic method, called Geronemo, aims to identify the mechanism by which genetic changes perturb the regulatory network. Geronemo automatically constructs a set of coregulated genes (modules), whose regulation can involve both sequence variations and expression of regulators. By exploiting the modularity of genetic regulatory systems, it reveals regulatory relationships that are indiscernible when

genes are considered in isolation, allowing the recovery of intricate combinatorial regulation. By incorporating both expression and genotype of regulators, Geronemo captures cases where the effect of sequence variation on its targets is indirect. The results suggest that a significant part of individual variation of expression in yeast arises from the evolution of a small number of chromatin structure modifiers (Lee S-I et al 2006 Proc Natl Acad Sci USA 103:14062).

Time-series microarray expression experiments can provide dynamic information about the expression of thousands of genes that are activated or repressed in response to stimuli such as environmental stress. Transcriptional modules, subsets of transcription

factors (TF) and genes, such that genes in the same module tend to be similarly expressed and regulated by the same TFs across a number of experimental conditions. Integrated chromatin immunoprecipitation (ChIP-chip) data with expression data can identify active motifs and combinations of motifs and target genes under certain conditions. A computational method integrates the time-series expression data and ChIP-chip or motif information to infer an annotated *global* temporal map. This map describes the main transcriptional regulatory events leading to the observed time-series expression patterns and the factors controlling these events during a cell's response to stimuli (Ernst J et al 2007 Mol Systems Biol 3:74).

Mechanisms exist for signaling pathways that share components to respond specifically to any one stimulus. One of these mechanisms is insulation, i.e., the shared component(s) are relegated into distinct and specific macromolecular complexes or to different subcellular complexes. Another mechanism can be mutual inhibition to eliminate unwanted interactions between the pathways. These mechanisms can maintain the identity and specificity of different signaling pathways despite shared components (McClellan MN et al 2007 Nature Genet 39:409).

Genetic Nomenclature: ►gene symbols, ►databases, ►Genew; http://www.mblogic.net/point_of_view/1/.

Genetic Polymorphism: Gene loci (or chromosomal arrangements, organelles) in a population are represented by more than one (allelic) form. ►allele

Genetic Predisposition: Genetic predisposition implies that the genetic constitution is favorable for the development of a disease or anomaly.

Genetic Privacy: The right of an individual to keep his/her genetic record closed to the public. There are two aspects of this right: protection from discrimination by employers, insurance companies, etc.; and its possible hinderance of research on genetic disorders and development of new drugs. In the USA, law now recognizes “protected medical information.” ►genetic testing, ►wrongful life, ►ethics, ►privacy rules; Hall MA, Rich SS 2000 Am J Hum Genet 66:293; Skene L 2002 Trends Mol Med 8:48; Roche PA, Annas GJ 2001 Nature Rev Genet 2:392.

Genetic Profile: Electrophoretic pattern of microsatellites, restriction fragments, PCR products, etc. The purpose of the procedures is to detect potential health risks. It requires consent by the individuals or parents unless state law mandates screening. It should not violate privacy and should not be used for any kind of discrimination. ►electrophoresis, ►RFLP, ►PCR, ►genetic screening; Almond B 2006 Nature Rev Genet 7:67.

Genetic Recombination: ►recombination, ►recombination frequency, ►crossing over, ►bacterial recombination frequency, ►intragenic recombination, ►mapping genetic, ►illegitimate recombination, ►unequal crossing over, ►site-specific recombination, ►sister chromatid exchange, ►recombination variations of, ►recombination molecular mechanism prokaryotes, ►mtDNA, ►mitochondrial genetics, ►chloroplast genetics, ►recombination mechanisms eukaryotes, ►recombination models, ►gene conversion, ►targeting genes, ►homologous recombination, ►bacterial recombination frequency

Genetic Repair: ►DNA repair

Genetic Risk: The chance that an offspring will be affected by a hereditary defect. The risk can be inferred from the heritability of a particular gene or gene complex in a population. In case of simple Mendelian inheritance, for example in cystic fibrosis, in some Caucasian populations in genetic equilibrium, the frequency of this anomaly is $\approx 1/2,000 = 0.0005$. Thus, the frequency of the recessive allele is $\sqrt{0.0005} \approx 0.022 = q$. At genetic equilibrium, the frequency of carriers (heterozygotes) is $H = 2pq = 2 \times (1 - q) \times q = 0.043 = 1/23$. If a person heterozygous for such a deleterious gene ($q = 0.5$) marries a spouse by random choice ($q = 0.022$), the chance that they will have an afflicted offspring is $0.5 \times 0.022 = 0.011$, i.e., approximately $1/91$. If the same heterozygous person marries a first cousin who may have a 0.25 chance carrying the same allele, the probability that they will have an afflicted child may be as high as $0.5 \times 0.25 = 0.125$, i.e., $1/8$. If, however, an average Caucasian will have an offspring with an average Japanese spouse ($q = 0.004$) the probability that their child

would be afflicted by cystic fibrosis is only $0.022 \times 0.004 = 0.000088$ or $1/11,363$. The genetic risk will slowly rise with the application of medical care that compensates for the hereditary defects, e.g., administration of insulin to diabetics or by the use of gene therapy without replacing the defective gene(s). The remedial treatments will not much affect the incidence of rare diseases in the shorter term. If the incidence of a dominant human anomaly is 1×10^{-5} at the present, it may take 3,000 years (100 generations) to increase its prevalence to 1×10^{-3} . The incidence of recessive anomalies will rise at a much slower rate because the alleles are already sheltered from selection in the heterozygotes. The genetic risk can now be estimated with good precision if molecular information is available on the nucleotide sequences of a gene. E.g., in familial hypercholesterolemia in the gene encoding cardiac β -myosin, a substitution of Glu for Gly at position 256 involves only 0.56 chance for the penetrance of the disease, whereas a Gln \rightarrow Arg change at position 403 predicts a 100% penetrance and thus sudden death. ►genetic load, ►genetic counseling, ►empirical risk, ►risk, ►genotypic risk ratio, ►Hardy-Weinberg theorem, ►allelic frequencies, ►amniocentesis, ►clinical tests for heterozygosity, ►mutation rate, ►genetic screening, ►prenatal tests, ►transgenic, ►selection–medical care; Falconer DS 1965 *Ann Hum Genet* 29:51; Coulson AS et al 2001 *Methods Inf Med* 40(4):315.

Genetic Scanning: ►genotyping

Genetic Screening: This type of screening is applied to an asymptomatic population as (i) *prenatal tests* during pregnancy such as for mucopolysaccharidosis, muscular dystrophy, cytological tests for Down syndrome and fragile X conditions, ultrasound test for developmental anomalies, blood groups (Rh), and infections (syphilis, toxoplasmosis, cytomegalovirus). These tests may be mandated or voluntary. Screening of (ii) *newborns* aims to reveal whether they are afflicted by autosomal recessive disorders that require immediate medical attention to prevent severe later consequences. Most frequently the tests include biotinidase deficiency, congenital hypothyroidism, galactosemia, hereditary tyrosinemia, homocystinuria, maple syrup urine disease, phenylketonuria, and sickle-cell anemia. Law in the USA mandates some of these tests. Congenital adrenal hyperplasia, cystic fibrosis, hyperphenylalaninemia, arginosuccinase deficiency, galactokinase deficiency, phosphoglucomutase deficiency, homocystinuria, glucose-6-phosphate dehydrogenase deficiency and others (altogether more than 1000 diseases) may also be involved. The frequency of the genetic defects may vary in different ethnic groups and some of the tests are limited to families

where history provides clues to potential risk. The tests may be performed on blood withdrawn from the neonates by specialized laboratories using standard and reliable procedures such as ELISA, enzyme assays, immuno assays, Guthrie test and DNA tests, radioimmune assays, high-performance liquid chromatography, tandem mass spectrometry, cytological tests, etc. (iii) *Carrier testing* detects heterozygotes for “recessive” disorders in order to facilitate informed decisions by prospective parents regarding risks, especially in populations where the frequency of the deleterious genes is expected to be high, as in the cases of Tay-Sachs disease among Ashkenazi Jews (0.02), thalassemia in people of Mediterranean ethnicity occurring at frequencies exceeding 0.1 in high malaria areas, and cystic fibrosis with variable (generally about 0.02) frequency but much higher in ethnic populations with high degree of consanguinity. About 70% of those afflicted by cystic fibrosis had a CTT (Phe) deletion of codon 508 in exon 10 ($\Delta F508$). This assay is not yet used widely. (iv) *Presymptomatic* and susceptibility screening may be applied to younger individuals with liability to late onset genetic anomalies such as autosomal polycystic kidney disease, Charcot-Marie-Tooth disease, Huntington chorea, familial hypercholesterolemia, retinitis pigmentosa. Some tests predict susceptibility to diabetes mellitus, coronary heart disease, breast cancer, etc. In some countries, predictive premarital testing is mandated for some diseases. Some tests, e.g., Factor V Leiden (parahemophilia, 1q23, heterozygosity for the deficiency is in the range of 10^{-3} , homozygosity 10^{-6}) may involve venous thrombosis for women taking oral contraceptives and the test is not recommended (Grody WW et al 2001 *Genet Med* 3:139).

Testing for predispositions must require confidentiality because of the obvious relevance to finding jobs or health insurance. Genetic screening of individuals who do not have a family history of disorder may involve psychosocial and ethical issues. It is important that screening be conducted only for essential diseases or pre-disposition, for conditions that are medically treatable and for which, informed choices are available in case the test proves positive. Appropriate and safe procedure should be available, the test should not be objectionable to the population in general, and should be acceptable by the subjects. Genetic screening raises several ethical question regarding the right or advisability of withholding information, disclosure of the information to members of the family, what is the right to know or not to know by whom, and storage, safe-keep, and release of the information. (See terms used under specific entries, ►prenatal diagnosis, ►GMS, ►RDA, ►polymerase chain reaction, ►tandem mass

Genetic Segregation: ►Mendelian segregation, ►modified segregation ratios, ►meiosis, ►preferential segregation, ►somatic segregation

Genetic Sexing Lines: Mechanical separation of insects by sex is often very difficult or nearly impossible at larger scale although this may be required for control by genetic sterilization. By genetic engineering, strains can be developed where under defined conditions, either the female or the male individuals can be selectively eliminated upon induction. ►sex-ing, ►autosexing, ►genetic sterilization; Robinson AS, Franz G 2000 In: Handler AM, James AJ (eds) Insect Transgenesis: Methods and Applications, CRC Press, Boca Raton, FL, p 307.

Genetic Similarity Index: The genetic similarity index expresses the similarities between different strains on the basis of the number of shared restriction fragments, identified by probes such as DNA minisatellite sequences, etc. ►minisatellite, ►microsatellite, ►probe, ►genetic distance

Genetic Stability: Genetic stability is good if the gene and chromosomal mutabilities are relatively rare, transposable elements are absent, and the population is in genetic equilibrium. ►mutability, ►genetic equilibrium, ►transposable elements, ►genetic homeostasis; Li SL, Rédei GP 1969 Theor Appl Genet 39:68.

Genetic Sterilization (sterile insect technique, SIT): In genetic sterilization, heavy doses of ionizing radiation (X-rays) break the chromosomes but do not necessarily kill the irradiated animals that are even capable of mating. However, because of the chromosomal rearrangements that follow, sterility or lethality may occur in their progeny, or, although the irradiated males may copulate, they cannot fertilize the eggs of the females and leave no offspring. This basic genetic knowledge was successfully applied to insect eradication. The screwworm (*Cochliomya hominivorax*), a tropical and subtropical parasite of warm-blooded animals, produces larvae that hatch in the wounds of livestock and cause great damage to the hide, making it inferior for the leather industry. Additional damage

results to agriculture by weight loss in cattle, sheep, and game; further, the fly may pose hazards even to people. The chemical control of this insect is difficult to achieve in live animals and not without danger of causing pollution and damaging health. Therefore, pupae were reared in a large laboratory and treated with about 7,500 R X-radiation, and every week two million irradiated males were released in the heavily-infested areas. The monogamous females so mated either failed to produce offspring, or more sophisticated chromosomal constructs were used to generate “genetic time bombs” (recurring genetic defects) that kept on killing the offspring due to chromosomal or genic defects (temperature-sensitive alleles).

In some areas and some years, this pest control was so effective that the screwworm population was reduced to 1% of that before the initiation of the program. A similar procedure was successfully applied for mosquito control as well. Particularly good results were observed in the control of lepidopteran insects with holocentric chromosomes where the delayed and sustained lethal effects could be best exploited.

Constructing a conditional lethal dominant genetic system may cause death without irradiation. The insect becomes lethal when specific conditions are met. In one construct designed in a *Drosophila* model, a tetracycline-repressible transactivator (tTa) protein was placed under the control of the Yp3 fat-body gene promoter. In the absence of tetracycline, any gene controlled by a tetracycline-responsive element (tRe) is normally expressed in the females. On a culture medium containing as low as 0.1 µg/mL tetracycline, females produced no progeny because the tTa prevented the synthesis of fat body (a yolk protein) that is required for storage of nutrients and for the insect immune system. The progeny of the males was not affected because they do not produce eggs and do not need fat body for fertility. In a similar manner, a mutant allele of the *male-specific lethal 2* gene (*msl-2^{NOPU}*), selectively killed the females by activating the dosage compensation mechanism in both males and females. By the same principles, insect-mediated (insect vector) human viral (Dengue fever, West Nile fever, Yellow fever), bacterial (Plague, Typhus, Lyme disease), protozoan (Malaria, Leishmaniasis, Sleeping sickness, Chagas disease), and worms-inflicted diseases (River blindness, Filariasis) may be controlled. With the increased knowledge of genetic transformation and the availability of various transposable elements, new approaches may open up in insect control. ►holocentric chromosomes, ►translocations, ►radiation effects, ►GSM, ►SIT, ►tetracycline, ►TetR, ►tTA, ►rtTA, ►sex determination, ►msl, ►high-dose/refuge strategy, ►refractory genes; Thomas DD et al 2000 Science 287:2474; Robinson AS 2002

Genetic Surgery: Genetic surgery replaces single or a few (defective) genes of an organism with the aid of (plasmid) vectors or introducing into cells foreign genetic material (organelles, chromosomes) with microsyringes or microcapillaries controlled by micro-manipulators under microscopes. ►gene replacement, ►gene therapy, ►genetic engineering, ►gene transfer by microinjection, ►targeting genes, ►transformation genetic

Genetic Switch: Mechanisms to turn genes on and off, based on interaction between specific DNA and protein sequences. ►regulation of gene activity, ►DNA binding proteins, ►DNA-binding protein domains, ►immunoglobulins, ►transposition, ►mating type determination in yeast, ►phase variation, ►Trypanosomas, ►Borrelia, ►serotype

Genetic Systems: Primarily the prevalent mode of reproduction (selfing, inbreeding, random mating, assortative mating, etc.). Generally, the mechanisms affecting variability (recombination, mutational mechanisms, etc.) are also included in this term. ►mating systems

Genetic Testing: Genetic testing may reveal the liabilities of an individual to certain diseases and genetic anomalies. The purpose of the tests can be diagnosis and/or risk assessment for symptomatic and asymptomatic cases, population screening, and reproductive decision-making. The test may consider family histories and environmental factors. Identification of carriers may be of particular importance for reproductive counseling. The results may aid prevention an/or treatment. Genetic information may facilitate the proper selection of drugs; e.g., mercaptopurine must be avoided for leukemia patients, and those deficient in thiopurinemethyl transferase. Cytogenetic, biochemical/pharmacogenetics and molecular tests can be used. DNA sequencing identifies alterations within genes, although heterozygotes may not necessarily bear a direct burden or risk. Microarray hybridization may also reveal genetic defects, although the tests are more expensive and the results may be ambiguous in case of heterozygosity of the diploid cells. Single strand conformation polymorphism and denaturing gradient gel electrophoresis are also applicable techniques. An individual may benefit from it because glucose-6-phosphate dehydrogenase deficiency may make a person more susceptible to

environmental oxidants (ozone, nitrogen dioxide). Thalassemias may increase the dangers of exposure to lead and benzene, porphyrias to chloroquine and barbiturates, pseudocholinesterase deficiency to organophosphate and insecticides, and so on. Molecular tests may reveal non-symptomatic heterozygosity for genetic diseases and may predict the risk for various disorders in the offspring. On the other hand, employers and health insurance companies may discriminate against individuals on the basis of genetic records. Genetic testing may not be applicable for the identification of certain anomalies or diseases, and the results of the tests for some conditions may not accurately predict the onset of a disease. With the approval of the Genetics and Insurance Committee of the United Kingdom, private health insurance companies in the UK already use seven tests for mutant alleles for the early onset Alzheimer disease, breast cancer, familial adenomatous polyposis coli, Huntington disease, and three other monogenic diseases. Those who are positive are obligated to pay higher premiums to obtain life insurance over £100,000 and have mortgage insurance. An extensive public welfare and healthcare system is available in the UK. Nevertheless, the ethical aspects of such a policy of insurance have been questioned. It must be recognized that genetic tests may not yet provide the wished answers to all health problems (Khoury MJ et al 2000 Genet Med 2:198), although 1,100 genetic tests had become available by 2007. Non-communication to patients of genetic risks may have legal liability to the physician or to the counselor (J. Clin. Oncology 21:2397 [2003]). Direct genetic testing of consumers (DTC) requires caution, and must not be considered without adequate context or counseling because some tests from laboratories of dubious quality mislead through unproven claims of benefit. In the USA, only about half of the states permit it (Hudson K et al 2007 Am J Hum Genet 81:635). ►genetic privacy, ►genetic screening, ►prenatal diagnosis, ►compliant mutation, ►refractory mutation, ►DNA sequencing, ►microarray hybridization, ►conversion, Yan H et al 2000 Science 289:1890; Cutler DJ et al 2001 Genome Res 11:1913; regulatory problems in genetic tests: Burke W, Zimmern RL 2004 Nature Rev Genet 5:955, <http://www4.od.nih.gov/oba/>, www.genetests.org, <http://www.geneclinics.org>.

Genetic Toxicology: ►gene-tox

Genetic Transfer: A genetic transfer may be mediated by the gametes during sexual reproduction, by cytoplasmic organelles, plasmids, episomes, infectious heredity, bacteriophages (transduction) or plasmids, fusion of somatic cells, transfer of isolated organelles,

transformation, vectors, viruses, retroviruses, prions, microinjection, electroporesis, and targeting genes.

Genetic Transformation: ►transformation genetic, ►transformation oncogenic, ►transfection

Genetic Transfusion: Transfer of organelles and cellular inclusions by protoplast fusion.

Genetic Translation: ►protein synthesis, ►regulation of gene activity

Genetic Tumors: More than two dozens tumor genes have been assigned to *Drosophila melanogaster* chromosomes 1, 2, and 3. The majority of these are not malignant and occur freely or attached to internal organs in the thorax and in the abdomen.

They are distinguished already at the third instar larva stage and persist through the life of the individuals. Most of the tumors become melanotic. The melanotic tumors determined by genes *mbn* and *Tum* have malignant characteristics. In several inbred mice strains, ovary tumors, testis tumors, B cell lymphoma, kidney adenocarcinoma, leukemia, and pulmonary tumors are under polygenic control. *Bilateral retinoblastoma* (tumor of the eyes) of humans is controlled by a dominant gene. Deficiencies involving the long arm of chromosome 13 may also induce retinoblastoma. Genes involved in the skin disease, *xeroderma pigmentosum*, is based on deficiency in the genetic repair mechanism. Initially the disease involves excessive freckle formation and may become tumorous. Exposure to ultraviolet light (sunlight) enhances the formation of skin tumors, particularly in fair skinned and albino individuals.

About 5–10% of human cancers (hereditary or sporadic) show definite genetic components. Cancer cells commonly display hypermethylation of promoter CpG islands and demethylation of the rest of the genome. The incidence of leukemia may increase in cases of trisomy or partial deficiency for chromosome 21. Both DNA (SV40, adenovirus, bovine papilloma virus, etc.) and RNA viruses (Epstein-Barr virus, retroviruses) can cause tumorigenesis in mammals. The loss or mutation in a gene controlling protein p53 may lead to tumorigenesis presumably due to lack of function of this suppressor gene. Genetic hybrids between the species of the platyfishes (*Xiphophorus*) are prone to develop melanoma. Approximately 30 species-crosses of tobaccos may produce tumorous offspring that form callus in vitro cultures without a requirement for phytohormones (see Fig. G31). In the *Nicotiana glauca* (2n = 24) × *N. langsdorffii* (2n = 18) hybrids, more than one locus is involved in tumor development. In the hybrids of *N. longiflora* (2n = 20) × *N. tabacum* (2n = 48), one chromosomal segment

Figure G31. Genetic tumors of interspecific tobacco hybrids. (Courtesy of Dr. H.H. Smith)

appears responsible for tumorigenesis. *N. saunderae* may inhibit the expression of tumors. In the majority of dicotyledonous and some monocotyledonous plants, agrobacterial infection and the insertion of the T-DNA of the Ti plasmid may lead to tumor formation by genetic transformation. Certain viral infections also result in tumorous growth in plants. Several insects stimulate the formation of gall tumors in plant tissues through their metabolic products. For the in vitro development of plant tumors, the additions of phytohormones (primarily natural or synthetic auxins) are required. Some cultures, however, become “habituated” after a course of culture and the exogenous auxin supply may no longer be required. The plant tumors are non-malignant. ►cancer, ►tumor, ►Knudson’s two-mutation theory of cancer, ►tumor suppressor, ►carcinogens, ►SV40, ►adenoviruses, ►retroviruses, ►reverse transcription, ►retinoblastoma, ►*Agrobacterium*; Purello M et al 2001; Oncogene 20:4877; Suhardja A et al 2001 J Neurooncol 52:195; Esteller M et al 2001 Hum Mol Genet 10:3001; Smith HH 1973 Brookhaven Symp 25:309.

Genetic Vaccine: ►immunization genetic

Genetic Variability: The ability or proneness (proclivity) to hereditary change. ►mutation, ►mutator genes, ►transposable elements, ►homeostasis, ►genetic homeostasis

Genetic Variance: Genetic variance is caused by the various effects of the genotype (V_g). The variance observed is usually the phenotypic variance (V_p) that

is the outcome of the mutual action of the genotype and the environmental variance (V_e). The genetic variance itself has three components: $V_g = V_a + V_d + V_i$, where V_a is the additive genetic variance or breeding value, V_d is the dominance variance, and V_i = interactions. The interactions can be epistatic effects among the individual quantitative traits and the effect of the environment on gene expression. The additive genetic variance may be expressed also as $V_a = 2pq^2(p[1-d] + qd)^2$ where t stands for displacement, The dominance variance $V_d = p^2q^2t^2(d-0.5)^2$. ▶variance, ▶midpoint value, ▶breeding value, ▶polygenes, ▶gain, ▶heritability, ▶displacement, ▶genotypic risk ratio

G

Genetic Variation: Hereditary differences within or between populations. Sequencing the genomes of many prokaryotic and eukaryotic organisms sheds light on earlier unforeseen variations such as SNIPS, minor duplications and deletions, and rearrangements in the chromosomes. For a review of human variations see: Serre D, Hudson TJ 2006 Annu Rev Genomics Hum Genet 7:443, <http://projects.tcag.ca/variation/>.

Genetical Genomics: Genetical genomics dissects regulation of transcription (Jansen RC 2003 Nature Rev Genet 4:145) by analysis of transcript expression pattern by high-throughput procedure (Jansen RC, Nap J 2001 Trends Genet 17:388) and segregation of genomic regions.

Genetically Directed Representational Difference

Analysis (acronym GDRDA): GDRDA targets and identifies traits that differ between congenic lines without prior knowledge concerning their biochemical

function. It determines linkage to known genes or to polymorphic DNA markers. ▶congenic, ▶DNA markers, RDA; Higo K et al 2000 Exp Anim 49[3]189.

Genetically Effective Cells: The cells of the germline that actually contribute to the formation of the gametes and thus to the offspring (see Fig. G32). The number of genetically effective cells can be determined in autogamous species on the basis of the segregation ratios after mutation. In case the genetically effective cell number (GECN) is 1, the segregation is either 3:1 or 1:2:1. If the GECN is 2, the segregation of dominant: recessives is 7:1, in case of GECN = 4, the expected ratio is 15:1 because only one of the cells of the germline segregates while the other cell(s) provide only non-mutant offspring. Thus, the pooled phenotypic numbers yield the 7:1 (4 + 3):1, and 15:1, (4 + 4 + 4 + 3):1 proportions. These ratios may be (slightly) altered if the transmission of the gametes carrying the recessive alleles is impaired, or if the viability of the recessive homozygotes is reduced. For the determination of GECN, the aberrant progenies should be left out of consideration. ▶planning of mutation experiments, ▶critical population size, ▶mutation rate; Rédei GP, Koncz C 1992 In: Koncz C. et al (eds) Methods in Arabidopsis Research, World Scientific, Singapore, p 16).

Figure G33. Geneticin

Genetics: The study of inheritance, variation, and the physical nature and function of the genetic material. William Bateson suggested the term in 1906 for the then entirely new discipline. [Professor Attila T. Szabó called my attention to a paper published in German in Brünn in 1819 (*Oekonomische Neuigkeiten und Verhandlungen* 22, April, p. 169–71) by Hungarian count Imre Festetics and used the expression “die genetische Gesätze der Natur” [the genetic rules of nature] in expounding his studies on heredity of farm animals.]

Genetics may be pursued as a basic science whose goals are only the discovery of new principle(s) and their integration into the store of knowledge. Alternatively, applied branches of genetics rely on established genetic principles and are used for agricultural (plant and animal breeding) or industrial (biotechnology) purposes, or for the improvement of human health (medical genetics). Applications of genetics are expanding into paleontology, archeology, and forensic areas. The tools of genetics are integrated today into all biological disciplines from taxonomy, evolution, cytology, development, behavior, and physiology, to biochemistry, biophysics, and molecular studies. Thus, genetics has escaped from its classical boundaries of heredity and cytology to become the core and unifying element of biology. ►heredity, ►inheritance, ►reversed genetics, ►population genetics, ►human genetics, ►medical genetics, ►clinical genetics, ►quantitative genetics, ►experiments, ►science, ►genetic engineering, ►synthetic genetics, ►criticism on genetics, ►GMO

Genetics and Privacy: The rapidly-accumulating information on risks based on various screening techniques and DNA sequencing may result in discrimination by insurance companies, potential

employers, and possibly by society in general. Therefore, there is considerable concern that such information not be divulged without the consent of the individual and the privacy be legally protected. ►bioethics, ►genetic privacy; Annas GJ 2001 *N Engl J Med* 345(5):385.

Genetics, Chronology of: A very broad overview includes only the most important milestones of basic genetics compiled somewhat subjectively. Paraphrasing GB Shaw, who would dare to say who is greater than Shakespeare? To keep the length minimal, applied aspects of genetics are not included. (See Rédei GP 1974 *Biol Zbl* 93:385; chronology of medical genetics through the career of a man: Victor McKusick 2006 *Annu Rev Genomics Hum Genet* 7:1).

200–300 B.C. Greek Philosophers discuss heredity

1694 Camerarius recognizes sex in plants

1761 Kölreuter reports thousands of attempted and (some) successful plant hybridizations

1839 Schleiden (plants) and Schwann (animals) discover cellular organization

1865 Mendel recognizes the basic principles of inheritance

1866 Haeckel points out the role of the nucleus in heredity

1869 Galton lays down the foundations of statistics-based inheritance

1871 Miescher reports about nuclein

1873-on Mitosis, meiosis, chromosome numbers, supremacy and continuity of chromosomes are recognized

1900 Mendel's work is rediscovered

1902 Sutton proposes the chromosomal theory of inheritance

1902 Benda recognizes mitochondria

1902 Garrod reports on alkaptonuria as an inherited biochemical trait

1906 Bateson suggests the term genetics

1909 Johannsen coins the terms gene, genotype, phenotype, and explains pure lines

1909 Correns and Baur discover non-Mendelian inheritance of chloroplasts

1910–11 Morgan discovers sex-linkage and crossing over

1910 von Dungern and Hirschfeld show that blood groups are inherited

1913 Sturtevant constructs the first linear map of 6 genes of the *Drosophila* X chromosome

1913–1925 Bridges and Sturtevant discover deficiency, nondisjunction, duplication, inversion, translocation

1926 Chetverikov and Helena Timoféeff-Ressovskaya found experimental population genetics

1926 D'Hérelle describes bacteriophages

1927 Landsteiner and Levine lay the foundations of immunogenetics

1927 Muller and then Stadler induce mutations by X-rays

1928 Griffiths observes bacterial transformation

1930-on Fisher, Wright, and Haldane, working independently, lay down the foundations of theoretical population genetics

1939-on Delbrück and Luria initiate phage genetics

1940 Beadle and Tatum conduct experiments leading to biochemical genetics and to the gene - polypeptide theory

1944 Auerbach and Robson discover chemical mutagenesis

1944 Avery, MacLeod and McCarty demonstrate that the transforming principle is DNA

1946 Lederberg and Tatum show bacterial recombination

1949 Chargaff discovers the variable base composition and A = T, G = C relations in different DNAs

1951 McClintock discovers transposable elements

1952 Lederberg reports transduction

1953 Watson and Crick construct a valid DNA model

1955 Fraenkel-Conrat and Williams prove that RNA can also be a genetic material

1956 Kornberg shows in vitro replication of DNA

1957 Taylor in plants, and in 1958 Meselson and Stahl show that DNA replication is semi-conservative

1957-on Beginning of the understanding of the machinery of protein synthesis

1960 Marmur and Lane hybridize nucleic acids

1960 Barski makes somatic cell hybrids

1961 Brenner and coworkers explain the nature of the mRNA

1961 Nirenberg and Ochoa laboratories independently demonstrate the nature of the genetic code

1961 Jacob and Monod propose the operon concept

1965 Southerland discovers cAMP and opens the ways into inquiries on signal transduction and transcription factors

1969 Shapiro et al. isolate the *lac* operon

1970 Temin and also Baltimore discover reverse transcription

1970 Khorana synthesizes in vitro a tRNA gene

1971 Danna and Nathans fragment SV40 DNA by a restriction enzyme discovered by Smith and Wilcox in 1970

1972 Transformation by recombinant DNA begins in the Cohen, Berg and Lobban laboratories using plasmid vectors

1977 Development of efficient DNA sequencing by Gilbert's and by Sanger's laboratories

1978 Shortle and Nathans make localized mutagenesis During the late 1970 Prusiner, S.B. isolates

the "scrapie" agent", which turns out to be an unorthodox infectious, hereditary protein, the prion, in violation of the 'nucleic dogma'

1980 Capecchi et al., Ruddle et al. transform mice

1980s Christiane Nüsslein-Volhard and E. Wieschaus based on earlier studies by EB Lewis establish a new approach to developmental genetics.

1981 Schell et al. transform plants by *Agrobacterium*

1981 Cech discovers ribozymes

1983 Varmus, Bishop and others identify c-oncogenes

1985 Mullis et al. develop the PCR procedure

1989 Saiki, Walsh & Erlich initiate microarray type analysis of amplified DNA with immobilized sequence-specific probes

1995-on Sequencing of complete DNA genomes of prokaryotes and also the eukaryote yeast

By 1996 Beginning of the mass identification of the function the sequenced genes. During the 1990s RNAi, microRNA and other small Interfering RNAs have been discovered in *Caenorhabditis*, plants and other organisms by several laboratories.

1999 the almost complete sequence of the 33.4 megabase human chromosome 22 was published by 217 authors. Craig Venter's Celera group, the Berkeley, Canadian and the European Genome Projects publish the first 'complete' sequence of the *Drosophila* genome. The sequencing of the *Arabidopsis* genome (2000) and the human genome (2001) followed this. On Apr. 14, 2003 completion of the Human Genome Project has been announced.

1999 marks the beginning of 'modular cell biology' and the development of genetic and protein networks by Hartwell LH and co-workers, Barabási A-L, Oltvai ZN and other laboratories, culminating in detailed functional networks of lower and higher eukaryotes by the laboratories of Chant, J. in 2003 and Vidal M 2004.

From 1996 on, the interest increased on the proteome, the complete complement of cellular proteins. Their number exceeds that of the genes because of the transcripts can be processed in multiple ways. How cells and organisms function will be fully understood when all genes will be annotated and the understanding of the complex, dynamic interactions within the proteome will unfold during the coming years. (See ENCODE 2007) It is a commonplace to say that genetics progresses at a breath-taking speed. Yet it is hard to give credit to the major current developments because there are so many and they are so intertwined.

During the preceding decades geneticists tried to reveal the function of single *good* genes or of genetically controlled pathways. By the turn of the millennium the field is turning toward synthesis and integration. The goal of the future research is not less than understanding the function of entire organisms

(proteome), including their descent and cooperation. In the coming years we can expect major progress in the understanding of developmental control (epigenetics), the organization and function of the nervous system, evolution, application of gene and cancer gene therapy, in developing more productive and safer agricultural plants and livestock, moving from databases to complex Information Systems. Although genetics is again in a golden age, the excitement may last indefinitely. Yet one must keep in mind the words of the immunologist Peter Medawar: wise people may have expectations but only the fools make predictions. (See Lander ES, Weinberg RA 2000 Science 287:1777).

Genetics, Digital: Digital genetics is the computer modeling of the behavior of virtual genes and their function, interaction, organization, mutation, recombination, and evolution. ►digital genes, ►avidian; Adami C 2006 Nature Rev Genet 7:109.

Genetics of Behavior: ►behavior genetics

Genetics of Cancer: ►cancer, ►genetic tumors, ►cancer gene therapy

Genetics, Public Understanding and Social Needs: In democratic societies public understanding of social and technological developments is of great importance because research and applications are influenced by the collective wisdom of individuals. Individual rights imply responsibilities. Because of rapid progress, it is increasingly more difficult to keep up with the current knowledge. Although newspapers, popular magazines, television, internet and various commercial resources are available for information transfer, the quality and trustworthiness of these resources are quite variable. Genetics knowledge is now available on the advantages and perils of various energy sources (atomic and fossil fuels), polluting industrial and agricultural chemicals (mutagens and carcinogens), drugs and side effects of medications, food processing, additives and food supplements. There is a continuous debate about the advantages and potential perils of genetically modified organisms. In the area of human health, the use of vaccination, microbial resistance to antibiotics, biological weapons, emergence of new pathogens, origin and risks of cancer, the problems of stem cell research, gene therapy, cancer gene therapy, artificial insemination, in vitro fertilization, preimplantation screening, twin studies, incest and inbreeding risks, genetic counseling, genetic testing and screening, hereditary and sporadic diseases and their penetrance and expressivity, pharmacogenetics and human individuality, race and disease prevalence, and concerns about eugenics, privacy, and ethics are areas where sound genetic information may facilitate forming

relatively best opinions. The sequencing and annotation of human and other genomes are expensive for society and citizens must be able to form sound judgments. Genetic principles in forensics, such as fingerprinting, DNA analysis, and testing of blood groups are frequently discussed without adequate information for laymen. There are genetic consequences of the use of various weapon systems (nuclear, chemical, biological, and conventional). Abortion and other means of medical practices too have certain consequences in human evolution. Evolution and its relation to faith and religions are often presented with conflicting views. Obviously, it is impossible to be an expert in the broad field of genetics and its application but there is a large array of condensed information to consult in this book and references cited. Schools (elementary through college or even graduate school) do not have time enough for dealing with all the existing problems and with those yet evolving. The review of Haga SB 2006 Nature Rev Genet 7:223 discusses teaching resources for genetics.

Généthon: Research Center for Genetics and Gene Therapy (Every, France, <http://www.genethon.fr/php/index.php>; <http://www.cephb.fr/ceph-genethon-map.html>).

GeneTide: ►GeneCard

Gene-Tox: Genetic toxicology; study of factors (physical and chemical agents) that are responsible for mutation and cancer or both. ►environmental mutagens, ►carcinogen, ►toxicogenomics, ►comparative toxicogenomics; gene-chemical interactions: <http://ctd.mdibl.org/>; <http://toxnet.nlm.nih.gov>; structure-searchable toxicity database: <http://www.epa.gov/nheerl/dsstox>).

GeneTrek: A method to sequence and annotate a small portion of the large genome to obtain information about its general nature (Liu R et al 2007 Proc Natl Acad Sci USA 104:11844).

GENEW (Human Gene Nomenclature Database): ►genetic nomenclature, ►gene symbols; <http://www.gene.ucl.ac.uk/cgi-bin/nomenclature/searchgenes.pl>.

GeneWise: GeneWise compares genomic and protein sequences. ►gene; Birney E et al 2004 Genome Res 14:988; www.sanger.ac.uk/Software/Wise2/.

Genic Balance: The proportion of the sex chromosomes and autosomes has a crucial role in sex determination in some organisms (e.g., *Drosophila*). In *Drosophila* (1 X):(2 sets of auto-somes) means male, whereas (2X):(2 set of autosomes) = females (1:1). In general, all individuals with chromosomal ratios above 1 are females and those between 0.5 and <1 are inter-sexes.

In humans and mice, the XO is female while in *Drosophila* XO is male. In trisomics and nullisomics, the nature of the individual chromosome(s) present or absent makes a great difference in the phenotype.

►sex determination, ►trisomy, ►nullisomic, ►nullisomic compensation

Geniculate Body (geniculate nucleus): A knee-like structure in the brain where optic and auditory fibers are received.

Genie: A gene predictor program. ►GENSCAN, ►FGENE, ►MZEF; Reese MG et al 2000 Genome Res 10:529.

G

Genistein (4,5,7-trihydroxyflavone): A phytoestrogen (common in soybean products), an inhibitor of protein tyrosine kinases and frequently used for probing signal transduction pathways. ►leukemia BCP; X-ray crystallography: Manas ES et al 2004 Structure 12:2197.

Genital Anomaly Syndromes: In males, these syndromes may involve hypospadias or cryptorchidism or micropenis. In hypospadias the urethra may open at the lower side of the penis or between the anus and the scrotum. Cryptorchidism indicates that the testes do not descend from the abdominal cavity into the scrotum (the testicular bag). In females, commonly either the ovaries, uterus, or the fallopian tubes (connecting the ovaries with the uterus), or the vagina fail to develop normally, and clitoromegaly and fusion of the labia occur. ►hermaphroditism, ►pseudohermaphroditism, ►gonadal dysgenesis, ►Smith-Lemli-Opitz syndrome, ►Opitz syndrome, ►Wilms tumors, ►Robinow syndrome, ►Fraser syndrome, ►Wolf-Hirsch-horn syndrome, ►Bardet-Biedel syndrome, ►adrenal hyperplasia, ►trisomy, ►testicular feminization

Genius: According to the Latin meaning of the word, a genius is a guarding spirit influencing a person for better or worse. CD Darlington (1964) defined it as a person who “changes the environment of others for his own and even for succeeding generations, for his own species and even for the whole living world.” Francis Galton in his book *Hereditary Genius* (1869) came to the conclusion that eminence is biologically inherited. Darlington had a less asserting view “the sons of great men are given the best chances with the worst results”. Human intelligence cannot be exempted from the general biological laws (offspring-parent regression), although environment has great influence on the development of hereditary qualities. A good example is Marie Curie Skłodowska who became the first woman who received, along with her husband Pierre, the Nobel Prize for physics in 1903 (see Fig. G34). She received her second Nobel Prize

in 1911 for chemistry. In 1935, their daughter Irene and her husband Frédéric Joliot received the Nobel Prize for chemistry, and this indicated the roles of inheritance and assortative mating on the manifestation of a genius.

Figure G34. Marie Curie Skłodowska

Albert Einstein, probably the most influential physicist in history, was a slow child (suspected to be dyslexic) and neither of his two sons matched their father although, in his words, their mother Mileva was comparable to her husband in intellectual abilities (see Fig. G35). Actually the younger son, Eduard, an aspiring psychologist died in an asylum as a schizophrenic. His brother Hans Albert became a hydraulic engineering professor. An extensive study of Nobel-laureate and literary prize-winner families suggest that outstanding creativity is not much biologically inherited rather it may be influenced primarily by the same-sex parent (Rothenberg A, Wyshak G 2004 Can J Psychiatry 49(3):185). ►human intelligence, ►musical talent; Andreasen NC 2005 *The Creating Brain: The Neuroscience of Genius*, Dana Press, New York.

Figure G35. Mileva and Albert Einstein wedding picture (Courtesy of Joachim Reinhardt, University of Frankfurt, Germany)

Genmap: A computer program for mapping genetic data based on least squares. ►least squares

Genocopy: A genetically determined phenotype that imitates or resembles a similar phenotype, which is controlled by another gene. ►phenocopy

Genomatron: A gene-mapping machine.

Genome: A complete single set of genes of an organism (taxonomic unit) or organelle, also the basic haploid chromosome set. The size of genomes, in rounded nucleotide numbers, varies in the different taxonomic categories (See tabulation below).

The average genome size of birds is almost 1/3 that of mammals, mainly because the avian introns are shorter. Endosymbionts usually reduce the size of

their genomes during evolution. The nucleomorph of the chlorarachniophyte protist *Bigelowiella natans* is composed of only 373,000 bp representing the smallest eukaryotic nuclear genome. It has three chromosomes, 331 genes, and several very short introns in this endosymbiont within the chloroplast (Gilson PR et al 2006 Proc Natl Acad Sci USA 103:9566). The larger plant genomes contain many LTR retrotransposon families with >10,000 copies per haploid genome, whereas the smaller genomes contain few or no LTR retrotransposon families with >1,000 copies, suggesting that this differential potential for retroelement amplification is a primary

factor in angiosperm genome size variation. Besides amplification of transposable elements, ejection of redundant copies by unequal homologous recombination and nonhomologous recombination determine the actual, extant genome size (Vitte C, Bennetzen JL 2006 Proc Natl Acad Sci USA 103:17638). ▶**mtDNA**, ▶**chloroplasts**, ▶**nucleomorph**, ▶**endosymbiont**, plants: Bennett MD, Leitch IJ 1995 Ann Bot 76:113; bacterial genomes: Casjens S 1998 Annu Rev Genet 32:307; Genetica Vol 115: issue 1 (2002); ▶**minimal genome size**, ▶**C value paradox**, ▶**human genome**, ▶**gene numbers**, ▶**Map Viewer**, ▶**genome sizes**; <http://www.cbs.dtu.dk/data/bases/DOGS/>; ▶**animal genome size**; <http://www.genomesize.com/search.php>; <http://www.ensembl.org/index.html>; number and organismal genomes sequenced and sequencing underway: <http://www.genomesonline.org/>.

Genome Analysis: Initially, genome analysis meant determining the origin of the component genomes in allopolyploid species on the basis of chromosome pairing, univalent(s) and multivalent associations, chiasma frequencies, chromosome substitution, chromosome morphology, chromosome banding, and hemizygous ineffective alleles. Today, it is used more generally for studying DNA base sequences, microsatellites, etc. (See terms under separate entries, genome elements such as ▶**intron splice sites**, ▶**3' untranslated regions**, ▶**promoters**, and ▶**cis-regulatory elements**, novel methods for predicting DNase I hypersensitive sites, for predicting noncoding RNA genes, including microRNA genes and their targets: Jones SM 2006 Annu Rev Genomics Hum Genet 7:315).

Genome Annotation: Identification of nucleotide sequences to reveal their function. ▶**annotation**; Stein L 2001 Nature Rev Genet 2:P493; Devos D, Valencia A 2001 Trends Genet 17:429; Zhang MQ 2002 Nature Rev Genet 3:698; Miller W et al 2004 Annu Rev Genomics Hum Genet 5:15.

Genome Bioinformatics (<http://genome.ucsc.edu/>): Genome bioinformatics carries information on human, *Caenorhabditis elegans* and *C. briggsae*, mouse, rat, zebrafish, yeast, and SARS genomes, including news and updates.

Genome Conservation: Genome conservation analyses the sequence and gene content among organisms and thus provide a reliable view on phylogenesis. ▶**phylogeny**; Kunin V et al 2005 Nucleic Acids Res 33:616.

Genome Database: ▶**Map Viewer**; human: <http://gdbwww.gdb.org>; integrated microbial genomes: <http://img.jgi.doe.gov/cgi-bin/pub/main.cgi>; genome databases of 468 organisms: <http://pedant.gsf.de>.

Genome Domain: Histone modifications, transcription pattern, and DNA replication timing can define discrete active and repressed functional domains ranging from 20 kb to 1 Mb in size within the human genome (ENCODE). Active and repressed domains differ markedly from one another with respect to annotated genomic features including gene content, CpG islands, the spectrum of repetitive elements, and the density of conserved nonexonic sequences (Thurman RE et al 2007 Genome Res 17:917). ▶**domain**, ▶**ENCODE**

Genome Equivalent: In a genome equivalent, the mass of the DNA/RNA is the same as that of a genome.

Genome Evolution: Evolution may be based on duplication of single genes or duplication of larger chromosomal segments including hundreds of genes. The duplication may be rearranged and modified to fill a need for evolutionary advantage in the particular environment. Exons and to a lesser extent, regulatory sequences, evolve slower than introns, which contain many mutations because generally having little or no function they are not subject to selection pressure. Some of the duplicated copies may also be lost. If an organism becomes a parasite, some of its genes are no longer needed because the host can provide the required function(s). In *Salmonella enterica*, the estimated DNA loss per generation was 0.05 bp but about 50 times higher in mutants defective in repair (MutS). Deletion ranged in size from 1 to 202 kb and were not involved with repeat sequences, indicating that the losses did not depend on RecA-mediated recombination (Nilsson AI et al 2005 Proc Natl Acad Sci USA 102:12112). Within a single bacterial phylum genome, sizes vary by more by an order of magnitude, e.g., 600 kb in *Buchnera aphidicola* to 7,000 kb in *Pseudomonas fluorescense* (Ochman H 2005 Proc Natl Acad Sci USA 102:11959). The sequenced genome of *E. coli* is 4,639,221 but megabase size variations occur in different isolates. The sequenced and annotated genomes of related organisms provide opportunities for analyses of the evolutionary paths. ▶**genome analysis**, ▶**evolution of the karyotype**, ▶**evolution**, ▶**gene evolution**; Dujon B et al 2004 Nature [Lond] 430:35.

Genome Hitchhiking: ▶**überoperon**

Genome Information Broker (GIB): A database for genomics of prokaryotes, fungi, and *Arabidopsis*. ▶**genomics**; <http://gib.genes.nig.ac.jp>.

GenomeInspector: A computer program for assessing distance correlations between large sets of sequence elements, which can be used for the identification and definition of basic patterns of functional units such as

promoters and transcription factors. (See Quandt K et al 1996 Comput Appl Biosci 12:405).

Genome-Linked Viral Protein: ►VPg

Genome Mutation: Genome mutation affects chromosome numbers. ►aneuploid, ►polyploid

Genome Organization: As per genome organization, although genes are situated in a linear order within the chromosomes, temporal and hierarchical spatial arrangement of the genome affects the turning on/off the functions. ►genome, ►chromosome territories, ►transcription factories, ►DNA looping, ►chromatin, ►euchromatin, ►heterochromatin, ►repetitive DNA; Misteli T 2007 Cell 128:787.

Genome Projects: Genome projects are focused on the physical mapping and sequencing of entire genomes of humans and other higher and lower eukaryotes as well as of prokaryotes. Upon completion of these projects, a detailed inventory of all genes will become available. This in turn will facilitate new generalization of organization and function of the cells and will permit the application of the new principles and the new technologies to human economic fields, as well as for preventing and curing diseases. The complete nucleotide sequence of the four genes of the MS2 RNA virus had been determined by 1976, and

by 1995 all the 1749 genes of *Haemophilus influenzae* bacterium had been sequenced. The genome of *Saccharomyces cerevisiae* yeast has also been completely sequenced.

The large eukaryotic genomes such as that of humans, containing about 3 billion bps are ordered first into sequential stretches by the use of overlapping fragments. The first step is breaking up the human chromosomal DNAs (average of 250 Mb) into 100–2,000 kb fragments and cloned them in YACs. The YACs are cleaved into an average of 40-kb fragments and cloned by cosmids. The contents of the cosmids are then cloned in 5–10-kb capacity double-stranded DNA plasmid vectors or into the single-stranded filamentous phage M13 vector of 1-kb load. The fragments at each step can be tied into contigs by “chromosome walking.” The nucleotide sequences of the smaller clones can be analyzed.

The entire human genome requires a minimum of about 3,000 YAC or 20,000 BAC or 75,000 cosmid or 600,000 plasmid or 3,000,000 M13 phage clones. An alternative approach, the complete sequencing is to proceed from sequence-tagged connectors (STC). The human chromosomes would be cloned in BAC vectors and sequence 300–500 nucleotides at the ends. The 600,000 BAC end sequences represent 10% of the genome and are scattered at

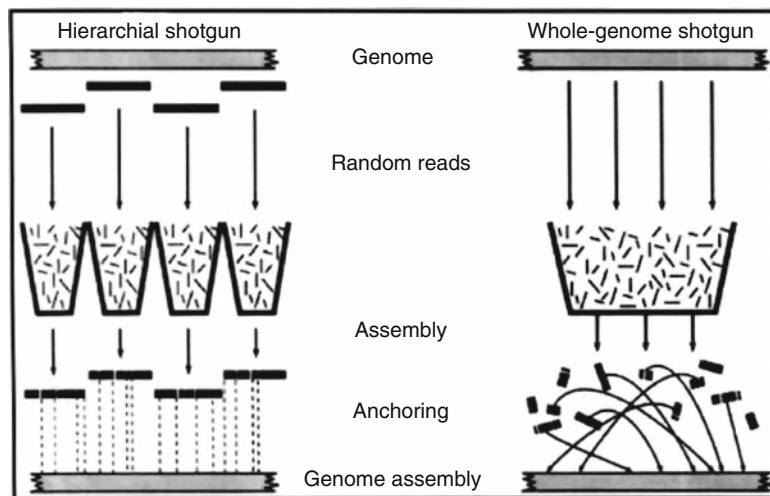

Figure G36. The human genome sequencing projects reported in Feb. 15, 2001 Science 295 and Nature [Lond] Febr. 16, 2001 used two somewhat different sequencing strategies. The *hierarchical shotgun* procedure cut up the genome into BAC clones and arranged them in a somewhat overlapping tiling path. Then after shotgun sequencing reassembled each BAC clone and then merged the sequences of adjacent clones. This had the advantage that all sequence contigs and scaffolds derived from a BAC belong to a single compartment with respect to anchoring to the genome. The *whole genome shotgun* strategy shotgun sequenced the entire genome and then reassembled the entire collection. With this method, each contig and scaffold is an independent component that had to be anchored to the genome. In general many scaffolds might have been difficult to anchor to the genome. (From Robert H. Waterston, Eric S. Lander, and John E. Sulston. 2002 Proceedings of the Natl. Acad. Sci. USA 99:3712-3716. Copyright 2002 National Academy of Sciences USA)

every 5-kb across the genome. They are called *sequence-tagged connectors* because they allow each BAC clone to be connected to about 30 others (150 kb insert/5 kb \cong 30, Mahairas GG et al 1999 Proc Natl Acad Sci USA 96:9739). The BAC inserts are digested by a restriction enzyme to determine their size. The sequencing templates have pUC18 based plasmids with \sim 2-kbp templates. A “seed” BAC is sequenced and checked. A “seed” BAC is sequenced and checked against the data of sequence-tagged connectors to identify the overlapping clones.

G

In a following step, two BACs that show internal homology by the restriction enzyme digests and minimal overlap at their end are completely sequenced. By such a procedure the entire human genome could be sequenced in 20,000 clones. The advantage of this proposal (Venter JC Smit HO, Hood L 1996 Nature 381:364) is that some of the low-resolution mapping (YAC and cosmid steps) could be eliminated and automatic sequencing procedures could be applied, reducing cost and labors. Many groups worldwide could do the BAC clone sequencing. The already known sequence-tagged sites (STS) and expressed sequence tags (EST) could be readily located and additional genes could be easier placed. The procedure suggested would greatly facilitate the sequencing other smaller genomes of interest. The Perkin-Elmer Corporation and Craig Venter use very high efficiency DNA sequencing apparatuses (230ABI PRISM 3700) based on capillary electrophoresis (\sim 1,000 samples/day) and robotization and to expedite the process and substantially reduce the cost of sequencing. The completed sequencing information of entire genomes reveals that homologous genes from *Saccharomyces* to *Caenorhabditis*, *Drosophila*, *Homo* and *Arabidopsis* direct the majority, but not all, of cellular functions. Yet the regulation of the functions show differences to account for the differences among these organisms. The number of genes used by the different organisms varies. Apparently and unexpectedly *Arabidopsis* needs about twice as many genes as *Drosophila* and *Caenorhabditis* relies on nearly 45% more genes than *Drosophila*. *Drosophila* has about 700 transcription factors versus 500 in *Caenorhabditis*. Among the fully sequenced microbial genomes, on the average, about 25% of the open reading frames are unique to each organism. Dunham I 2000 in Trends Genet 16:458 tabulates a chronology of the innovations facilitating the realization of the genome projects. For the best understanding of the genome sequences comparative data of many species are very helpful. Unfortunately all species cannot be sequenced because of technical and financial cost. The species to be sequenced are chosen by several criteria: (1) phylogenetic relationships, (2) relevance to human biology,

(3) economic importance, (4) genome size and characteristics, (5) developmental and organizational specialization, (6) consideration for the more ancestral evolutionary forms. Unfortunately there are hard choices and no better criteria in the organismal selection (O’Brian SJ et al 2001 Science 292:21264). By 2006 more than 400 genomes have been sequenced and many other projects are underway. **physical mapping**, **YAC**, **cosmid**, **vectors**, **restriction enzyme**, **DNA sequencing**, **DNA sequencing automated**, **capillary electrophoresis**, **STS**, **EST**, **BAC**, **YAC**, **cosmid**, **DNA chips**, **contigs**, **seeding**, **parking**, **tiling**, **gap**, **finishing**, **clone validation**, **databases**, **shotgun sequencing**, **WGS**, **Gene Ontology**, **sequence-tagged connectors**, **scaffolds in genome sequencing**, **human genome**; Venter JC et al 1998 Science 280:1540; Mullikin JC, McMurray AA 1999 Science 283:1867; Adams MD et al 2000 Science 287:2185; Waterston RH et al 2002 Proc Natl Acad Sci USA 99:3712; Myers EW et al 2002 Proc Natl Acad Sci USA 99:3712; Internet guides to the majority of genome-related databases: Nature Genet 32 suppl. 1–79 [2002]; Birney E et al 2002 Annu Rev Genomics Hum Genet 3:293; Cozzarelli NR 2003 Proc Natl Acad Sci USA 100:3021; theory of species selection criteria for sequencing: McAuliffe JD et al 2005 Proc Natl Acad Sci USA 102:7900). <http://www.ncbi.nlm.nih.gov/genome/guide>; sequencing projects and related resources: <http://www.intlgenome.org/>; <http://compbio.ornl.gov/channel>; published genomes: <http://www.genomesonline.org/>; bacterial genomes: <http://xbase.bham.ac.uk/>; integrated genomes: <http://www.ebi.ac.uk/integr8/EBI-Integr8-HomePage.do?jsessionid=8F34D370D1F714C23FC63A07B65D67D0>.

Genome Reviews: Genome reviews contain information on sequencing and annotation of the majority of organisms: <http://www.ebi.ac.uk/GenomeReviews>.

GeneScan: Gene identification algorithm. Applicable to large genomes, including pertinent protein sequences. **gene prediction**; Yeh RF et al 2001 Genome Res 11:803.

GeneVar: GeneVar program is based on GeneWise and it analyzes an annotated genome, automatically identifies missed gene calls and sequence variants such as genes with disrupted reading frames (split genes) and those with insertions and deletions (indels). **GeneWise**, **base-calling**; Yu GX et al 2007 Nucleic Acids Res 35:3953.

Genome Scanning: Genome scanning comprises of cutting up the genome first by 8-bp-recognizing restriction endonuclease(s) into large fragments, followed by using more-frequent-cutter enzymes to generate physical information on the entire genome.

These fragments can then be used to establish a physical map. ► [physical map](#), ► [restriction enzyme](#), ► [gene finding](#); Rouillard JM et al 2001 *Genome Res* 11:1453; Beekman M et al 2001 *Genet Res* 77:129.

Genome Sequence Database (GSDb): <http://www.ncgr.org>; interrupted sequences in prokaryotes: <http://www-bio3d-igbmc.u-strasbg.fr/ICDS/>.

Genome Sequence Sampling (GSS): In GSS, chromosomal DNA, digested with several restriction enzymes, is cloned into cosmids. Hybridization with YAC clones of the same chromosomal DNA identifies all the cosmids that contain sequences present within the YAC. The cosmids are then broken down into contigs and their ends are identified by hybridization to pure cosmid DNA. The 300–500 bps of the ends are sequenced and aligned in sequence, permitting the generation of a rather high-density physical map.

Genome Size: ► [genome](#), ► [C value paradox](#); Gregory TR 2005 *Nature Rev Genet* 6:699; animals: <http://www.genomesize.com>; C value of plants: <http://www.kew.org/genomesize/homepage.html>; fungi: <http://www.zbi.ce/fungal-genomesize/>; ► [virus](#)

Genome Surveys: Sequences of genomic origin, rather than cDNA (similar to EST); the sequence represented may be interrupted when compared to genomic sequence: <http://www.ncbi.nlm.nih.gov/dbGSS/index.html>; genomic clones and libraries: <http://www.ncbi.nlm.nih.gov/genome/clone>.

Genome Transplantation: ► [mycoplasma](#)

Genome-Defence Model: In the genome-defence model, generally multiple, different transposable elements occur in all organisms and their movements from one chromosomal location to another may bring about rearrangements in the genome. The cell keeps these transpositions in check by methylation of the transposase, and thus restricts deleterious alterations in the genome. (See Miura A et al 2001 *Nature [Lond]* 411:212).

Genomere: A hypothetical subunit of genes, proposed by Eyster WH 1924 *Genetics* 9:372 for explaining the behavior of unstable genes. Demerec M 1935 *Bot Rev* 1:233 has argued against the plausibility of the existence of such particles, and the term has been abandoned. ► [unstable genes](#)

GenomeScan: A gene identification algorithm (Yef R-F et al 2001 *Genome Res* 11:803).

Genometrics: Biometric analysis of chromosomes. ► [biometry](#), ► [genomics](#); Roten C-A H et al 2002 *Nucleic Acids Res* 30:142; http://www.unil.ch/dmf/page14997_en.html.

Genome-Wide Analysis: ► [GWA](#)

Genome-Wide Functional Analysis: In genome-wide functional analysis, in contrast to hitting genes by random mutations, the procedures aim at specific genes by homologous recombination mediated gene replacement. Unfortunately, the efficiency of the latter procedure is quite variable among different organisms. An alternative approach is the use of RNAi (~300 nucleotide long double-stranded precursors), which can be injected, fed, or transferred by the use of plasmids into *Caenorhabditis* or *Drosophila*. In contrast to flies and worms, the introduction of long dsRNA in mammalian cells induces a non-sequence-specific interferon response and shut-down of translation. This response can however be bypassed by the direct introduction of Dicer products of short interfering RNAs.

The SID-1 protein (systemic RNA interference-deficient) of *C. elegans* may greatly facilitate the uptake (Feinberg EH, Hunter CP 2003 *Science* 301:1545). Insertional mutagenesis, degron, peptide aptamer inhibitors, or other function specific tags are also useful. The perturbed genes may be detected by high-throughput optical devices such as automatic microscopes, particle-size counters, reporter genes, fluorescent labels, FRET analysis, and cell sorters. Z-factor determinations may be a useful statistical device to assess the significance of differences of quantitative measurements. ► [RNAi](#), ► [insertional mutation](#), ► [targeting genes](#), ► [degron](#), ► [aptamer](#), ► [synthetic lethal](#), ► [FRET](#), ► [cell sorter](#), ► [Z](#), ► [mutagenesis](#), ► [genetic networks](#), ► [networks](#), ► [small-world networks](#), ► [probabilistic graphical models of cellular networks](#), ► [synthetic genetic array](#), ► [GAIN](#); Carpenter AE, Sabatini DM 2004 *Nature Rev Genet* 5:11; Friedman A, Perrimon N 2004 *Curr Opin Genet Developm* 14:470; technique for use in mouse: Wu S et al 2007 *Nature Genet* 39:922.

Genome-Wide Location Analysis: The genome-wide location analysis or genome-wide binding analysis reveals the genes bound in vivo by transcriptional regulators of the genome. The procedure may be epitope tagging and microarray hybridization. The 2343 promoter regions of the 6270 genes of yeast were found to bind one or more of the 106 transcriptional regulators. On the average, each regulator was found to bind 38 promoter regions. The Abf1 regulator bound 181 promoter sites. The Thi2 activator of thiamine biosynthesis, however, bound only three promoters. 295 combinations of two or more regulators may bind to common sets of promoters, thus regulating yeast genes in response to specific environmental inputs. The regulators may function in a sequential manner in which, one regulator may affect the promoter of a second regulator, which in turn may regulate a third promoter

and so on. Also, by inserting—by homologous recombination—structural genes fused to green fluorescent protein markers, the subcellular location of various proteins and groups of proteins can be determined (Huh W-K et al 2003 Nature [Lond] 425:686). The abundance of individual proteins detected by similar optical means is >50 to 10^6 molecules/yeast cell (Ghaemmaghani S et al 2003 Nature [Lond] 425:737). ▶transcription factors, ▶epitope tagging, ▶microarray hybridization, ▶ABF-1, ▶genetic networks; GAIN; Lee TI et al 2002 Science 298:799; Jorgenson E, Witte JS 2006 Nature Rev Genet 7:885.

G

Genomewise: A program for the analysis of gene structure across cDNA and EST-defined spliced structure; it is suitable for annotation. ▶GeneWise; Birney E et al 2004 Genome Res 14988.

Genomic Clone: A genomic clone is prepared from chromosomal DNA, rather than from cDNA. ▶genomic DNA, ▶cDNA; <http://www.ncbi.nlm.nih.gov/genome/clone>.

Genomic Control: A statistical method for the estimation of population structure in a manner somewhat similar to case-control design or transmission disequilibrium tests. ▶case-control design, ▶transmission disequilibrium test; Bacanu SA et al 2000 Am J Hum Genet 66:1933.

Genomic Disorder: A genetically determined disease caused by deletions, duplications, inversions, translocations, transpositions in chromosomes.

Genomic DNA (gDNA): The native DNA including exons, introns and spacer sequences (versus the processed genes which are transcribed from mRNA to DNA by reverse transcription and have only the coding sequences). ▶processed genes, ▶reverse transcription

Genomic Exclusion: Genomic exclusion takes place in the ciliate *Tetrahymena pyriformis* in case one of the two mates has a defective genome (micronucleus) that is therefore not included in the meiotic progeny. The first progeny becomes heterokaryotic, having only the normal diploid micro-nucleus and an old macronucleus that is genetically not concordant with the micronucleus. After subsequent matings the normal micronucleus forms a macronucleus concordant with its own genetic constitution. As a result the strain is purged from the defect. ▶conjugation *Paramecia*; Cole ES et al 2001 J Eukaryot Microbiol 48(3):266.

Genomic Formulas: n = haploid, $2n$ = diploid, $3n$ = triploid etc. and $n-1$ or $2n-2$ = nullisomic, $2n-1$ monosomic, $2n+1$ = trisomic, $2n+2$ = tetrasomic,

etc., where n = haploid chromosome number. The basic chromosome number, however, is x and the diploids may be $2x = 2n$. ▶polyploids, ▶aneuploids

Genomic Fractionation: ▶RDA

Genomic Hybridization: ▶comparative genomic hybridization

Genomic Library: A set of cloned genomic DNAs; it is expected that a good library includes at least one copy of all the genes of a particular genome. ▶cloning, ▶genome, ▶fragment recovery probability

Genomic Medicine: Genomic medicine studies genetic variations in human populations concerning the genetic bases of disease. It is based on single nucleotide polymorphisms, oligonucleotide microarrays, molecular characterization of drug responses, etc. It uses global genomic information in connection clinical data to assess individual risks and multidimensional analysis for efficient management of disease. It combines predictive, preventive, and personalized medicine. ▶SNIP, ▶drug discovery, ▶medical genetics, needs and some available resources for practicing physicians: Guttmacher AE et al 2007 Nature Rev Genet 8:151.

Genomic Mismatch Scanning: ▶GMS

Genomic Profiling: The detection of concurrent occurrence of multiple generic variations that predispose humans to a particular disease. Identification of such genetic factors may assist in personalized medication and preventive means of health maintenance. The currently suggested commercial procedures have not yet been adequately tested. Although genomic profiling may have significance in the future, at present it is not entirely safe to follow some of the recommendations. (See Haga SB et al 2003 Nature Genet 34:347; <http://www.genovations.com/home/index.html>; <http://www.bankdna.com/>).

Genomic Prospecting: Searching of diverse species (e.g., different mammalian genomes) for DNA sequences, which could alleviate human disease with the aid of gene therapy. ▶gene therapy; O'Brien SJ 1995 Nature Med 1:742.

Genomic Screening: Genomic screening is used for the localization of genetics markers (genes). For *random genomic screening*, usually anonymous polymorphic markers are employed. For *directed genomic screening*, specific polymorphic markers, which have already been located in the vicinity of a targeted gene(s) are suitable. The best markers are easy to recognize, are highly heterozygous, and have established chromosomal location. In human genetics, the Généthon (http://www.genethon.fr/genethon_en.html) map containing more than 5,000 dinucleotide

markers covering the entire genome by ~ 2 cM average spacing is used. Alternatively, the Cooperative Human Linkage Project (CHLC, <http://www.chlc.org>) covers the genome by 3600 tri- and tetranucleotide markers with an average spacing of 1 cM. The Utah Human Genetics Institute (<http://www.genetics.utah.edu/home.html>) has developed tetranucleotide markers at 10–15 cM spacing. These spacings are average and are not evenly distributed. The standard sets of markers are called *mapping sets*. Using lod scores, a value of 3 is considered to be significant. In case when two genes are tested, the lod score probability may be corrected for more accuracy and should be $3 + \log 2 \approx 3.3$, and in case of say 20 genes it should be $3 + \log 20 \approx 4.3$. Sib pair data sets may be evaluated with the aid of the χ^2 procedure and the appropriate degrees of freedom, but general probability may be determined by using $\text{lod} = (\chi^2)/4.605$. ($2\ln 10 \approx 4.605$, and converts the lod scores to χ^2 with 1 degree of freedom. Lod score of 3 corresponds to a P value of 0.001, and $\chi^2 \approx 4.605 \times 3 \approx 13.83$). Jianfeng Xu et al. (1998) present the justification for the very high significance level of 0.001 as follows. If the human genome is 3000 cM and it is divided into sixty 50 cM segments and the studied locus is in one of them, then the chance for the location of this gene is $1/60 \approx 0.02$. In other words, under this assumption, the *a priori* chance of linkage for any single locus is $\sim 2\%$. According to Bayes' theorem, with a lod score of 3, the posterior probability for linkage is about 95%, a conventional limit for level of significance. Usually these linkage data are loaded with false positive results and the best statistical procedures have not been agreed upon or generally accepted. Directed genomic screening may identify *locational candidate regions* where the investigated genetic difference is likely to be situated. As a general rule large relative risk, determined by λ_S is very helpful in locating genes. ►physical mapping, ►mapping, ►minisatellite, ►microsatellite, ►microarrays, ►lod score, ►chi square, ►candidate gene, ► λ_S , ►Bayes' theorem

Genomic Stress: Genomic stress, such as dissimilar genetic backgrounds in hybrids, in vitro cell culture, etc., may activate dormant transposable elements and cause genetic instability. ►transposable elements, ►somaclonal variation

Genomic Subtraction: A method that removes from wild type DNA all the sequences that are present in a deletion mutant, but retains the wild type DNA sequences corresponding to the deletions by denaturing a mixture of wild type and biotinylated mutant DNA. Allowing the mix to reassociate, the biotinylated sequences are subtracted by several repeated cycles of binding to avidin-coated polystyrene beads

(that have great affinity for biotin). The remaining (non-biotinylated) DNA is wild type and contains only the sequences that were deleted in the mutant but present in the wild type. This DNA can then be amplified by PCR and studied by standard techniques of sequencing. This method also permits the isolation of genes affected by the deletion (caused by, e.g., ionizing radiation). ►physical mutagens, ►gene isolation, ►biotinylation, ►avidin, ►PCR, ►DNA sequencing, ►RDA, ►RFLP subtraction, ►subtractive hybridization; Kingsley PD et al 2001 Dev Growth Differ 43(2):133.

Genomic Variation: Genetic variation, chromosomal rearrangements, polyploidy, copy number estimates, and human genome variation: <http://www.sanger.ac.uk/humgen/cnv/data/>.

Genomics: The study of the molecular organization of genomic DNA and physical mapping. *Structural genomics* studies the folds of macromolecules, the three-dimensional shape of biological molecules with the aid of physical instruments (X-ray crystallography, etc.) and bioinformatics, and classifies these molecules into functional families (see Fig. G37).

Figure G37. Identification of gene function

Biochemical genomics studies pools of purified proteins and the corresponding open reading frames (ORF). This is accomplished by generation and expression, e.g., a large set of glutathione-ORF fusion proteins are purified and mapped to a specific ORF and the proteins are further analyzed in subpools (Martzen MR et al 1999 Science 286:1153). *Chemical genomics* studies the effects of small molecules to ascertain their modulating effects on cellular states or on gene expression, preferably in high-throughput systems (Stegmaier K et al 2004 Nature Genet 36:257). The *functional genomics/physiological*

genomics deals with genome-wide functional analyses and integration of structure of the DNA and the molecular function and interaction of genes and gene products (Wu LF et al 2002 *Nature Genet* 31:255; Liang P et al 2002 *Physiol Genomics* 9:15). After the completion of sequencing of the organisms, interest is now turning to the determination of the function(s) of genetics. Such studies can now be conducted with high-throughput procedures (see diagram modified after Ross-Macdonald P et al 1999 *Nature [Lond]* 402:413). These types of methods can identify the function of thousands of ORFs in combination with macroarray analysis. This area of study integrates genetics, molecular biology, biochemistry, pharmacology (*pharmacogenomics*: designing drugs that best fit the genetic constitution of an individual), agriculture, medicine, and other disciplines. In 1996 alone, a half million patents were proposed from the field. *Epigenomics* studies the interaction between proteomes and genomes, global patterns of methylation, and methylation signals, and surveys this type of information in different species. *Comparative genomics/phylogenomics* seeks to determine (i) the number of distinct protein families encoded by different genomes, (ii) the distribution of the coding genes within the genomes and (iii) and how many of the genes are shared by the different genomes (Ureta-Vidal A et al 2003 *Nature Rev Genet* 4:251). *Orthogenomics* deals with the genomes of orthologous descent whereas *paragenomics* studies paralogous genomes. The study includes the composition and organization of protein domains in the different organisms. *Genetical genomics* involves expression profiles and marker-based fingerprints of each individual in a segregating population. The data are analyzed by QTL methods (Jansen RC, Nap JP 2001 *Trends Genet* 17:388). *Computational genomics* quantitatively or qualitatively measures a property of interest in ten or more inbred mouse strains. Genetic factors are then computationally identified in genomic regions where the pattern of genetic variation correlates with the distribution of trait values among the inbred strains analyzed. The extent of correlation between the trait values and strain groupings within each haplotype block is determined by analysis of variance (Wang J et al 2005 *Trends Genet* 21:526). *Nutrigenomics* has the goal to reveal the consequences of macro- and micronutrients on health and disease on different genotypes (Müller M, Kersten S 2003 *Nature Rev Genet* 4:315). *Toxicogenomics* seeks understanding the complexities in the biological system responding to toxic, mutagenic and carcinogenic factors. Special consideration is given to homologies of genes involved in controlling disease in the human genome, to sharing fundamental functions such as the cell cycle and structure, cell

adhesion, signaling, apoptosis, neuronal controls and the defense system (immune reactions). Finished genomic sequence is contiguous and has no more errors than 1/10,000 bases. ►genomic DNA, ►DNA sequencing, ►DNA chips, ►macroarray analysis, ►microarray hybridization, ►maldi/tof/ms, ►physical mapping, ►mass spectrometer, ►genome projects, ►gene numbers, ►duplications, ►proteome, ►SAGE, ►biotechnology, ►genetic engineering, ►ORF, ►Cre/Lox, ►knockin, ►X-ray diffraction analysis, ►orthology, ►paralogy, ►comparative genomics, ►TWINSCAN, ►bioinformatics, ►analysis of variance; Craig AG, Hoheisel JD 1999 *Automation: Genome and Functional Analyses*. Academic Press, San Diego, California; Trends Guide to Bioinformatics, Sup. Elsevier, 1998, Rubin GM et al 2000 *Science* 287:2204; Koonin EV 2001 *Curr Biol* 11:R155; Reboul J et al 2001 *Nature Genet* 27:227; Gopal S 2001 *Nature Genet* 27:337; genomics; Meyerowitz EM 2002 *Science* 295:1482; Aardema MJ, MacGregor JT 2002 *Mutation Res* 499:13; human genomics reviews: *Human Mol Genet* 15 Rev. issue 1; <http://www.functionalgenomics.org.uk/>; chemical genomics: <http://www.genome.jp/kegg/>; <http://gib.genes.nig.ac.jp/>; public population genomics: <http://www.p3gconsortium.org/>; structural genomics targets: <http://www.ysbl.york.ac.uk/sgTar/get/>; agriculturally relevant species: <http://www.agbase.msstate.edu/>; plant genomes: <http://mips.gsf.de/projects/plants>.

Genomics-Guided Transgenes (GGT): GGT are homologous genes obtained from native species or from related species. GGTs are expected to provide useful features to crops without potential drawbacks of induced mutant genes. ►transgene, ►GMO; Strauss SH 2003 *Science* 300:61.

Genomotyping: Genomotyping hybridizes the DNA of a particular strain/isolate to the genome of a sequenced standard line to assess the difference between the two.

Genophore: gene string not associated with large amounts of protein (bacterial chromosome). (See Ris H, Chandler BL 1963 *Cold Spring Harbor Symp Quant Biol* 18:1).

Genotator: is a program for sequence annotation and gene finding. ►gene prediction, ►annotation of the genome; <http://www.fruitfly.org/~nomi/genotator/user-manual.html>.

Genotoxic Chemicals: Genotoxic chemicals cause gene mutation, chromosomal aberration, and cancer. Genotoxic stress activates cell cycle checkpoints to allow time for repair, if possible. The most recommended tests involve bacterial mutation assays, in vitro test for chromosomal damage using mammalian

cells (rodent hematopoietic cells), and in vitro assay of mouse lymphoma $tk^{+/-}$ cells (MLA). Molecular effects of genotoxic chemicals can be assessed by single nucleotide polymorphism analysis. ►[gene-tox](#), ►[databases](#), ►[environmental mutagens](#), ►[mutagen assays](#), ►[SNIP](#), ►[cell cycle](#), ►[checkpoint](#), ►[pharmaceuticals](#); Müller L et al 1999 Mutation Res 436:195.

Genotype: The genetic constitution, the full set of genes.

Genotype Elimination: In genotypic elimination, statistical algorithms are used for the identification of genotypes that are inconsistent with the pedigree information. (See O'Connell JR, Weeks DE 1999 Am J Hum Genet 65:1733).

Genotypic Frequencies: ►[Hardy-Weinberg theorem](#)

Genotypic Mixing: In genotypic mixing, after infecting a cell with viruses of different genotypes, in a single viral capsid more than one type of viral DNA may be included. ►[rounds of matings](#)

Genotypic Risk Ratio (GRR): The total number of offspring affected/twice the number of affected homozygotes. ►[genetic hazards](#), ►[risk](#), ►[genetic risk](#), ►[empirical risk](#), ►[displacement](#)

Genotypic Segregation: ►[trinomial distribution](#)

Genotypic Value: A quantitative genetics term indicating the genetically determined component (G) of the phenotypic variation; phenotypic value (P) = G + E, where (E) stands for environmental variation. ►[midpoint](#), ►[breeding value](#), ►[additive effects](#)

Genotyping: Identification of the genotypic constitution at one or more loci by genetic, molecular, immunological, or any other means using cells, tissues, or whole organisms. Single-sperm genotyping permits detection of recombination in humans at large scale and sheds light on the extent of linkage disequilibrium. Naturally, this procedure does not reveal recombinational differences among females, if any. Quite commonly RFLP, mini- and microsatellites, trinucleotide repeats, single nucleotide polymorphism, and PCR are used. Immobilizing DNA on silicon chips and the use of MALDI has developed high-throughput methods. Statistical methods based on inheritance are available for the detection of genotyping errors (Douglas JA et al 2002 Am J Hum Genet 70:487; Sobel E et al 2002 Am J Hum Genet 70:496). ►[genotype](#), ►[RFLP](#), ►[SNIP](#), ►[PCR](#), ►[minisatellite](#), ►[microsatellite](#), ►[trinucleotide repeats](#), ►[DNA chips](#), ►[microarray hybridization](#), ►[MALDI](#), ►[haplotype analysis](#), ►[GWA](#); Tang K et al 1999 Proc Natl Acad Sci USA 96:10016; Ranade K et al 2001 Genome Res 11:1262; Beaulieu M et al 2001 Nucleic Acids Res 29:1114; Wolfe JL et al 2002 Proc Natl

Acad Sci USA 99:11073; genotyping errors and estimation of errors: Pompanon F et al 2005 Nature Rev Genet 6:847; Wang L et al 2007 Adv Exp Med Biol 593:105.

Gens (plural gentes): Organisms with shared relations (a sub-race).

GENSAT (<http://www.gensat.org/login.jsp>): is a gene expression atlas of the central nervous system.

Genscan: is a gene predictor program. (See Burle C, Karlin S 1997 J Mol Biol 268:78, <http://genes.mit.edu/GENSCAN.html>).

GENT Algorithm: The GENT algorithm generates contigs from optical mapping data. ►[contig](#), ►[optical mapping](#); Mathe C et al 1999 J Mol Biol 285:1977.

Gentamycin (gentamycin): A broad-spectrum aminoglycoside antibiotic. Gentamicin may facilitate reading through nonsense termination codons during translation. It may cause irreversible hearing loss that is preventable by aspirin (see Fig. [G38](#)). (See New England J Med 354:1856; ►[readthrough](#), formula).

Figure G38. Gentamycin sulphate

Genus: A taxonomic category including usually several species of common descent. e.g., *Drosophila* (genus) *melanogaster* (species), the fruitfly most commonly used in genetics studies. Some genera are monotypic, however, inasmuch as they consist of a single species, e.g., *Arabidopsis*. ►[species](#)

Genus (in statistics): A topologically invariant property of a surface defined as the largest number of nonisotopic simple closed curves that can be drawn on the surface without separating it, i.e., the number of handles on the surface (Tuminello M 2005 Proc Natl Acad Sci USA 102:10421).

Gene2XML: A program, which converts ENTREZ GENE ASN1 into XML. ►[ASN.1](#), ►[XML](#); [ftp.ncbi.nih.gov/toolbox/ncbi/s\do5\(t\)ools/converters/by\s\do5\(p\)rogram/gene2xml/](ftp.ncbi.nih.gov/toolbox/ncbi/s\do5(t)ools/converters/by\s\do5(p)rogram/gene2xml/)

GEO (Gene Expression Omnibus): The GEO lists genes by name, type, organism, database, etc. <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gds>.

Geographic Isolation: Geographically isolated populations cannot exchange genes because physical distance or other physical factors (mountain ranges, lakes, etc.) keep them apart. ► [speciation](#)

Geographical Race: A topologically separate population with distinctive gene frequencies.

Geological Age: ► [evolutionary clock](#)

Geological–Evolutionary Time Periods: (~ millions of years ago) formation of the Earth—4600—origin of Life—3000—Cambrian—600—Ordovician—450—Silurian—410—Devonian—345—Carboniferous—280—Permian—225—Triassic—190—Jurassic—135—Cretaceous—65—Eocene—36—Oligocene—Miocene—13—Pliocene—3—Pleistocene—0.01—Recent. ► [Archeozoic](#), ► [Pterozoic](#), ► [Paleozoic](#), ► [Mesozoic](#), ► [Cenozoic](#), ► [origin of life](#), ► [evolution prebiotic](#), ► [extinction](#), ► [evolution of the genetic code](#), ► [missing link](#)

Geometric Mean: ► [mean](#)

Geometric Progression: A series of elements increasing by the same factor, e.g., 2, 6, 18, 54 (i.e., by a factor of 3 in this example). ► [arithmetic progression](#)

Geometric Solids: (see Fig. [G39](#)).

Surface: $\square 6a^2$; $\square 2(ab + ac + bc)$; $\square 2\pi r((h + r))$; \square base surface + $[(ah)/2 \times n]$

$\square r\pi(r + s)$; \square side areas $\times 4$; $\square \pi[r^2 + (r + r_1)s + r_1^2]$

Volume: $\square a^3$; $\square a \times b \times c$; $\square r^2\pi h$; \square base surface $\times h$; $\square (r^2\pi h)/3$,

$\square h/3(aba) \sqrt{(axa)(a1xa1) + (a1xa1)}$; $\square (\pi h)/3(r^2 + rxr1 + (r1)^2)$

*SPHERE: surface: $4r^2\pi$; volume: $(4/3)r^3\pi$ ($\pi \cong 3.132857$). ► [circle](#)

George III: This mad king of England (1738–1820) might have been a victim of porphyria. ► [porphyria](#)

Geotropism: Growth influenced by gravity; positive (+) geotropism directed toward and negative (–) away

from gravity. Plant roots grow downward (+) and the shoots upward (–).

GEP: Guanine nucleotide exchange proteins.

Gephyrin (93 kDa): Peripheral nervous system membrane protein binding the inhibitory β subunit of the motor neural glycine receptor to tubulin in the cytoskeleton encoded in human chromosome 14 (Heilig R et al 2003 Nature [Lond] 421:601). It is also used for a co-factor that regulates molybdenum-dependent enzymes. ► [cytoskeleton](#), ► [tubulin](#), ► [neuron](#); Sola M et al 2001 J Biol Chem 276:25294.

Geranyl Pyrophosphate: A precursor of farnesyl pyrophosphate. Two molecules of farnesyl pyrophosphate join by the pyrophosphate end and squalene is formed through the elimination of both pyrophosphates. Squalene is then cyclicized to form lanosterol before being converted into cholesterol. ► [prenylation](#), ► [cholesterols](#)

GERBICH (Ge blood group): The Ge blood group is distinguished by its encoding β and γ sialoglycoproteins (glycophorins). These red blood cell membrane proteins are suspected of being the receptors of the *Plasmodium falciparum* merozoite (malaria-causing protozoon). ► [blood group](#), ► [malaria](#); Mayer DC et al 2001 Proc Natl Acad Sci USA 98:5222.

Gerbil: *Gerbillus cheesmani* $2n = 38$; *Gerbillus gerbillus* $2n = 43$ male, 42 female.

Germ: (Pathogenic) microorganism or an initial cellular structure capable of differentiation and development into a special organ or organism.

Germ Cells: The reproductive (sex) cells of eukaryotes, such as spores, eggs, and spermatozoa. The spores frequently come about by non-sexual processes such as the conidia of fungi and may not function like sex cells. The egg and spermatozoa are direct or indirect products of meiosis that have undergone a process of differentiation without division, e.g., the spermatozoa of animals arise from the spermatids and the sperms of plants are formed by post-meiotic division of the microspore nuclei. The eggs of animals arise by an additional division of the haploid secondary oocytes.

Figure G39. Geometric solids

Primordial germ cells of animals are sexually undifferentiated and can develop into oogonia or spermatogonia by mitosis before the meiotic path is set. Retinoic acid causes germ cells in the ovary to enter meiosis and initiates oogenesis. In the fetal testis, a retinoid-degrading enzyme (CYP26B1) retards meiosis and ultimately spermatogenesis takes place. Thus retinoid levels specify germ cell fate during gonad development (Bowles J et al 2006 Science 312:596). In mice, the *Stra8* gene (stimulated by retinoic acid 8) controls the transition into meiosis in both sexes. In females *Stra 8* is expressed in embryonic ovaries just before meiosis whereas in males it is expressed in the testes after birth (Koubova J et al 2006 Proc Natl Acad Sci USA 103:2474).

Primordial germ cells of mouse obtained from fetuses 8.5 p.c. when transplanted into the seminiferous tubules of infertile mice permitted the production of fertile offspring (Chuma S et al 2005 Development 132:117). The spermatogonial stem cells of animals can divide throughout life and produce spermatozoa. Adult testicular germ cells of the fish, trout (*Oncorhynchus mykiss*), contain spermatogonial stem cells, which when transplanted into the peritoneal cavity of newly hatched male or female embryos differentiated into functional spermatozoa in males and into functional eggs in the female recipients, and were capable of producing normal offspring (Okutsu T et al 2006 Proc Natl Acad Sci USA 103:2725). The egg of plants is formed through three divisions from one of the haploid megaspores. ► [gametogenesis](#), ► [germ plasm](#), ► [conidia](#), ► [egg](#), ► [sperm](#), ► [spore](#), ► [megaspore](#), ► [microspore](#), ► [histone variants](#), ► [protamines](#), ► [embryoid body](#), ► [p.c.](#); Raz E 2003 Nature Rev Genet 4:690; Santos AC, Lehmann R 2004 Current Biol 14:R578; germline transmission of genetically modified primordial germ cells: van de Lavoie M-C et al 2006 Nature [Lond] 441:766; conserved gametogenesis transcriptome in humans mouse and rat: Chalmel F et al 2007 Proc Natl Acad Sci USA 104:8346; genome browser: <http://www.germonline.org/index.html>.

Germ Layers: Gastrulation forms the most inner layer, *endoderm*, the surface layer, *ectoderm* (epithelium), and the in-between mesenchyme cell layer the *mesoderm*. Some embryologists attribute the differentiation to the neural crest. ► [gastrula](#), ► [neural crest](#)

Germ Plasm: Development (in *Drosophila*) begins with the formation of the primordial germ cells also called pole cells. The syncytial nuclei congregate at the posterior segment of the pole. Cellularization begins after about two hours. During gastrulation, the germ cells move to the embryonic gonad and form the germline stem cells. In both males and females, after four rounds of cell divisions 16 cells are formed. In

the male, all 16 contribute to sperm formation. In the female these 16 cells remain interconnected but only one becomes an oocyte, while the 15 others become polyploid nurse cells and nourish the oocyte. The oocyte proceeds with meiosis. About 80 maternal (somatic) follicle cells surround the oocyte and nurse cells. The development of the germ plasm (the cytoplasmic determinants of the germ cells) is controlled by the interacting products of a series of genes. ► [morphogenesis in *Drosophila*](#), ► [germ cells](#), ► [germline](#), ► [germplasm](#), ► [Drosophila](#)

German (germen): Closely related, such as having the same parents. ► [cousin german](#)

German Measles: ► [rubella virus](#)

Germanium: The location of the pro-oocytes which through mitotic divisions gives rise to the oocysts, one of which, becomes the oocyte. ► [oocyte primary](#), ► [karyosome](#)

Germinal Center: A group of naive (uncommitted) B cells. When activated by a specific antigen, they may develop into either memory B cells after antigen selection or become plasma cells. In the presence of interleukin-1,-10, and CD40 ligands they become memory B cells. By removal of CD40 ligand, the cells differentiate into plasma cells. A rapidly growing center also includes antigen-specific helper T cells. CD21 may be required for the B cells to survive in the germinal center. The germinal center has an open structure that enables competition for rare high-affinity B cells to participate in antigen responses (Schwickerts T et al 2007 Nature [Lond] 446:83). ► [T lymphocyte](#), ► [clonal selection](#), ► [antigen](#), ► [CD40](#), ► [CD21](#), ► [plasma cell](#), ► [memory immunological](#), ► [OBF](#), ► [somatic hypermutation](#), ► [B lymphocyte](#); Schebesta M et al 2002 Curr Opin Immunol 14:216.

Germinal Choice: Germinal choice is the idea that parents should not necessarily rely on their own gametes for producing offspring but adopt eggs, sperms, or even fertilized eggs from superior gene pools as a practical measure of positive eugenics. ► [sperm bank](#), ► [in vitro fertilization](#), ► [eugenics](#), ► [ART](#); Stock G 2005 Reprod Biol Online 10(1):27.

Germinal Mutation: Germinal mutation occurs in the germline, gonads, or in the gametes. ► [germline](#), ► [gonad](#), ► [gamete](#)

Germinal Vesicle: The large nucleus of the amphibian oocyte. This nucleus contains the three eukaryotic RNA polymerases and can also transcribe exogenous (microinjected) DNA. The oocyte then translates the mRNAs into a variety of proteins. ► [in vitro translation systems](#)

Germinoma: The neoplasm of the male or female gonads. ►gonad

Germline: The cell lineage that contributes to the formation of the gametes. In the majority of animals, the germline is determined very early in the zygote although the embryonic stem cells have pluripotent capability. In mice, the germ cells originate from extra-embryonic ectoderm under the influence of an inducible transmembrane protein encoded by the *fragilis* gene. Then gene *stella* is expressed in the cells that are restricted to the germline. The latter gene represses homeobox genes in the cells and thus they retain pluripotency (Saitou M et al 2002 Nature [Lond] 418:293). The segregation of the germline from the soma line involves the degradation of CCCH finger proteins in the soma by the ZIF-1 protein complex, which interacts with cullin-dependent ubiquitination system. In the germline, the PAR-1 kinase protects these proteins (DeRenzo C et al 2003 Nature [Lond] 424:685).

According to some views, plants do not have germline, certainly not in the sense of animals, because the generative cell lineage is not set aside definitely in early development and plant cells may retain totipotency for almost the entire life of the individuals. Nevertheless, by “fate maps”, the cell lineages giving rise to megaspores and microspores of plants can be traced to origin. In *Drosophila*, for the development of the germline the product of the *nanos* (*na*) gene locus is essential. In animals, the germline progenitor cells and gonadal somatic cells form the embryonic gonads, which develop into gamete-producing organs. In the embryonic gonads of *Drosophila*, 101 genes are expressed preferentially out of which 39 were expressed predominantly in the germline, whereas 58 in the somatic cells and 45 genes in both lineages (Shiegenobu S et al 2006 Proc Natl Acad Sci USA 103:13728). If mutation occurs in the germline, the genetically mosaic tissue may produce different gametes. Some mutations, which appear recessive in the somatic tissues may display reversal and function as dominant. In such cases, selection is possible before the formation of the gametes. ►cell lineages, ►*Drosophila* life cycle, ►genetically effective cell number, ►morphogenesis in *Drosophila*, ►germ plasm, ►gonads, ►gametogenesis, ►stem cells, ►somatic embryogenesis, ►CCCH protein, ►cullin, ►PAR, ►ubiquitin, ►Keimbahn for illustration; Lin H 1997 Annu Rev Genet 31:455; Saffman EE, Lasko P 1999 Cell Mol Life Sci 55:1141; Extavour C, García-Bellido A 2001 Proc Natl Acad Sci USA 98:11341; Crittenden SL et al 2002 Nature [Lond] 417:660.

Germline Transcripts (sterile RNA): Germline transcripts are not translated into protein. These specific

guanine-rich RNAs are transcribed from the immunoglobulin heavy chain S (switch) sequences in the B lymphocytes. These RNAs of 1 to 10-kb in length and containing repeats of 20 to 100 bp, anneal with the cytosine-rich DNA template. The sterile transcripts—although have similar overall structure—are specific for each switch sequence preceding a heavy chain gene, and each mediates in cis position class switching of a specific heavy chain gene. It has been hypothesized that these RNA-DNA hybrids are the recognition sites for the endonuclease that cuts the DNA double strands in the process of class switching.

►immunoglobulins, ►antibody gene switching, cis arrangements; Tracy RB et al 2000 Science 288:1058.

Germplasm (Keimplasma): The sum of the genetic determinants transmitted through the gametes to the progeny. In a broader sense, it is used for the designation of a collection of genotypes of organisms usable as plant and animal breeding resource.

►genotype, ►germ plasm

Gerontology: The clinical, biological, and sociological study of aging. ►aging, ►apoptosis, ►Hayflick's limit

Gerstmann-Sträussler Disease (GSD): A chromosome 20p12-pter dominant brain disease with substantial similarities to the Creutzfeldt-Jakob disease. There are some apparent differences inasmuch that in GSD there are numerous multicentric tuft-like plaques in the cerebral and cerebellar cortex, in the basal ganglia, and in the white matter of the brain. GSD appears to involve a greater recurrence risk than the Creutzfeldt-Jakob disease. ►Creutzfeldt-Jakob disease, ►scrapie, ►prion, ►encephalopathies, ►encephalopathy bovine spongiform

Gestation: The time from fertilization of the ovum (ova) to the delivery of the newborns in viviparous animals. The average term of gestation, in days: opossum 13, hamster 17, mouse 19, rat 21, rabbit 31, giant kangaroo 39, dog 61, cat 63, guinea pig 68, sow 114, sheep and goat 151, Virginia deer 215, Rhesus monkey 164, chimpanzee 238, woman 267, cow 284, mare 340, and elephant 624. There may be substantial deviations from these averages. Some of the differences in literature data are due to either biological or developmental variations, or the information indicates the time between ovulation and birth. ►hatching time in poultry

Gestational Drive (green beard effect): As per gestational drive, maternal genes recognizing and favoring special genes of the offspring, already during gestation, and favoring or disfavoring a genetic constitution may lead to consequences somewhat similar to meiotic drive. Population geneticists do not generally accept the concept. ►meiotic drive, ►green beard effect

GFAP (glial fibrillary acidic protein): GFAP affects myelination of the peripheral nerve cells and brain and its defect causes long-term depression. ▶myelin, ▶depression, ▶leukemia, ▶inhibitory factor; Headley SA et al 2001 J Comp Pathol 125(2–3):90.

GFF (General Feature Format): A document software format for finding in higher organisms a variety of recognition methods that give scores to likely signals (starts, splice sites, stops, motifs, etc.) or to extended regions (exons, introns, protein domains etc.), and then combine these to give complete gene, RNA transcript, or protein structures. Normally, the combination step is done in the same program as the feature detection, often using dynamic programming methods. To enable these processes to be decoupled, a format called GFF (“Gene-Finding Format” or “General Feature Format”) was proposed as a protocol for the transfer of feature information. (See http://www.sanger.ac.uk/Software/formats/GFF/GFF_Spec.shtml).

GFP: ▶green fluorescing protein

GGAs: Proteins that sort mannose phosphate receptors (MPR) into vesicles budding from the transgolgi network (TGN). The proteins are eventually delivered to endosomal and lysosomal compartments. The GGA is composed of a VHS (VPS27, Hrs, STAM) domain at the NH₂ end and a GAT domain that is flexibly hinged to a GAE domain at the carboxyl end. The GGA is moved to the transgolgi membrane after the GAT (transporter) domain interacts with the ARF-GTP (ADP-ribosylation factor–guanosine triphosphate) complex on the TGN membrane. The VHS domain binds the acidic cluster dileucine motif (ACLL) of the MPR. The GGA recruits at the GAE hinge a clathrin triskelion and accessory proteins γ -synergin (controlling clathrin-coated vesicle traffic) and the endosome fusion regulator protein rabaptin 5. ▶mannose phosphate receptor, ▶transgolgi network, ▶endocytosis, ▶lysosome, ▶triskelion; Tooze SA 2001 Science 292:1663.

γ -Glutamyl Carboxylase (GGC): The enzyme required for the post-translational modification of vitamin K dependent proteins used for blood clotting and bone proteins. ▶vitamin K-dependent blood clotting factors

GH: Growth hormone such as the hGH (human, encoded in 17q22-q24) or rGH (rat) growth hormones. ▶hormone response elements, ▶hormones, ▶pituitary dwarfism, ▶growth hormone relapsing hormone, ▶GHRH, ▶GHRHR

Ghost: An empty phage capsid without its genetic material. Also, electronic noise.

Ghost QTL: An erroneous localization result obtained by QTL analysis. ▶QTL

G_h: G protein with GTP-binding signaling function and transglutaminase activity. ▶G-protein

Ghrelin: An acetylated, 28-amino acid secretagogue produced in the hypothalamus that releases growth hormone from its receptor. It promotes feeding and is an antagonist of leptin. Ghrelin regulates neuropeptide Y and agouti-related protein neurons. The fatty acid synthase inhibitor, C75, blocks the synthesis of ghrelin. Oxyntomodulin suppresses it. ▶secretagogue, ▶growth hormone pituitary, ▶leptin, ▶agouti, ▶neuropeptide Y, ▶obesity, ▶obestatin, ▶oxyntomodulin; Inui A 2001 Nature Rev Neurosci 2:551; Hosoda H et al 2003 J Biol Chem 278:64; Hu Z et al 2005 Proc Natl Acad Sci USA 102:3972.

GHRH (growth hormone release hormone, 20q11.2): GHRH stimulates the release of growth hormones from the pituitary. Antagonists of GHRH receptors suppress cancerous proliferation. Somatostatin inhibits growth hormone secretion. ▶animal hormones, ▶pituitary, ▶somatostatin, ▶brain human, ▶GH; GHRH antagonists with improved antitumor activity: Zarandi M et al 2006 Proc Natl Acad Sci USA 103:4610.

GHRHR (growth hormone-releasing hormone receptor, 7p15-p14): GHRHR results in dwarfism. Several variants are known. ▶dwarfism, ▶GH; Szepesházi K et al 2001 Endocrinology 142:4341.

gi: An identification number in the GenBank data base that is used in addition to the accession number. This permits a closer identification of later discovered variations in a particular sequence to which—as new information becomes available for that particular DNA—a string of gi-s may be added. ▶accession number, ▶asn.1, ▶GenBank, ▶identifier syntax

G_i Protein: A member of the trimeric G-protein family; it activates adenylate cyclase and thus opens K⁺ channels. The $\beta\gamma$ subunits activate the ERK/MAPK signal transduction path through tyrosine kinase. This pathway responds positively to RAS and antagonized by RAP1. ▶G-proteins, ▶signal transduction, ▶adenylate cyclase, ▶ion channels, ▶RAS, ▶RAP1

GI₅₀: A chemical dose that provides 50% growth inhibition, e.g., for a certain cancer cell line.

Giant Axonal Neuropathy (GAN, 16q24): A recessive sensory and motor disease of the central and peripheral nervous system. Its onset is at early childhood and usually causes death by late adolescence of curly haired individuals. It causes swelling of the axons due to a defect in the protein gigaxonin affecting the axonal cytoskeleton. Gigaxonin binds to

ubiquitin-activating enzyme E1 through its amino-terminal BVTB domain, and the carboxyterminal kelch repeat interacts with the light chain of microtubule-associated protein 1B (MAP1B). Over-expression of gigaxonin enhances the degradation of MAP1B, and loss of gigaxonin has the opposite effect (Allen E et al 2005 Nature [Lond] 438:224). A similar disease also afflicts some German Shepherd dogs. ▶neuropathy, ▶BTB, ▶microtubule, ▶kelch motif

Giant Chromosomes: Polytenic chromosomes and lampbrush chromosomes. ▶lampbrush chromosomes, ▶polytenic chromosomes, ▶salivary gland chromosomes

Giant Platelet Syndrome (Bernard-Soulier syndrome, 22q11.2, 17pter-p12): The giant platelet syndrome is caused by deficiency of a major platelet glycoprotein (glycoprotein Ib-β, GP1BB), resulting in a bleeding disorder. ▶thrombophilia, ▶May-Hegglin anomaly, ▶thrombocytopenia

Giardia: *Giardia* is an intestinal protozoan parasite causing sensitive people severe, debilitating diarrhea and abdominal pain (see Fig. G40). It generally infests through unsanitized water. Its genome is less than 12 Mb. The *G. lamblia* genome is tightly packaged. Bidirectional transcription is a common feature and produces, not only the appropriate downstream sense transcript, but also leads to the production of either an upstream sense transcript (for promoters between genes in a head-to-head arrangement) or an upstream sterile antisense transcript (for promoters between genes in a head-to-tail arrangement). Bidirectional transcription seems to contribute to the abundance of sterile antisense transcripts observed (Teodorovic S et al 2007 Nucleic Acids Res 35:2544). The cells do not have mitochondria but mitosomes. ▶mitosome, ▶*Entamoeba*, ▶*Trichomonas*; Adam, RD 2007 Clin Microbiol Rev 14: 447.

Figure G40. *Giardia* (Courtesy of CDC Public Health Image Library)

GIB: ▶Genome Information Broker (<http://gib.genes.nig.ac.jp>).

Gibberella fujikuroi: A plant-pathogenic fungus that produces by its normal metabolism the plant hormones gibberellins. ▶plant hormones

Gibberellins: ▶plant hormones, ▶*Gibberella fujikuroi*, ▶dwarfism, ▶florigen; Rojas MC et al 2001 Proc Natl Acad Sci USA 98:5838; Richards DE et al 2001 Annu Rev Plant Physiol Mol Biol 52: 67; Olszewski N et al 2002 Plant Cell 14:S61; genes and enzymes in fungi and plants; Tudzynski B 2005 Appl Microbiol Biotechnol 66:597 (see Fig. G41).

Figure G41. Gibberellic acid

Gibbon: ▶Pongidae, ▶primates

Giemsa Stain: The Giemsa stain contains azure II, azure-eosin, glycerol, and methanol. The dark bands appear to be poor in GC and the light, rich in GC content. ▶G banding, ▶chromosome banding, ▶rye; Niimura Y, Gojobori T 2002 Proc Natl Acad Sci USA 99:797.

Gierke's Disease: ▶glycogen storage disease type I

GIFT (gamete intrafallopian transfer): A method of artificial insemination. ▶artificial insemination, ▶ART

GIGA: Prefix for 10⁹ size or quantity.

GigAssembler: An algorithm suitable for preparing the human genome working draft, including about 88% of the 400,000 initial contigs. ▶contig, ▶human genome, ▶genome projects; Kent WJ, Haussler D 2001 Genome Res 11:1541.

Gilbert Syndrome: A very common human chromosome 2, dominant hyperbilirubinemia, similar to the Crigler-Najjar syndrome and probably controlled by genes allelic to it. ▶Crigler-Najjar syndrome, ▶Dubin-Johnson syndrome, ▶hyperbilirubinemia

Gilles de la Tourette Syndrome: ▶Tourette disease

Gillespie Equation: The Gillespie equation can be used to estimate the stochastic regulation of chemical reactions, including interacting gene systems. The paper cited here presents a computational simpler

form. (See Gillespie DT 2001 J Chem Phys 115:1716).

Gin: An invertase. ►invertases

Ginger (*Zingiber officinale*, $2n = 2x = 22$): Perennial rhizome spice. It dilates blood vessels, relieves pain, reduces flatulence, increases perspiration, and it is a stimulant. ►phenolics

Ginkgo biloba: An ornamental tree in the USA. Its leaves are considered as herbal medicine for neurological disorders associated with aging such as Alzheimer disease, hearing and memory loss, attention deficit, etc. Its flavonoids appear to be effective scavengers of free radicals. Microarray hybridization was found to reveal higher level of tyrosine/threonine phosphatase and other mRNAs involved in up-regulation of activity in the brain cortex of mice upon consuming leaf extracts. Ginkgos are very old species. (See Watanabe CMH et al 2001 Proc Natl Acad Sci USA 98:6577; Zhu Z, Zheng S 2003 Nature [Lond] 423:821).

GIP: A G protein subunit, and a potential oncoprotein. ►G protein, ►oncoprotein

GINs: One of the accessory factors for replication by DNA polymerases ϵ and α ; it is a heterotetrameric complex consisting of Sld5, Psf1 (partner of Sld5-1), Psf2, and Psf3. ►SLD; Chang YP et al 2007 Proc Natl Acad Sci USA 104:12685.

GIP (glucose-dependent insulinotropic polypeptides): GIPs mediate insulin secretion. (See Hinke SA 2001 Biochim Biophys Acta 1547:143).

Giraffe (*Giraffa camelopardalis*): $2n = 30$; the *Okapia johnstoni* is $2n = 45$.

Girdle Bands: Concentric rings of thylakoids. ►chloroplasts, ►thylakoids

GIRK (G-protein-gated inwardly rectifying K^+ channel): A heterotrimeric guanine nucleotide-binding protein. ►ion channels, ►G proteins; Seeger T, Alzheimer C 2001 J Physiol 535[pt 2]:383.

GIS (gene identification signature): See Liu T-B, Ruan Y 2005 Nature Meth 2:105; ►transcriptome

GISH: Genomic in situ hybridization (see Fig. G42). It may identify chromosomes in species hybrids and reveal crossovers among homoeologues. ►in situ hybridization, ►FISH, ►genome, ►homoeologous chromosome

Figure G42. GISH. Introgression of *Allium fistulosum* chromosomes into *A. cepa*, mediated by bridging cross to *A. roylei*. The *A. fistulosum* chromosomes are labeled red (biotin, CY3), *A. roylei* shows green fluorescence (FITC) and *A. cepa* chromatin is blue (DAPI). (From Khrustaleva LI, Kik C 2000 Theor Appl Genet 100:17–26. Copyright Springer Verlag, 2000)

GIS-PET: Gene-identification signature analysis using paired-end ditags. Paired-end ditags from the two ends of each expressed transcript (18 bp from 5' end and 18 bp from 3' end) are extracted, concatenated, and subjected to sequencing analysis. ►GIS, ►paired-end diTag

giSNP (genetically indistinguishable SNP): About 50% of SNPs in human chromosome 20 shows at least one SNP partner in perfect linkage disequilibrium within < 20 kb clusters. Such giSNPs may make difficult the association mapping of disease genes. (Lawrence R et al 2005 Genome Res 15:1503). ►SNIPs, ►linkage disequilibrium

Gitelman Syndrome (16q13): Hypocalciuria, hypomagnesemia, and hypertension. ►Bartter syndrome, ►Liddle syndrome, ►hypoaldosteronism, ►hypertension, ►hypokalemia

GITR (glucocorticoid-induced tumor necrosis factor receptor-related, 1p36.3): GITR regulates cell proliferation, differentiation, and cell survival. Its ligand is AITR (activation-inducible TNFR). ►TNF; Nocentini G et al 2000 DNA Cell Biol 19(4):205.

GIY-YIG: A family of homing endonuclease with a GIY (X_{10-11})-YIG amino acid motif. These enzymes occur in T4 bacteriophage, either free, or within mobile group I introns. They occur in fungal and algal

mitochondrial introns and in algal chloroplasts. ▶**homing endonucleases**; Chevalier BS, Stoddard BL 2001 *Nucleic Acids Res* 29:3757.

Glanzmann's Disease: A variety of blood platelet anomalies determined by autosomal recessive genes. The overall symptoms include bleeding under the skin (ecchymosis), tiny, round and flat purplish (later yellow or blue) spots under the skin caused by blood release (petechia), bleeding of the tooth gum (gingiva), nosebleeds (epistaxes), gastrointestinal bleeding, excessive uterine bleeding (menorrhagia), or bleeding from the uterus at irregular intervals (metrorrhagia). The platelets may appear normal yet their number is reduced (thrombocytopenia). Sometimes the size of the platelets increases and their shape becomes abnormal and they appear isolated rather than aggregated. ▶**platelet abnormalities**, ▶**hemophilias**, ▶**von Willebrand disease**, and other terms under separate entries.

Glast: Na⁺-dependent transporters of glutamate and aspartate; GLASTs may have 68% homology with another glutamate transporter GLT. β-Lactam antibiotics increase the expression of glutamate transporters and may protect against some neurological diseases (Rothstein JD et al 2005 *Nature [Lond]* 433:73). ▶**transporters**, ▶**β-lactamase**, ▶**antibiotics**, ▶**neurological disorders**; Gegelashvili G et al 2001 *Progr Brain Res* 132:267; structure of *Pyrococcus* homolog: Yarnol D et al 2004 *Nature [Lond]* 431:811.

Glaucoma: Glaucoma may be controlled by autosomal dominant or recessive genes and may be manifested at birth, during juvenile years, or in adults (see Fig. G43). The incidence of the different forms may vary from 10⁻⁴ to a couple of percent in the general population, usually presenting a higher risk in adult life. The most general features are opacity of the eye lens caused by a gray gleam on the iris and an increased intraocular pressure, which eventually distorts the vision. In the early stages or in any mild forms, the anterior chamber of the eye is open (open angle glaucoma). This stage may pass into an intermittent form that may be transient but can last for several months, and eventually the angle becomes closed resulting in great pressure and swelling of the

Figure G43. Glaucoma. (From Bergsma, D. ed. 1973 *Birth Defects. Atlas and Compendium*. National Foundation-March of Dimes)

cornea accompanied by substantial pain. Eventually, if untreated, total blindness may follow.

Testing the eye (intraocular) pressure before the visible onset of the condition may monitor it. In some cases, the increased intraocular pressure does not result in glaucoma and in some individuals glaucoma develops without eye pressure. In the early stages, the majority of people are unaware of the disease. The penetrance and expressivity of this disease is highly variable. The basic defect is degeneration of the optic nerve in the retinal ganglion cells. Amyloid β (Aβ) has an important role in retinal ganglion cell apoptosis (Guo L 2007 *Proc Natl Acad Sci USA* 104:13444). Radiation treatment of the receiver (1000 rad in two doses to whole body) and syngeneic (T cell-depleted) bone marrow injection from donor was found to provide very successful treatment in mice (Anderson MG et al 2005 *Proc Natl Acad Sci, USA* 102:4566). The most common forms of glaucoma are not monogenic but show complex inheritance due to multiple genetic and environmental factors. The gene (GLC1A) coding for juvenile open angle glaucoma (JOAG) was assigned to human chromosome 1q23-q25. GLC1B is at 2cen-q13 and GLC1C at 3q. The GC3B (buphtalmos) locus is at 1p36. The gene encodes the trabecular (supportive connective tissue) meshwork-inducible glucocorticoid response (TIGR) or myocilin. The dominant glaucoma at 6p25 encodes a forkhead type transcription factor. For early detection of glaucoma, the endothelial leukocyte adhesion molecule (ELAM-1, 1q23-q25) test has been suggested. ▶**eye diseases**, ▶**syngeneic**, ▶**FKH**, ▶**amyloids**, ▶**Axenfeld-Rieger anomaly**; Jacobson N et al 2001 *Hum Mol Genet* 10:117; Libby RT et al 2005 *Annu Rev Genomics Hum Genet* 6:15.

GLC: ▶**gas liquid chromatography**

Gle1: ▶**RNA export**, ▶**export adaptors**

Gleason Score: A classification of prostate cancer on the basis of histology with predictive value for progression. (See Gleason DF 1992 *Hum Pathol* 23:273; prostate cancer).

Gleevec (Glivec, Imatinib, STI-571): An inhibitor of Abelson murine leukemia virus oncogene-encoded tyrosine kinase and an anticancer drug effective against some sarcomas and hematopoietic cancer (see Fig. G44). In some cases, cardiac failure may result from this drug. It is an inhibitor of platelet-derived growth factor receptor (PDGFR) and cancers where this growth factor is involved. Resistance may arise to the drug through mutation in the kinase domain. The new drug BMS-3548725, however, is effective against most of the cells resistant to Gleevec (Shah NP et al 2004 *Science* 305:399). Recently,

some physicians reported improvement of diabetes II in a few patients treated by Gleevec. The drug seems to be a potent inhibitor of differentiated myeloid leukemic cells (CML), but does not deplete leukemic stem cells (Michor F et al 2005 Nature [Lond] 435:1267). A new generation of inhibitor of CML is Desatinib. For gastrointestinal tumors, Sutent may replace Imatinib. ►hematopoiesis, ►leukemia, ►diabetes, ►genetic medicine, ►biomarkers; Capdeville R et al 2002 Nature Rev Drug Discovery 1:493.

Figure G44. Gleevec

GLGF Repeats: Same as DHR domain or PDZ domain. (See Tochio H et al 2000 J Mol Biol 295:225).

GLI1 Oncogene (glioma): GLI1 has been located to human chromosome 12q13. It is highly amplified in gliomas. GLI2 in chromosome 2q14 (appears homologous to the *Krüppel* gene of *Drosophila* encoding a DNA-binding protein, regulating embryo morphogenesis). Similarly, GLI2 is also expressed in embryonal carcinomas but not in late developing ones. GLI3 (7q13) is apparently not an oncogene but it is involved in the Greig syndrome and in the Pallister Hall syndrome. Other homologous genes were also found in the human genome, altogether six loci in five different chromosomes. Some of the homologs (GLI4, 8q24.3) are denoted as HKR (human *Krüppel*). Gli transcription factors are suspected in the transduction of sonic hedgehog signals. Carboxy-terminal deletions in Gli3 facilitate its association with SMADs. ►oncogenes, ►*Krüppel*, ►Greig's cephalopolysyndactyly syndrome, ►Pallister-Hall syndrome, ►Rubinstein-Taybi syndrome, ►nevoid basal cell carcinoma, ►hedgehog, ►sonic hedgehog, ►syndactyly, ►polydactyly, ►DNA-binding protein domains, ►SMAD, ►glioma; Kim Y-S et al 2002 J Biol Chem 277:30901.

Gliadin: ►zein, ►glutenin

Glial Cell (neuroglia): Glial cells can be either astrocytes or oligodendrocytes or microcytes; the first two have supportive roles, the latter phagocytize the waste products of the nerves. Glial cells modulate synaptic transmission though an acetylcholine binding protein. ►FGF, ►acetylcholine

Glimmer: A program for locating (bacterial) genes based on interpolated Markov models. ►ORF, ►Markov chain statistics; Salzberg SL et al 1998 Nucleic Acids Res 26:544; <http://glimmer.sourceforge.net/>.

Glioma: A tumor of the tissues supporting the nerve cells (astrocytes) but it may spread beyond these. The glioma may be benign yet the malignant forms lead to rapid death. The most active glioma (glioblastoma multiformis, GBM) develops by an interaction of Ras and Akt in mice. GBM, although highly heterogeneous, can be grouped into rapidly progressing and slow progressing groups on the basis of expression ~70 genes, especially FABP7, and it can serve as a prognostic marker (Liang Y et al 2005 Proc Natl Acad Sci USA 102:5814). Gliomas seem to secrete glutamate that activates the NMDA receptors and further facilitates the expansion of the tumor. Surgery, radiation treatment supplemented with chemotherapy, and gene therapy with adenoviral vector carried herpes simplex virus thymidine kinase (HSVTK) and gancyclovir are used, but none give entirely satisfactory results. Bone morphogenetic protein inhibits glioblastoma stem cell proliferation (Piccirillo SGM et al 2006 Nature [Lond] 444:761). ►cancer gene therapy, ►GLI oncogene, ►angiogenesis, ►adenovirus, ►gancyclovir, ►RAS, ►Akt, ►FABP, ►NMDA, ►p110α, ►CD133, ►bone morphogenetic protein; Lam PYP, Breakfield XO 2001 Hum Mol Genet 10:777; Holland EC 2001 Nature Rev Genet 2:120; Takano T et al 2001 Nature Med 7:1010.

glnA: Bacterial glutamine synthase.

glnAp2, glnAp1: Major and minor glutamine synthase promoters, respectively, in bacteria.

Global Genetic Effects: Global genetic effects involve most or all of the genome. With the availability of microarray hybridization a very large number of gene loci can be studied (Rockman MV, Kruglyak L 2006 Nature Rev Genet 7:862). ►microarray hybridization, ►QTL

Global Single Cell Reverse Transcription-Polymerase Chain Reaction (GSC RT-PCR): The aim of the GSC RT-PCR method is to determine differences in gene expression among individual cells within a population of cells. This may be of interest for determining the process of metastasis, changes in gene expression during development, etc. A description of the procedure

can be found: Brailo LH et al 1999 *Mutation Res Genomics* 406:45. Although much difference is detectable among different cells, the components of the procedure introduce substantial variations too.

►microarray hybridization, ►SAGE

Globins: Ancestral protein molecules that diverged over a billion years ago into the oxygen-carrying muscle protein myoglobin and into the respiratory hemoglobins of the red blood cells. The neuroglobin, encoded at human chromosome 14q24, is expressed predominantly in the brain. The hemoglobin α locus is at human chromosome 16pter-p13.3, the β locus is at 11p15.5, δ is at 11p15.5, θ is at 16pter-13.3, the ζ is at 16pter-p13.3, and the ϵ is at 11p15.5. ►myoglobin, ►hemoglobin, ►leghemoglobin, ►haptoglobin, ►LCR, ►thalassemia, evolution of globins: Vinogradov SN et al 2005 *Proc Natl Acad Sci USA* 102:11385; <http://globin.cse.psu.edu/>.

Globo H: A glycosphingolipid present in breast cancer, ovarian, gastric, pancreatic, endometrial, prostate and small cell lung carcinomas. It may be employed in cancer vaccines. ►cancer gene therapy; Keusch JJ et al 2000 *J Biol Chem* 275:25315.

Globoid Cell Leukodystrophy: ►Krabbe's leukodystrophy

Globoside: Glycosphingolipid with the most common structure: acetylgalactoseamine-galactose-galactose-glucose-ceramide. ►sphingolipids, ►ceramides; Puri V et al 2001 *J Biol Chem* 154:535.

Globozoospermia (round-headed spermatozoa): A developmental anomaly caused by the loss of α' subunit of casein kinase II. This enzyme has many substrates and is involved in numerous metabolic controls. (See Larson KL et al 2001 *J Androl* 22 (3):424).

Globulin: Salt-soluble proteins with many diverse cellular functions.

Glofish: A genetically modified zebrafish expressing a red fluorescent protein transgene under a muscle-specific promoter, a pet novelty. ►transgene, ►zebrafish

Glomerulocystic Kidney Disease, Hypoplastic, Familial (GCKD, 17 cen-q21.3): Dominant mutations in the hepatocyte nuclear factor-1- β gene causing chronic renal failure, renal cysts and diabetes-like symptoms. ►HNF, ►kidney diseases

Glomerulonephritis: An autosomal dominant kidney disease associated with very sparse hairs and red lesions due to dilation of the blood vessels (telangiectasis). This disease (membrano proliferative glomerulonephritis) is frequently associated with

reduced levels of C3 complement component. More recent information indicates that the Fc γ R (fragment crystalline gamma receptor) of the antibody molecule is the most critical factor in the disease. Complement factor H-deficient mice showed significant reduction of nephritis if deficient in C5 but not in C6. Antimurine C5 antibody reversed renal injury (Pickering MC et al 2006 *Proc Natl Acad Sci USA* 103:9649). The dominant IgA nephropathy (6q22-q23) occurs at a frequency of 1×10^{-3} and may cause death in ~20% of the afflicted, despite dialysis.

►hair, ►kidney diseases, ►skin diseases, ►telangiectasis, ►complement, ►antibody, ►immunoglobulins, ►gene copy number

Glomerulosclerosis, Focal and Segmental, Familial:

Glomerulosclerosis involves increased urinary protein excretion and decreasing kidney function or even morbid kidney defects. The α -actinin gene at human chromosome 19q13.1 may be one of the causes for the stronger than normal binding of this protein to filamentous actin. Another dominant locus is in chromosome 11q22-q24 (encoding a transient receptor potential cation channel) and a recessive steroid-resistant NPHS2 gene has been assigned to 1q25-q31. The latter locus encodes the transmembrane protein podocin. ►actinin, ►actin, ►kidney diseases; Winn MP et al 2005 *Science* 308:1801.

Glomerulus (plural glomeruli): Cluster of blood vessels or nerve fibers.

Gloves: Gloves are frequently recommended for laboratory work when handling hazardous material or when contamination by hands must be avoided. Remember that surgical latex gloves easily develop invisible holes and permit unseen contamination of the hands. (Mercury penetrates latex disposable gloves in 15 seconds.) Latex gloves may cause (serious) allergic reactions to about 10% of the regular users and food allergies may aggravate it. Longer than 15-minute use of a latex glove may result in leakage. Organic solvents damage some plastic gloves and they may develop holes easily. For most operations neoprene gloves provide the greatest safety. For very hazardous material, the use of double gloves may be advisable. Washing hands after the removal of the gloves is recommended. (See laboratory safety).

GLT: ►GAST

Glucagon: A polypeptide hormone secreted by the α cells of the pancreas when the level of blood glucose sinks below a certain level. The hormone then increases the concentration of blood sugar by breaking down glycogen with the cooperation of epinephrine. ►epinephrine, ►animal hormones, ►cAMP, ►diabetes mellitus

Glucan: A polymer (repeating units) of glucose, the same as glucosan. ►[glucosan](#)

Glucanase: Glucan-digesting enzyme. ►[glucan](#), ►[host–pathogen relation](#)

Glucocorticoid: A kidney cortex hormone which regulates carbohydrate, lipid, and protein metabolism, muscle tone, blood pressure, the nervous system, etc. It inhibits the release of adrenocorticotropin, slows down cartilage synthesis, and mitigates inflammation, allergy and various immunological responses. Cortisol (hydroxycortisone) is an important natural glucocorticoid, whereas dexamethasone is a synthetic product that is two orders of magnitude more potent than cortisol. The glucocorticoid-mediated immunosuppression involves the activation of the I κ B α gene and an increase of its cytoplasmic protein product. When the nuclear regulator factor NF- κ B is active (because of the expression of TNF), its inhibitor, the I κ B α protein is degraded and NF- κ B moves into the nucleus and activates the immune system. Dexamethasone—in contrast with natural glucocorticoids—causes an increased transcription of I κ B α . Thus, the NF- κ B translocation to the nucleus is inhibited, leading to less nuclear NF- κ B and reduction of inflammation because the immune system is suppressed. Familial and sporadic glucocorticoid deficiencies are caused by defective adrenocorticotrophic hormone receptors. Glucocorticoids can affect serotonin levels and brain function. The deficiency of the glucocorticoid receptor (94-kDa, encoded at 5q31) causes cortisol and dexamethasone resistance. The melanocortin unresponsiveness is due to receptor deficiency at 18p11.2. The glucocorticoid receptor is an indispensable transcription factor, and it can attach to naked DNA as well as to nucleosomal structures. ►[adrenocorticotropin](#), ►[NF- \$\kappa\$ B](#), ►[I \$\kappa\$ B](#), ►[cortisol](#), ►[dexamethasone](#), ►[opiocortin](#), ►[immunosuppression](#), ►[apoptosis](#), ►[Cushing syndrome](#), ►[calreticulin](#), ►[immunophilins](#), ►[GRE](#), ►[stress](#), ►[serotonin](#), ►[allergy](#)

Glucocorticoid Response Elements (GRE): GREs are located generally about 100 to 2,000 nucleotide pairs upstream from the transcription initiation site (the human growth hormone response element is within the transcribed region). These elements, such as the mammary tumor virus (MTV), metallothionein (MTIIA), tyrosine oxidase (TO), and the tyrosine amino transferase receptor element, respond to different activating proteins as indicated by their names. Despite differences in structure they share a consensus: CGTACANNNTGTTCT. ►[hormone response elements](#), ►[regulation of gene activity](#), ►[DNA looping](#), ►[mammary tumor virus](#), ►[metallothionein](#),

►[tyrosine aminotransferase](#); Herrlich P 2001 *Oncogene* 20:2465.

Glucogenic Amino Acids: Glucogenic amino acids can be converted into glucose or glycogen through pyruvate (alanine, cysteine, glycine, serine, tryptophan), α -ketoglutarate (arginine, glutamine, histidine, proline), succinyl CoA (isoleucine, methionine, threonine, valine), fumarate, (phenylalanine, tyrosine) and oxaloacetate (asparagine, aspartate). ►[amino acids](#)

Glucokinase (GK): GK phosphorylates glucose to form glucose-6-phosphate. Heterozygosity for GK mutation in the fetus may cause mild hyperglycemia and may reduce insulin secretion by the fetus resulting in reduced intrauterine growth. In case of maternal glucokinase mutation, hyperglycemia stimulates fetal insulin secretion and increase in growth. ►[insulin](#); Grimsby J et al 2003 *Science* 301:370.

Gluconeogenesis: Gluconeogenesis is the synthesis of sugars from non-carbohydrate precursors (such as oxaloacetate, pyruvate, citrate, malate, TORC).

Glucosan (polyglucosan): Different types of polysaccharides (starch, glycogen, cellulose) containing repeating glucose subunits.

Glucose (glycose): A 6-carbon sugar (dextrose), an aldohexose. Besides being a source of energy, it induces and represses many genes. In chemostat cultures of yeast on galactose media, by small pulses of glucose additions, ~25% of the genes changed their expression (monitored by microarrays) primarily due to five transcription factors (Ronen M, Botstein D 2006 *Proc Natl Acad Sci USA* 103:389). Glucose influx triggers gene expression changes in hepatocytes to suppress endogenous glucose production and convert excess glucose into glycogen or fatty acids to be stored in adipose tissue. This process is controlled by insulin. Glucose also regulates the activity of ChREBP, a transcription factor that modulates lipogenesis. Glucose binds and stimulates the transcriptional activity of the liver X receptor (LXR), a nuclear receptor that coordinates hepatic lipid metabolism (Mitro N et al 2007 *Nature [Lond]* 445:219). ►[galactose](#) [for formula], ►[insulin](#), ►[lipidogenesis](#)

Glucose Effect: A form of catabolite repression when as long as glucose is available in the nutrient medium, the synthesis of enzymes involved in the utilization of other carbohydrates is prevented. The preferential growth on, e.g., glucose is followed by a temporary pause before the utilization of another carbon source is commonly called *diauxic growth*. Glucose may act at three levels: (1) inhibits the uptake of inducer molecules by relying on the dephosphorylated component of the phosphoenolpyruvate-dependent

glucose phosphotransferase. (2) Lowers the level of cAMP and its receptor and activates indirectly adenylate cyclase. (3) Increases the level of catabolites that repress the synthesis of inducible enzymes. In fungi, the mechanism of glucose effect may be mediated through the function of hexokinase. In yeast, *SNF1* (sucrose non-fermenting) encoding a transactivator protein (protein threonine/serine kinase) gene can relieve *SUC* and *GAL* glucose repression. The Mig1/CREA Zinc-finger DNA-binding protein, Glc7 protein phosphatase and the Tup1 general suppressor have also been implicated in the regulation. Two glucose signaling loci (*gsf1* and 2) also affect the glucose repression of *SUC2* and *Gall10*. Glucose suppression has been analyzed in prokaryotes and lower and higher eukaryotes, animals as well as plants. The *PRL1* locus of *Arabidopsis* encodes an α -importin WD protein that regulates glucose/sucrose sensitivity as well as hormone responses in the plant. ►feedback control, ►repression, ►catabolite repression, ►Zinc finger, ►Tup1, ►WD-40, ►SW1, ►transactivator, ►SUC2, ►GAL; Ronne H 1995 Trends Genet 11:12; Németh K et al 1998 Genes & Development 12:3059; Stülke J, Hillen W 1999 Curr Opin Microbiol 2:195; Rolland F et al 2002 Plant Cell 14:S185.

Glucose Induction: Glucose sensors *SNF* and *RGT1* genes monitor glucose in the cell membrane of yeast. Glucose most likely causes a conformation change in these proteins by attaching to their N-terminal domains outside the cell membrane. Both of these are transmembrane proteins with their C-terminus tail within the cytoplasm. That tail probably recruits the Hxt glucose transporters. The transcriptional suppressor Zn-finger protein, Rgt1, represses the *HXT* glucose transporter genes and the SCF^{Grr1} complex inhibits Rgt1 (regulator of transport) when a low concentration of glucose appears in the culture medium. (SCF is an acronym for Skp1, Cdc53 and Cdc34; it includes an F-box protein. Grr is a Cdc34-dependent protein factor of ubiquitination of cyclins). Then, *HXT* genes are activated. When the level of sucrose is increased beyond a certain level, the Mig1 suppressor system becomes active. When the concentration of glucose becomes high, Rgt1 turns into an activator of *HXT1*. ►glucose effect, ►SNF, ►SCF, ►Skp, ►Cdc34, ►Cdc53, ►F-box, ►glucose transporters; Vaultont S et al 2000 J Biol Chem 275:31555.

Glucose Repression: ►glucose effect

Glucose Tolerance Test: ►diabetes

Glucose Toxicity: Normally, insulin regulates the physiological range of glucose in the cells. When the level of glucose is raised for a longer period of

time, glucose toxicity results. Glucose may generate reactive oxygen species (ROS). Antioxidants as well as binding transcription factors PDX-1/STF and RIPE-3b1 to the insulin promoter may increase insulin production and reduce toxicity. (See Shimoi K et al 2001 Mutation Res 480–481:371).

Glucose Transporters: GLUT (12p13.3) is a 49-kDa protein involved in moving glucose. GLUT2 (3q26.1-q26.3) is another solute/sugar carrier (Fanconi-Bickel syndrome). GLUT1 (1p35-p31.3) mediates sugar transport to the brain across the blood/brain barrier membrane. The GLUT4 (17p13) defect seems to be involved in the resistance to insulin in diabetes type 2. GLUT5 (1p36.2) is a fructose transporter. GLUT10 (20q13.1) deficiency upregulated TGF. ►diabetes, ►BBB; Brown GK 2000 J Inher Metab Dis 23:237; Coucke PJ et al 2006 Nature Genet 38:452.

Glucose-Galactose Malabsorption (GGM): ►SGLT

Glucose-6-Phosphate Dehydrogenase: The first enzyme in the pentosephosphate pathway that converts G-6-P into 6-phosphoglucone- δ -lactone (see Fig. G45). The final product of the pathway is D-ribose-5-phosphate, and NADPH is also generated. Although about 90% of the cellular glucose in mammals is converted to lactate by glycolysis, 10% is driven through the pentose phosphate path and this is the principal reaction to provide the erythrocytes with NADPH for the reduction of glutathion. The deficiency of the enzyme caused by Xq28-chromosomal genes was first identified as a hemolytic anemia caused by the antimalarial drug 8-aminoquinoline. Most of the afflicted individuals are essentially asymptomatic until exposed to drugs such as certain analgesics, sulfonamides, antimalarial drugs (atabrine), quinine, etc., or afflicted by other diseases (see Fig. G46). G-6-P dehydrogenase deficiency is widespread in human populations, probably because the heterozygotes and hemizygous males are protected against falciparum malaria by a 46–58% reduction of the infectious disease. Heterozygotes (XX) may display lyonization. In the Jewish populations of Kurdistan, Caucasus, and Iraq, the frequency of the defect reached 58.2, 28.0 and 24.8%, respectively, whereas in geographical areas free of malaria it was generally less than 2%. Cavalli-Sforza and Bodmer estimated that G-6-P dehydrogenase deficiency conveyed an extremely high 0.15% selective advantage against malaria (Saunders MA et al 2002 Genetics 162:1849). A similar sequence is situated in human chromosome 17 and it may be a pseudogene. ►analgesic, ►malaria, ►selection coefficient, ►selection conditions, ►pentose phosphate pathway, ►glycolysis, ►glutathion, ►glycogen storage

diseases, ►atabrine; Tishkoff SA et al 2001 Science 293:455; <http://www.rubic.rdg.ac.uk/g6pd/>.

Figure G45. Glucose-6-phosphate

Figure G46. G-6-P deficient erythrocyte peripheral "BITE"

Glucose-Phosphate Isomerase: ►phosphohexose isomerase

Glucosidase (GCS1): An enzyme that digests 1,2-N-linked glycoproteins and other glucose linkages; in humans it is encoded in chromosome 2p13-p12. ►acid maltase, ►Pompe diseases, ►Gaucher disease

Glucosides: When D-(+) glucose is treated with an alcohol (methanol) and HCl, methyl D-(+)glucoside is formed that still has one methyl group attached, yet its properties resemble that of an acetal. Acetals may be formed from aldehydes and they are common in different plants. Cardiac glucosides present in plants such as *Digitalis*, *Scilla*, etc. have cardiotonic effect (strengthen heart function) and used as medicine. Many of the plant glucosides are highly toxic and cause anorexia (loss of appetite), nausea, vomiting, salivation, diarrhea, headache, drowsiness, delirium, hallucinations, and possibly death. Glycosides linked to cyanides also occur in common food plants such as beans, apricot, and almond seed, etc. Forage plants such as Sudan grass, white clover, etc. may contain enough cyanide to kill a 50 kg animal if it eats 1 to 2 kg fresh plant material. Through plant breeding efforts, the synthesis of the glucoside (lotoaustralin) may be blocked or the production of the enzyme linamarase may reduce the toxicity. ►lotoaustralin, ►cyanide; Tattersall DB et al 2001 Science 293:1826.

Glycosylation: Attaching glucose to another molecule. Defective N-glycosylation is the cause of mucopolisaccharidosis II and impacts the immune systems. Glycosylation has many important consequences on plant metabolism. ►mucopolisaccharidosis, ►glycosylation,

►congenital disorders of glycosylation; Lowe JB 2001 Cell 104:809; congenital disorders: Jaeken J, Matthijs G 2007 Annu Rev Genomics Hum Genet 8:261.

Glucuronic Acid: A derivative of uronic acid (a derivative of glucose) and it is present in glucosaminoglycans (see Fig. G47). ►mucopolysaccharidosis, ►GUS

Figure G47. D-glucuronic acid

Glume: The lower-most bract of the grass florets (see Fig. G48). The glume is generally free from the fruit, in some cases however, it may be firmly associated with the kernels.

Figure G48. Glumes

GluR: ►glutamate receptor

GLUTs: Insulin-dependent glucose transporters encoded by the genes SLC. GLUT may be homologous to the cJun amino-terminal kinase-interacting protein JIP. MAPK81P1 (11p11.2-p12), a potential SLC transactivator, may be a major gene for type-2 diabetes. There are also several other glucose transporters. ►insulin, ►MAPK, ►diabetes, ►MODY, ►MAPK; Doege H et al 2001 Biochem J 359[pt2]:443)

Glutamate ($\text{HOOCCH}[\text{NH}_2]\text{CH}_2\text{CH}_2\text{CONH}_2$): An uncharged derivative of glutamic acid, which also has a key role as a nitrogen donor in the cell. The glutamate neurotransmitter activates the glutamate receptors (iGluR) regulating ion uptake and (mGluR) nerve synaptic strength and frequency. Mitochondrial glutamate facilitates insulin secretion. ►amino acids, ►glutamine, ►glutamate synthase, ►glutamate synthetase, ►neurotransmitter

Glutamate Decarboxylase Deficiency Disease (GAD):

A pyridoxine-dependent epilepsy. The two enzymes require the cofactor pyridoxal phosphate. These enzymes convert glutamic acid into γ -aminobutyric acid (GABA) that controls neurotransmission in vertebrates and invertebrates. The phenotype is autosomal recessive (GAD1 at 2q31, GAD2 at 10p11.23).

►epilepsy, ►GABA, ►amino acid metabolism

Glutamate Dehydrogenase (M_r 330,000):

Glutamate dehydrogenase catalyzes oxidative deamination of glutamate in the mitochondria, resulting in the formation of α -ketoglutarate. The reaction requires NAD^+ or $NADP^+$ as cofactors and is regulated allosterically by GTP and ADP. Then in turn, α -ketoglutarate and ammonia may again form glutamate. If the concentration of NH_3 is low, glutamate dehydrogenase cannot function to an appreciable extent. In such a case, NH_3 plus glutamate are converted to glutamine by non-adenylylated glutamine synthetase. In the presence of high amount of NH_3 , glutamine synthetase is adenylylated and becomes inactive and in this form it represses its own synthesis (autoregulation). In its non-adenylylated state (when the level of ammonia is low), it represses glutamate dehydrogenase instead. From glutamine and α -ketoglutarate, glutamate can be synthesized by glutamate synthase in the presence of $NADPH + H^+$. Glutamate synthase also serves as an inducer for tryptophan permease, which together with tryptophan transaminase may also contribute to glutamate synthesis. In its non-adenylylated state, glutamine synthetase activates also the histidine utilization operon (*hut*). This operon also yields glutamate and ammonia. In humans, a small multienzyme family codes this enzyme (GLUD); its level is relatively high in the brain. The principal and functional *GLUD1* is located in human chromosome 10q23. This gene is homologous to mouse locus *Glud-2* in chromosome 14. ►UTase, ►glutamate synthase, ►olivopontocerebellar atrophy, ►autoregulation

Glutamate Formiminotransferase: An autosomal recessive deficiency of this enzyme leads to the accumulation of formiminoglutamate and folic acid in the urine and in the serum causing physical and mental retardation (see Fig. G49). ►amino acid metabolism, ►mental retardation

Glutamate Oxaloacetate Transaminase (GOT2): GOT2 is encoded in human chromosome 16q21 but the protein is mitochondrially located. In many plants and lower animals, the enzyme is mitochondrially

Figure G49. Formiminoglutamate

coded. Pseudogenes were found at two locations in human chromosome 1 and in chromosome 12.

►mtDNA, ►aspartate aminotransferase mitochondrial, ►tyrosine aminotransferase

Glutamate Receptors (GluR): GluR are cation channels mediating the post-synaptic current in the central neurons. Certain mutations in GluR-B subunits lead to increased calcium uptake and concomitant seizures if, e.g., the position 586 arginine prevents editing of pre-mRNA. The glutamate receptors are tetrameric. GluR genes with 63% to 16% homology to animal GluRs have been identified in both monocot and dicot plants with role in light signal transmission. ►neurotransmitters, ►NMDA, ►GABA, ►ion channels; Borges K, Dingledine R 2001 J Biol Chem 276:25929.

Glutamate Synthase: Glutamate synthase catalyzes the reaction that leads to: α -ketoglutarate + glutamine + $NADPH + H^+ \rightarrow 2$ glutamate + $NADP^+$. The result of the combined action of glutamate synthetase and glutamate synthase in bacteria is:

►glutamate dehydrogenase, ►glutamine, ►autoregulation

Glutamate Synthetase: Glutamate synthetase in *E. coli* is a ca. 800,000 M_r protein containing flavin, iron, and S^{2-} . ►glutamate synthase, ►glutamate dehydrogenase, ►glutamic acid, ►glutamine, ►autoregulation

Glutamate Transporter: ►GLAST

Glutamate-Pyruvate Transaminase (GPT1): GPT1 catalyzes the reversible reaction:

The soluble enzyme is encoded in human chromosome 8q24.2-qter. Cytosolic and mitochondrial forms exist. It is also called alanine aminotransferase (AAT1). ►amino, ►acid metabolism; ►glutamine; ►alanine aminotransferase

Glutamic Acid: $\text{HOOC} \cdot \text{CH}(\text{NH}_2) \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{COOH}$ (L(+), amino-glutaric acid)

Glutaminase (GLS): An enzyme converting glutamine into glutamic acid and it has been mapped to human chromosome 2q32-q34. It is activated by phosphate and may affect the neurotransmitter role of glutamate. ▶ amino acid metabolism, ▶ glutamine, ▶ glutamic acid

Glutamine: $\text{HOOC} \cdot \text{CH}(\text{NH}_2) \cdot (\text{CH}_2)_2 \cdot \text{C}(\text{O})\text{NH}_2$. ▶ glutamic acid

Glutamine Amidotransferases: A group of enzymes with two domains, one binds glutamine and the other binds another molecule. After cleaving ammonia from glutamine they transfer it to the other substrate, generally in the presence of ATP.

Glutamine-Repeat Diseases: ▶ Huntington's chorea, ▶ Kennedy disease, ▶ dentatorubral-pallidolusian atrophy, ▶ olivopontocerebral atrophy, ▶ Macho-Joseph disease, ▶ fragile sites, ▶ trinucleotide repeat

Glutamyl Ribose-5-Phosphate Glycoproteinosis: An ADP ribose protein hydrolase deficiency resulting in proteinuria and neurological disorders. It is also regarded as a lysosomal storage disease. It may be X-linked. ▶ lysosomal storage diseases

Glutamyl-tRNA Synthetase (QARS): The enzyme charging the cognate tRNA with glutamic acid; it is encoded in human chromosome 1q32-q34. ▶ aminocyl tRNA synthetase

Glutaraldehyde: ▶ fixatives

Glutaredoxin: Glutaredoxin catalyzes NADPH-dependent reduction of disulfides usually in a complex with glutathione and glutathione reductase. ▶ thioredoxin, ▶ DsbA

Glutaricacidemia (GA): GAI autosomal recessive (19p13.2) glutaryl-CoA dehydrogenase deficiency results in increase in glutaric acid in the blood and in the urine resulting in neurodegenerative disorders. GAIC encoded in human chromosome 4q32-qter involves deficiency in the electron transfer flavoprotein oxidoreductase. GAIIA (15q23-q25) causes the excretion, besides glutaric acid, also lactic, ethylmalonic, isovaleric and different forms of butyric acids. Similarly, an X-linked (Xq26-q28) acyl-CoA dehydrogenase deficiency results in the abnormal excretion of glutaric and other organic acids. ▶ glutaricaciduria, ▶ aminoacidurias

Glutaricaciduria: An autosomal recessive glutaryl-CoA dehydrogenase deficiency leading to accumulation of glutaric acid in the urine, degeneration of the nervous system, and impairment of muscle functions. Limiting amino acid intake may alleviate the

symptoms. An autosomal dominant form (15q23-q25) was identified as a defect in an electron-transfer flavoprotein. Some glutaricacidemias are also called glutaricaciduria, e.g., glutaryl-CoA dehydrogenase deficiency (GAI, 19p13.2). Glutaricaciduria IIC (GAIIIC) was assigned to 4q32-qter. ▶ neuromuscular diseases, ▶ aminoacidurias, ▶ glutaricacidemia

Glutathione: Glutathione or γ -L-glutamyl-L-cysteinylglycine is a reducing agent that protects SH groups in proteins. About 10% of the blood glucose is oxidized to 6-phosphogluconate by glucose-6-phosphate dehydrogenase (G6PD) using NADP^+ , and the reducer NADPH keeps glutathione reduced. Deficiency of G6PD results in destruction of red blood cells and thus anemia. Glutathione is indispensable for development. Protozoa with anaerobic metabolism lack glutathione and mitochondria. ▶ glucose-6-phosphate dehydrogenase; Meister A 1988 J Biol Chem 263:17205; Spector D et al 2001 J Biol Chem 276:7011.

Glutathione Peroxidase (GPX1): GPX1 was assigned to human chromosome 3p21.3 (earlier it was assigned to 3q11). Its deficiency causes hemolysis and jaundice. The frequency of the GPX1 gene is >0.5 in Mediterranean Jewish populations but it is <0.2 in Northern Europeans. Locus GPX2 is in 14q24.1, GPX2 is in 5q32-q33.1, and GPX4 is in 19p13.3. The ailment may also be caused by selenium-deficient diet. ▶ hemolytic anemia, ▶ glutathione reductase, ▶ glutathione synthetase, ▶ deficiency

Glutathione Reductase (GSR): The GSR gene was located to human chromosome 8p21. Its deficiency results in hemolytic anemia. In insects thioredoxin substitutes for GSR. ▶ hemolytic anemia

Glutathione Synthetase Deficiency: A form of human chromosome 20q11.2 recessive hemolytic anemia and/or 5-oxoprolineuria. It may also result in excess metabolic pyroglutamic acid in the urine and in a variety of ailments. GST2 (γ -glutamylcysteine synthetase) gene was assigned to human chromosome 6p12 also causes hemolytic anemia. ▶ hemolytic anemia, ▶ glutathione, ▶ anemia

Glutathione-S-Transferases (GST): A family of enzymes metabolizing and detoxifying mutagens and carcinogens (some alkylating agents, cisplatin, carbonyl, peroxide, and epoxide groups) GST 3 was assigned to 11q13, GST2 to 6p12, GST1, GST4, GST5 all at 1p13.3. GSTPL (glutathione transferase-like enzyme) is encoded in 12q13-q14. These enzymes, despite different locations of the coding units, show homology. GST is also used for protein labeling. It is extremely stable and facilitates the solubilization of proteins fused with. ▶ multidrug resistance, ▶ cisplatin

Glutathionuria (GGT): A recessive defect (human chromosome 22q11.1-q11.2) in γ -glutamyl transpeptidase enzyme and accumulation of glutathione in the urine.

Gluten: A mixture of several seed proteins in cereals. The main fractions are the alcohol-soluble gliadin and the alkali-soluble glutenin. The proportion of the components is genetically determined and defines nutritional value and baking quality. ►glutenin, ►zein

Glutenin: Glutenin is about half of the seed storage protein in wheat; it is soluble in 70% ethanol and alkali but insoluble in water. It is a polymer of extremely large molecular weight, up to tens of millions. Its composition bears similarity to the muscle protein titin, comprising about 27,000 amino acid residues. The similarities based on (PEVK) proline, glutamate, valine, and lysine sequences may be attributed to the fact that both proteins require great elasticity in the bread dough. It was (indirectly selected by humans) to retain gas bubbles in the dough to return to the original position after extension. In wheat, gliadin occurs with glutenin. The former conveys resistance to extension while the latter provides the softness and viscosity of the dough. ►gluten, ►gliadin, ►celiac disease, ►Triticum, ►resilin; Kobrehel K et al 1992 Plant Physiol 99:919.

Glycan: A general old term for polysaccharides. Glycans associated with proteins have very important role in the cell (immune system, transport, etc.) and defects in their synthesis or association are involved in a large number of human diseases (galactosemia, fucosidosis, etc). ►lectins, ►polysaccharide, ►immune response; Lowe JB, Marth JD 2003 Annu Rev Biochem 72:643; bacterial glycans in immune response: Comstock LE, Kasper DL 2006 Cell 126:847; glycans technologies: Prescher JA, Bertozzi CR 2006 Cell 126:851.

Glycemia: Blood sugar content.

Glycerol ($\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2\text{OH}$): An intermediate in carbohydrate and lipid biosynthesis.

Glycerol Kinase Deficiency (GKD, Xp21-p21.2): Physical and mental retardation, osteoporosis, myopathy, eye defects, and hyperglycerolemia. Chromosomal deletions may overlap with several other genes in the region of the X chromosome. ►contiguous gene syndrome; Gaudet D et al 2000 Am J Hum Genet 66:1558.

Glycerophospholipid: Glycerophospholipids are formed when fatty acids are esterified to glycerol and a polar alcohol is linked to it by phosphodiester bond. They are parts of cell membranes (synonymous with phosphoglycerides).

Glycine Biosynthesis: Glycine ($\text{NH}_2\text{CH}_2\text{COOH}$) is synthesized by hydroxymethyltrans-ferase from serine ($\text{HOCH}_2\text{CH}(\text{NH}_2)\text{COOH}$), while tetrahydrofolate is converted to N^5,N^{10} methylene tetrahydrofolate. The transferase gene has been located to human chromosome 12q12-q14, whereas the tetrahydrofolate cyclases are in human chromosomes 8q21, 18qter. Glycine is synthesized alternatively from CO_2 and NH_4 by glycine synthase in the liver of vertebrates. ►glycinemia ketotic, ►hyperglycinemia

Glycine max (soybean): A leguminous plant (basic chromosome number 20). The seed contains 20 to 23% oil and its protein content (meal) may exceed 40%. It is one of the most important source for vegetable oil products and textured proteins for human food. Also, it is used as supplements to animal feed mixtures.

Glycinemia, Ketotic (PCC): PCC is caused by two genes at two human chromosomal locations (PCCB at 3q21-q22 and PCCA at 13q32). The biochemical defect is propionyl-CoA carboxylase deficiency. This enzyme's primary known role is the generation of D-methyl-malonyl-CoA, which is epimerized into the L form and subsequently by a mutase—with vitamin B12 cofactor—to succinyl-CoA. These processes concomitantly somehow produce ketosis, hypoglycemia, and hyperglycinemia. The symptoms are growth retardation, vomiting, lethargy, protein intolerance, low level of neutrophilic leukocytes, reduction in platelet number, etc. ►ketoacidosis, ►amino acid metabolism, ►glycine biosynthesis, ►methylmalonicaciduria, ►hyperglycinemia

Glycocalyx: A carbohydrate-rich membrane glycoprotein-lipid layer of prokaryotic and eukaryotic cell surface.

Glycoform: Proteins with differences in glycosylation. ►glycosylation

Glycogen: The main storage polysaccharide in animal cells. About 7% of the wet weight of the liver is glycogen and glycogen is present in the muscle cells too. It is branched at every 8 to 12 residues. As needed, glycogen is hydrolyzed into glucose to supply energy, with the aid of enzymes that are associated with its granular form. Glycogen is synthesized from glucose-6-phosphate by first being changed into glucose-1-phosphate by phosphoglucomutase. Then UDP-glucose pyrophosphorylase converts G-1-P and UTP into UDP-glucose and pyrophosphate (PPi). Glycogen synthase then converts UDP-glucose into glycogen. *Glycogen synthase a* is the dephosphorylated active form of the enzyme, whereas the phosphorylated *glycogen synthase b* is inactive. The reaction requires a primer of α 1-4 polyglucose and the protein glycogenin. The branching is generated by

branching enzymes amylo-(1→4) to (1→6) transglucosylase or glycosyl-(4→6) transferase. The glycogen metabolism is regulated by glucagon and insulin in the liver and mainly by epinephrine and insulin in the muscles. The level of glucagon is regulated by cAMP. *Glycogen synthase kinase-3* regulates glycogen and protein synthesis by insulin and modulates transcription factor AP-1, CREB, the dorso-ventral patterning of embryogenesis, and apoptosis. ▶epinephrine, ▶insulin, ▶diseases, ▶AP, ▶CREB, ▶Akt, ▶PTG; Weston CR, Davis RJ 2001 Science 292:2439.

Glycogen Storage Diseases: Several hereditary defects have been identified as being associated with the synthesis and catabolism of glycogen: 1. *von Gierke's disease* (type I glycogen storage disease, 17q21) involves a deficiency of glucose-6-phosphatase, determined by an autosomal recessive gene (see Fig. G50). The patients develop liver enlargement (hepatomegaly as indicated by the extended abdomen, see photo), subnormal level of blood sugar content (hypoglycemia), increased levels of ketone bodies (acetone) in tissues and fluids (ketosis), as well as high amounts of lactic and uric acids in the blood. 2. *Type II glycogen disease* (Pompe disease, GAA, chromosome 17q25.2-q25.3) is determined by an autosomal recessive condition causing a deficiency of lysosomal α -1,4-glucosidase (acid maltase). Infants develop excessive enlargement of the heart (cardiomegaly) because of the deposition of glycogen in the lysosomes and, under severe conditions, in the heart. By the age of two they succumb to cardiorespiratory failure. The defect can be diagnosed prenatally from amniocentesis. A milder form of the disease exists, with prolonged survival. Intravenous injection of the normal GAA gene in an adenovirus vector construct significantly alleviated the disease in a mouse model. 3. *Type III glycogen disease* (see Forbes disease) is also caused by autosomal recessive (1p21) mutations. The basic physiological defects involve, in variable forms, the glycogen debranching process. The symptoms are not as severe as in Type II disease and the patients may survive longer; with age some of the symptoms may even be somewhat alleviated. 4. *Type IV disease* involves a 3p21 recessive defect of the glycogen branching enzymes. The progressive destruction of liver cells is accompanied by an increase in connective tissues and the liver substance (cirrhosis). An increase in the size of the liver and spleen and accumulation of fluids in the abdominal cavity (ascites) results in death before age two. 5. In *Type V McArdle's disease* (chromosome 11q13), the homozygosity of autosomal recessive glucose-6-phosphate translocase gene causes variable symptoms accompanied by glycogen accumulation. Phosphorylating activity in the muscle tissues is deficient. Painful cramps accompanying physical

exercise are the first symptom of the disease, the onset of which is around age 20. There is no hypoglycemia or increase of lactate in the blood but some patients excrete myoglobins in the urine. 6. *Type VI* (chromosome 14q21-q22) patients accumulate glycogen and some show reduced phosphorylating activity. 7. *Type VII disease* (Tarui disease), determined by chromosome 12q13.3 recessive genes, resembles Type V disease but the patients have reduced phosphofructokinase activity as well. 8. *Type VIII glycogen storage disease* is caused by a Xp22.2-p22.1-chromosomal recessive gene and thus affects primarily males. It is based on a leukocyte phosphorylase b activation deficiency. Some glycogen diseases involve multiple enzyme defects. These diseases are frequently associated with muscle weakness and various other adverse effects. ▶glucose-6-phosphate dehydrogenase, ▶glycogen, ▶epilepsy, ▶acid maltase deficiency, ▶neuromuscular disease, ▶enzyme replacement therapy

Figure G50. Glycogen storage diseases

Glycogen Synthase: ▶glycogen

Glycogenosis: The term “glycogenosis” is used to designate glycogen storage diseases. ▶glycogen storage

Glycolipid: A lipid with a carbohydrate group. Glycolipids are derivatives of sphingosine with one or more sugar. ▶sphingosine

Glycolysis: The catabolic pathway from carbohydrates to pyruvate; anaerobic breakdown of glucose for the synthesis of ATP. ▶Embden-Meyerhof pathway, ▶pentose monophosphate shunt

Glycome: The sugar chains in the cell, including glycosylated proteins, chaperones, and lipids. The size of glycomes exceeds that of proteins by orders of magnitude. Large numbers of human diseases are caused by disorders of the glycome (Freeze HH 2006 Nature Rev Genet 7:537). ▶glycosylation, ▶phosphomannomutase deficiency, ▶phosphomannose isomerase, ▶glycosyltransferases, ▶mannosyltransferases, ▶glycosidase, ▶lissencephaly,

►Ehlers-Danlos syndrome, ►exostosis, ►Kniest dysplasia, ►glycolipids, ►mucopolidoses, ►mucopolysaccharidosis, ►galactosemia, ►fructose intolerance, ►Marfan syndrome, ►muscular dystrophy; ►Walker-Warburg syndrome, ►thrombocytopenia, ►leucopenia, ►leukotrienes, ►epilepsy; <http://www.glycosciences.de/>; <http://www.glyco.ac.ru/bcsdb/>.

Glycophorin: A 131 amino acid transmembrane glycoprotein. Serological glycophorin assays have been developed to detect somatic mutations. Glycophorin-spectrin/actin bridge determines membrane shape and stability. ►spectrin, ►actin; Gerber D, Shai Y 2001 J Biol Chem 276:31229.

Glycoprotein: Proteins with covalently linked carbohydrate(s). ►proteoglycan; <http://www.cbs.dtu.dk/data/bases/OGLYCBASE/>.

Glycosaminoglycan (synonym mucopolysaccharide): A heteropoly-saccharide alternating *N*-acetylglucosamine + uronic acid and *N*-acetylgalactosamine + uronic acid (glucuronic acid). This family of compounds includes chitins, chondroitin sulfate, heparan, heparin, hyaluronic acid, keratans, and keratin (see Fig. G51). Chemokines interact with glycosaminoglycans and play roles in inflammation, and in developmental and homeostatic functions. ►exostosis, ►mucopolysaccharidosis, ►proteoglycan, ►chemokines, ►glucuronic acid, ►hyaluronidase deficiency; Constantopolous G, Dekaban AS 1975 Clin Chim Acta 59[3]:321; Handel TM et al 2005 Annu Rev Biochem 74:385.

Figure G51. Glucosamine

Glycose: The generic name of monosaccharides, e.g., glucose, fructose, mannose, etc.

Glycosidase: Glycosidase digests glycosidic bonds and transfers of glycosyl moieties from a donor sugar to an acceptor of another sugar or other molecule(s).

Glycosidic Bond: A sugar linked to either alcohol or purine, or pyrimidine or sugar through an oxygen or nitrogen atom. (See conformation maps: <http://www.glycosciences.de/modeling/glycomapsdb/>).

Glycosome: Peroxisomes (microbodies) filled with glycolytic enzymes. ►glycolysis, ►microbody

Glycosphingolipids: Glycosphingolipids are present in plasma membrane rafts and caveolae and play an important role in differentiation and development ►sphingolipid, ►caveolae, ►RAFT

Glycosuria: An incompletely recessive defect in glucose reabsorption by the kidney, resulting in high sugar level in the urine. ►phlorizin, ►disaccharide intolerance

Glycosylases: Enzymes involved in excision of damaged purines and pyrimidines from the sugar-phosphate backbone of DNA. Different enzymes work on different bases (see Fig. G52). The uracil-DNA glycosylases (human gene UNG, chromosome 12q23-q24) remove uracils formed by spontaneous or induced deamination of cytosine, to avoid U-G mispairing potentially leading to GC→AT transitions.

Figure G52. T4-pdg (pyrimidine dimer glycosylase/AP lyase, a TDG) X-ray crystal structure as a ribbon diagram. The DNA is distorted and the flipped-out adenine and the thymine dimer are shown as ball and sticks. The 3' and 5' indicate the directions of the DNA strands. Gln23 is a mutant amino acid residue. (Courtesy of Lloyd, RS, see also McCullogh AK et al 1999 Annu Rev Biochem 68:266)

It works in the nucleus and the mitochondria as well. The thymine-DNA glycosylase (TDG/UDG, 12q24.1) is one of the most efficient of these repair enzymes. The enzyme pushes and pulls out the improper uracil nucleotide from the major groove of the DNA. Subsequently,

TDG excises U, AP endonuclease cleaves the DNA backbone, deoxyribo-phosphodiesterase removes the 5'-phosphate group, and DNA polymerase β replaces the correct nucleotide and ligase finishes the job. It has been estimated that in a human cell 100 to 500 cytosine residues are deaminated daily. MUG (mismatch-specific uracil DNA glycosylase, human

chromosome 12) removes uracil/thymine when mispaired with guanine. The human hSMUG1 operates primarily at single strands of DNA during replication and transcription. MBD4 glycosylase (3q21) may remove mismatched U or T nucleotides. The 3-methyladenine-DNA glycosylase (gene AAG/MPG, chromosome 16p-telomere) works on N-3- and N-7 methylation adducts of purines (including hypoxanthine) and cyclic adducts. The pyrimidine hydrate-DNA glycosylase removes damaged or altered pyrimidines. OGG1 (oxoguanine glycosylase, 3p25.3/ 3p26.2) removes 8-oxoguanine across cytosine. MYH (1p32.1-p34.3) glycosylase excises adenine when misincorporated across oxoguanine. The formamidopyrimidine-DNA glycosylase (NTHL1, 16p13.3-p13.2) excises oxidatively damaged purines such as 8-oxoguanine, 8-hydroxyguanine, thymine glycol, and cytosine glycole, but requires the cofactor XPG (xeroderma pigmentosum G, 13q33). This DNA glycosylase also removes deaminated 5-methylcytosines that are common in eukaryotic DNA. All these excision repair enzymes maintain the working conditions of the human cells each of which suffers more than 10,000 damages each day. The yeast or *E. coli* glycosylases have similar functions but the proteins involved are different in size. ▶excinucleases; ▶AP endonucleases; ▶endonuclease III; ▶endonuclease VIII; ▶DNA repair; ▶mismatch repair; ▶transition; ▶adduct; ▶base flipping; ▶X-ray repair; ▶RAD27; ▶pyrimidine dimer; ▶cyclobutane ring; McCullough AK et al 1999 Annu Rev Biochem 68:255; Hollis T et al 2000 Mutation Res 460:201; Ischenko AA, Saparbaev MK 2002 Nature [Lond] 415:183; MuTM glycosylase: Banerjee A et al 2006 Science 311:1153.

Glycosylation: The attachment of sugars to proteins either through a hydroxyl group of serine or threonine (O-glycosylation, Ser[Thr]-O-GlcNAcylation), or to the amide group of an asparagine (N-glycosylation). Glycosylated proteins have many different types of cellular functions. O-glycosylation occurs in proteins of the nuclear pore, in RNA polymerase II, transcription factors, oncoproteins (tumor suppressors), chromatin proteins, microtubule-associated proteins, cytoskeletal binding proteins, tyrosine phosphatase, SV40 T antigen, estrogen receptors, etc. Some antibiotics (tunicamycin) interfere with the process. Glycosylation increases the stability of proteins and may facilitate antigen recognition, appropriate folding, signal transduction, nerve function, etc. It plays an important role in the function of the immune system in the reproductive cell paths and several other health-related metabolic functions. A search for glycosylation in the Human Gene Mutation Data Base revealed 77 genes with 142 glycosylation

mutations that seem to affect disease susceptibility (Vogt G et al 2005 Nature Genet 37:692). ▶glycoform, ▶glycosylation, ▶glycome, ▶sialic acid, ▶mycobacterium; Rudd PM et al 2001 Science 291:2370; Lübke T et al 2001 Nature Genet 28:73; Varki A 2006 Cell 126:841; glycosylation in health and disease: Ohtsubo K, Marth JD. 2006 Cell 126:855; glycobiology reviews: Nature [Lond] 446:1030–1051.

Glycosyltransferases: Enzymes adding glucose to proteins and lipids involved in the formation of lipopolysaccharides used for bacterial cell wall. The ABO blood group alleles also encode glycosyltransferases (also the B gene product adds galactose). These enzymes shape the cell surface, determine cell to cell contacts, play some role in cancer, and have an important function in various sphingolipidoses. ▶sphingolipidoses, ▶ABO blood group; Cosgrove DJ 1999 Annu Rev Plant Physiol Plant Mol Biol 50:391; may catalyze reversible reactions: Zhang C et al 2006 Science 313:1291.

Glyoxalase: Glyoxalase I adds SH group from glutathione to the aldehyde carbonyl of methylglyoxal. The thioester product is then hydrolyzed by glyoxalase II (see Fig. G53). Glyoxal: OHCCCHO. Methylglyoxal: CH₃COCHO. ▶enzyme design

Figure G53. Glyoxylate

Glyoxylate Cycle: The glyoxylate cycle converts acetate into succinate and finally to carbohydrate. ▶Krebs-Szentgyörgyi cycle

Glyoxysome: Vesicles in plant seeds and special type of microbodies (peroxisomes) in plants mediate the conversion of fatty acids to succinic acid to produce peroxiacetyl CoA and glucose through the glyoxylate cycle. ▶microbody, ▶glyoxylate cycle

Glyphosate: ▶herbicides, ▶GMO

Glypicans: Transmembrane proteins with phosphatidyl inositol distal to the membrane and heparan sulphate outside but proximal to the membrane. Glypican-1, -3, -5 are encoded at human chromosomes 2q35-q37, Xq26, and 13q31-q32, respectively. In mice, glypican-3 regulates a quantitative trait locus (QTL) involved in the body mass determination (Oliver F et al 2005 PLoS Biol 3(5):e135). ▶phosphatidylinositol, ▶heparan sulphate, ▶syndecan, ▶Simpson-Golabi-Behmel syndrome; Filmus J, Selleck SB 2001 J Clin Invest 108[4]:497.

GLYT: Glycine-specific transporters to the nervous system; they may be inhibitory neurotransmitters through a ligand-gated Cl^- channels, activated by glycine or may modulate glutamate-mediated neurotransmission. ►transporters, ►ion channels; Hanley JG et al 2000 J Biol Chem 275:840.

GM: ►GMO

GMENDEL: A computer program for analysis of segregation and linkage. (See Hered J 81:407 [1990]).

GM1-Gangliosidosis: ►gangliosidosis type I

GM2-Gangliosidosis: ►Tay-Sach disease, ►Sandhoff disease

GM3-Gangliosidosis: ►gangliosidosis type III, ►Sandhoff disease

GM3 Synthase: GM3 synthase produces gangliosides and glycolipids. Homozygous mutations cause infantile-onset epilepsy. ►epilepsy; Simpson MA et al 2004 Nature Genet 36:1225.

GMHT: (genetically modified herbicide-tolerant plants) have an agronomic advantage by facilitating the elimination of undesirable weeds from crops but they may adversely affect the population of wild birds that feed on weed seeds. ►GMO

GM-CSF: The granulocyte-macrophage colony stimulating growth factor is a lymphokine. ►lymphokines, ►macrophage, ►granulocyte, ►M-CSF, ►M-CSF, ►G-CSF; Collins SJ et al 2001 Blood 98:2382.

GMO: Genetically modified organisms; a name actually used for transgenic plants and animals (see Fig. G54). Consumers may oppose genetically modified (GM) food, fearing that the products may cause allergic reactions (e.g., Brazil nut albumins in transgenic soybean). The modified organisms develop antibiotic resistance (in case antibiotic resistance genes were used in the transformation vectors) or the transgene may be transcribed and translated into harmful substances. Lectins and alkaloids in the GMO may create human or environmental hazards (e.g., transmitting glyphosate herbicide-resistance by cross-pollination to weeds [*Cruciferae*], harming useful insects [e.g., neuropteran lacewings] or other species such as the Monarch butterfly [by Bt]). Ecologists have expressed concerns about the potential selective advantage of genetically modified plants in the natural environment. In a 10-year-long study of rape, maize, beet, and potato carrying various transgenes, it was found, however, that in general these were no more invasive than conventional crops (Crawley MJ et al 2001 Nature [Lond] 409:682). Although the actual extent of cross-pollination between transgenic and wild type plants is difficult to determine, indirect

assessment may be feasible and useful (Wilkinson MJ et al 2003 Science 302:457).

Figure G54. Monarch (*Danaus*) butterfly larva

Transgenic rice producing more β -carotene and accumulating more iron may not entail any danger, but can reduce malnutrition, anemia, and some kinds of blindness in the underdeveloped areas of the world. It is worth considering that the transgenic organisms may be easier, cheaper, and safer to produce because of they offer resistance to pests and diseases and facilitate the curtailing of hunger. The extensive use of chemical pesticides may be reduced. Insect-resistant GM rice yields more and protects the health of farmers because pesticides do not harm the workers (Huang J et al 2005 Science 308:688). These opposing facts may mandate some regulations and/or labeling of the products and further research to clarify the cost/benefit dilemmas. Genetically modified proteins in excess of 0.1% are detectable by ELISA and PCR detects DNA modifications when present at 0.01% in the sample. By 2005, more than 12% of the crops were transgenic and the acreage has been increasing since, without any evidence of harm to the consumer (Raven PH 2005 Proc Natl Acad Sci USA 102:13003).

Rainbow trout (*Onorhynchus*) or salmon carrying engineered growth hormone genes may grow dramatically larger, especially the non-domesticated forms, which had not been subjected to selection for increased productivity. Genetically engineered cows may produce milk with higher β - and κ -casein (Brophy B et al 2003 Nature Biotechnol 21:157). One study of cattle produced by somatic cloning (offspring obtained by transfer of somatic cell nuclei into enucleated eggs and subsequent pregnancy and birth) was analyzed in detail in comparison with sexually produced progeny for the normal milk composition, including antibodies. No significant differences were detected. In the comparative analysis of the meat no significant differences were found, except higher fatty acid components in the muscles and the increase mesentery fat (in the membranes covering internal organs) of the modified animals. Internal organs were histologically analyzed for possible pathological changes and abnormalities. In the kidney and urinary ducts, calculi (mineral stones) were found in the clones but these were often detected in normal beef

cattle. This relatively small-scale study does not indicate differences beyond the range of natural variations of the breeds (Tian XC et al 2005 Proc Natl Acad Sci USA 102:6261). Another study with potatoes transgenic for insulin-type fructans (sucrose: sucrose 1-fructosyl transferase and fructan:fructan 1-fructosyltransferase) indicated overall substantial similarity in composition compared to the non-transgenic (original) cultivar, as demonstrated by gas chromatography, capillary electrophoresis, and mass spectrometry (Catchpole GS et al 2005 Proc Natl Acad Sci USA 102:14458).

One must keep in mind that a type of genetic modification, selection, raised the sugar content of beets from ~2% to ~20% from the middle of the eighteenth century to the present. Similarly, purposeful plant breeding increased maize production from about 1.25 metric tons/hectare to ~15 tons since the 1930s. The “green revolution” doubled cereal production since the 1960s. Nevertheless, even today about 40,000 children die daily from malnutrition-related diseases. Obviously, technological progress will involve a trade-off. The only question is whether it is worth the exchange. There was a general fear in the 1970s about the use of recombinant DNAs even for laboratory purposes. Most of these fears turned out to be unfounded but certain types of genetic engineering (e.g., using toxin genes) can be carried out only in a highly controlled environment and only when there is a special, justified need. The arguments against and for genetically modified organisms must be based on scientifically validated facts, rather than on political views or preconceived notions. Existing information indicates relatively fast (100–150 days) decomposition of most (60–70%) of the Bt toxin in soil and even in plant tissues. Paracelsus/Theophrastus of Hohenheim (1493–1541), the ‘Luther of Medicine’, remarked: “Guilty is he who does not know it properly and who does not apply it properly” (see Fig. G55).

Figure G55. Paracelsus

Interestingly, William Shakespeare in his play *Winter's Tale* (1611) (Act. 4, Scene 4) addressed the problem of genetically modified organisms:

“POLIXENES

Say there be;

Yet Nature is made better by no mean

But Nature makes that mean: so, over that art

Which you say adds to Nature is an art

That Nature makes. You see, sweet maid; we marry

A gentler scion to the wildest stock,

And make conceive a bark of baser kind

By bud of nobler race: this is an art

Which does mend Nature change it rather, but

The art itself is Nature.” (I am indebted to Professor AT Szabó for calling my attention to this quotation).

GMP: Guanosine monophosphate.

GMS (genomic mismatch scanning): A method designed to scan large genomic DNA samples for differences in order to identify alterations, e.g., those responsible for hereditary disease. The principles are as follows: two DNA samples (diseased and healthy) are digested with restriction endonuclease. Fragments of one of the samples are methylated. Then both samples are denatured and allowed to hybridize. From re-annealed DNA only those strands are subjected to further study, which are hybrids (i.e., one of the two strands is methylated but other is not). These hybrids are exposed to bacterial mismatch repair enzymes that recognize mismatches and at that site nick the unmethylated strand. The nicked strands

are then removed and the intact duplexes retained. These would be expected to include the desired marker(s). The method is very elegant in principle but cannot yet be applied to the very complex human genome with great amount of redundancy and complexity. Single genetic regions can, however, be studied with the aid of array hybridization. ►RDA, ►mismatch repair, ►genetic screening, ►array hybridization; Mirzayans F, Walter MA 2001 *Methods Mol Biol* 175:37.

Gnotobiota: The known microbes (animals and plants) associated with laboratory animals. The animals might be raised under germfree conditions and infected with a single, specific bacterium.

GnRHA (gonadotropin-releasing hormone agonist): When administered at a constant rate, GnRHA shuts down mammalian reproductive functions and induces a condition resembling the menopause. It can be employed as a fertility-controlling agent but must be supplemented with periodic treatments with other hormones to prevent menopause-like side effects. It can be also used to save an implanted ovum or zygote by preventing ovulation. GnRHA has many other medical applications. ►gonadotropin releasing factor, ►egg donation, ►in vitro fertilization, ►ART, ►menopause, ►menstruation; Smits J et al 1992 *Hum Reprod* 1:49.

GNRP (guanine nucleotide releasing protein): It is involved in signal transduction with RAS and affect several cellular functions. A rather detailed review of its basic function is in Quilliam RL et al 2002 *Progr Nucleic Acid Res Mol Biol* 71:391). GNRP, when activated by receptor tyrosine kinase in the signal transduction pathway, a RAS protein switch is turned on. ►RAS, ►signal transduction; Marshall M 1995 *Mol Reprod Dev* 42[4]:493.

GO: A dormant stage of cell divisions in fission yeast. ►cell cycle, ►*Schizosaccharomyces pombe*

GO: ►gene ontology

G_o Protein: A subunit of the trimeric G-protein; it activates K⁺ channels and shuts down Ca²⁺ ion channels. Mutations in the gene encoding it cause behavioral anomalies in *Caenorhabditis* similar to those caused by a defect in the serotonin receptor. The main symptoms are hyperactivity, premature egg laying, and male impotence due to defects in neuronal and muscle functions. ►signal transduction, ►ion channels, ►serotonin, ►G_α

GO Units: ►gene ontology

Goat (*Capra hircus*): 2n = 60. It was probably the first large herbivorous domesticated animal. (See MacHugh DE & Bradley DG 2001 *Proc Natl Acad*

Sci USA 98:5382, <http://locus.jouy.inra.fr/cgi-bin/lgbcmapping/common/intro2.pl?Base=goat>).

Goat-Sheep Hybrids: The domesticated sheep (*Ovis aries*, 2n = 54) can be impregnated by the domesticated goat (*Capra hircus*, 2n = 60), but the hybrid embryo rarely develops normally although, occasionally some hybrids do grow up. ►animal species hybrids; Hancock JL et al 1968 *J Reprod Fertil* 3:29; Ilbery PL et al 1967 *Aust J Biol Sci* 20:1245.

GOBASE: An organelle genome database. ►organelle genetics, ►OMIA; <http://megasun.bch.umontreal.ca/gobase/>; <http://gobase.bcm.umontreal.ca/>.

GOGAT: Glutamine-2-oxoglutarate transferase. ►nitrogen fixation

Goiter, Familial: A collection of various metabolic anomalies involving enlargement of the thyroid gland that may become obvious by viewing the neck. The defect may involve various dominant or recessive mutations in the thyroglobulin gene. The thyroglobulin gene (TG) is located in human chromosome 8q24 extending to about 300-kb genomic DNA, containing 37 exons and large introns. The dimeric thyroglobulin protein has a molecular weight of ca. 660,000. This protein is iodinated at tyrosine residues to form mono- and diiodotyrosines. *Thyroxine* is a tetraiodothyronine but *triiodothyronine* is also formed upon activation by peroxidase. The iodinated proteins are transported by the blood, increase the metabolism, and regulate the function of the nervous system, kidney, liver and heart. *Hyperthyroidism* occurs due to the overproduction of iodinated thyroglobulin hormones, resulting in goiter, fast heart rate, fatigue, muscular weakness, heat intolerance and sweating, tremors, and emotional instability. Excessive secretion of thyroid hormones is referred to by the synonymous *Graves* or *Basedow* disease, with susceptibility controlled by several sites (14q31, 6p21, 7q, 8q, 10q, 2q33, 20q13, Xq21). The New Graves Disease maps to 18q21. The latter condition may or may not be genetic, although its frequency may be quite high (0.008). The basic defect may involve autoimmunity of the receptor of the hormone. *Hypothyroidism* is the consequence of the underproduction of the thyroid hormone, resulting in fatigue, lethargy, low metabolism, cold-sensitivity, and menstrual problems in females. This condition may lead to *cretinism*, which is most commonly caused by failure of releasing *thyrotropin*, the glycoprotein thyroid-stimulating hormone of the anterior pituitary. Cretinism also means an arrest of physical and mental development, and is caused by this hormonal deficiency.

Hypothyroidism may also lead to deafness. Defects in deiodination of iodotyrosines could also cause hypothyroidism. *Permanent congenital hypothyroidism* has a prevalence of ~ 3 to 4×10^{-4} in newborns and unless it is caused by hypothalamic or pituitary defects, it is accompanied by over-expression of the thyroid-stimulating hormone and lower-than-normal thyroid function or thyroid dysgenesis. Thyroid therapy is required within the first two months to prevent neurological damage (cretinism). In some cases, mutation of the Pax8 gene at human chromosome 2q12-q14 has been detected. PAX8 seems to be required for the differentiation of endoderm primordia into thyroxine-producing follicular cells. Goiter-like diseases are known in the majority of mammals. Thyroxine binding globulin is encoded in human chromosome Xq28 and a thyroxine binding serum globulin is autosomal. The multinodular goiter—with 5:1 female:male ratio—has been assigned to Xp22. [▶hyperthyroidism](#), [▶Hashimoto disease](#), [▶animal hormones](#), [▶tyrosine](#), [▶thyroid stimulating hormone](#), [▶PAX](#), [▶NIS](#), [▶Pendred syndrome](#), [▶CTLA-4](#); Tomer Y et al 1997 J Clin Endocr Metab 82:1645; Vaidya B et al 2000 Am J Hum Genet 66:1710.

Gold Standard Test: The gold standard test in clinical trial involves (i) random allocation of the treatment, (ii) concurrent control and (iii) double blind trial of the drug or the treatment. [▶double-blind test](#)

Goldberg-Hogness Box: [▶Hogness box](#)

Goldenhar Syndrome: Autosomal dominant and recessive forms with different expressions of facial and other developmental deformities.

Golgi Apparatus: Flat vesicles (cisternae) containing cellular storage and transport material involved in glycosylation, sulfation, proteolysis, etc., in animals (see Fig. G56). Although the model shown indicates transport in one direction, evidence is accumulating for transport by the cisternae from the cell membrane toward the endoplasmic reticulum. The *coat protein I* (COPI) and SNARE seem to play important role in the transport. The homologous structures in plants are frequently called dictyosomes. Some of the Golgi structures are located next to endoplasmic reticulum and are called *cis Golgi*; others occur at a distance (*trans Golgi*). In these vesicles, some proteins are modified after the completion of their synthesis in the endoplasmic reticulum. In the stacked fragments, some of the functions seem compartmentalized (Yano H et al 2005 Proc Natl Acad Sci USA 102:13467). The Golgi complex is inherited by fragmentation of the elements into small vesicles, which are distributed at random during mitosis. According to more recent observations, the distribution may not be entirely random. The fragments were found to aggregate around the mitotic spindle pole and the motor proteins pulled them into the daughter cells. After cytokinesis, Cdc2 supposedly phosphorylates the

Figure G56. Transport function of the Golgi apparatus. From the nucleus, through the nuclear pores, mRNA reaches the ribosomes sitting on the endoplasmic reticulum (ER). The protein synthesized may enter the lumen of the ER with the assistance of a signal peptide transfer particle-mediated system. The proteins may emerge then in transport vesicles to enter the Golgi at the cis side end, exit at the "bulbous" ends of the stacked membrane vesicles. In the Golgi the proteins are glycosylated and modified post-translationally

p115 receptor and then of the fragments the Golgi structure is reconstituted probably via the endoplasmic reticulum. The exact mechanisms are not generally agreed upon, however.

G

G_{oif}Protein: A trimeric G-protein; stimulating cAMP in the control of olfactory neurons. ►G-proteins, ►olfactory, ►olfactogenetics

GOMBO Syndrome: Autosomal recessive growth retardation with eye, brain, skeletal, and mental defects. ►growth retardation

Gomori's (Gömöri's) Stain: Gomori's stain is used primarily for histological localization of phosphatases and lipases in sectioned specimens by the light microscope. The trichrome stain contains, in 200 mL H₂O, chromotrope 2R (2[phenylazo]chromotropic acid) 1.2g, fast green 0.6 g, phosphotungstic acid 1.6g, and glacial acetic acid 2mL. ►stains, ►histochemistry; Gomori G 1950 Am J Clin Path 20:665.

Gonadal Dysgenesis: The failure of normal differentiation of the gonads (ovary, testis). It is a common cause of sterility in aneuploids. Gonadal dysgenesis of XY chromosomal constitution occurs in mammalian females. They have "streak gonads" and fail to develop the secondary sexual characteristics. Gonadal neoplasias are frequent in these individuals. It has been shown that the testis-determining factor resides in a Y-chromosomal segment and either deletion or base substitution may lead to an inactive human SRY (Yp11.3) product, a DNA binding protein involved in testis determination. Transfection of the TDY (the mouse homolog of SRY) DNA into XX mouse was found to induce male development. Gonadal dysgenesis may occur also in XX females, which have higher than normal level of gonadotropins and underdeveloped male gonads. In XY females (GDXY, Xp22.11–21.2) gonadal dysgenesis causes multiple developmental anomalies and hypermuscular appearance. Premature ovarian failure (2p21-p26) is a mutation in the follicle-stimulating hormone receptor. The cause of the dysgenesis may reside either in autosomal recessive genes or in the sex chromosomes. Mutation in the human desert hedgehog (12q12-q31.1) may lead to partial gonadal dysgenesis and neuropathy. ►H - Y

antigen, ►FSH, ►testicular feminization, ►Swyer syndrome, ►Turner syndrome, ►Smith-Lemli-Opitz syndrome, ►hermaphroditism, ►pseudohermaphroditism, ►SRY, ►SOX, ►campomelic dysplasia, ►gonad, ►hedgehog, ►sex reversal

Gonadoblastoma: A rare type of neoplasm containing germ cell, immature Sertoli-like cells, and cells resembling the granulosa cell of the ovarian follicles. Mutation in a 1–2 Mb fragment encoding the testis-specific protein (TSPY) near the centromere in the short arm of the human Y chromosome may be responsible for it. ►Frasier syndrome

Gonadotropin: A group of hormones that regulate gonadal and placental functions. ►MSAFP, ►GnRHA, ►puberty

Gonadotrophin: Same as gonadotropin.

Gonadotropin-Releasing Factor: ►luteinizing hormone-releasing factor

Gonadotropin-Releasing Hormone Agonist: ►GnRHA

Gonads: The organs of gametogenesis, such as ovary and testis. In *Drosophila*, the male gonad includes about 15, the female about 12 cells that further proliferate during embryonic differentiation, and there are 60–110 primordial germ cells by the late instar stage (see Fig. G57). In the mouse, the primordial germ cells appear seven days after mating (dpc). In the female, the primordial germ cells stop mitosis 13–15 dpc and meiosis is initiated immediately. Spermatogenesis begins 5–6 days after birth and on the 9th day proleptotene spermatocytes appear.

By day 18, haploid spermatids are formed followed by spermiogenesis. The general pattern of gonadal development is similar in mammals too, as shown in the diagram. The testes and the ovary differentiate from sex neutral structures. From the Müllerian ducts, the fallopian tube, and at its base the uterus develops, while the primitive gonad is converted into the ovary. From the Wolffian duct, the vas deferens, and at its base the seminal vesicles are formed, and the primitive gonad is converted into testis. In the drawing (for saving space) only half of the female and male sexual apparatus is shown. At the undifferentiated stage, the steroidogenic factor, SF-1, the Wilms tumor 1 Zinc-finger protein, and the homeobox gene Lim-1 are important. During the sexual differentiation stage, the Y chromosomal testis determining gene, SRY, the autosomal male sex differentiation factors SOX9, glucoprotein WNT4 (female), WT1 (male), SF-1, and a general sexual differentiation factor, DMRT1 play key roles.

Müllerian inhibitory substance inhibits testosterone synthesis in the female, whereas promotes it in the male. The Dax-1 protein (originally considered as an

Figure G57. Gonads. The diagram was redrawn after H. Eldon Sutton & RP Wagner 1985 Genetics. A Human Concern. Macmillan, New York

ovary promoting substance) at higher dosage suppresses male development. The InsL3 protein has a role for the gubernaculum (a ligament) facilitating the descent of the testes into the testicular bag, the scrotum. Numerous other proteins are also involved.

►Müllerian duct, ►Wolffian duct, ►gametogenesis, ►cell cycle, ►germline, ►dpc, ►mismatch repair, ►sex, ►sex reversal, ►GDNF, ►puberty; Roberts LM et al 1999 Am J Hum Genet 65:933; Koopman P 2001 Curr Biol 11:R481; Mackay S 2000 Int Rev Cytol 200:47; Kobayashi A, Behringer RR 2003 Nature Rev Genet 4:969; Brennan J, Capel B 2004 Nature Rev Genet 5:509; <http://www.germonline.org/>.

Gonidia: Specialized asexual reproductive cells.

Gonioblast: A cell resulting from asymmetric division in the germline; the original stem cell gives rise by division to a new stem cell and to the gonioblast, which is destined for differentiation.

Gonochoirism: As per gonochorism, normally the species has separate male and female individuals. ►dioecious, ►hermaphrodite

Gonocytes: Progenitors of the spermatogonia. ►spermatogonia, ►gametogenesis

Gonosome: The sex chromosomes as distinct from the autosomes. ►autosome, ►sex chromosome

Gonotaxis: A genetically controlled ability of eggs or spermatozoa to be preferentially involved in the formation of a zygote. ►meiotic drive

Gonzalo of Spain: A great grandson of Queen Victoria of England who inherited from his grandmother, Beatrice, the classic X-chromosomal hemophilia gene and died by hemorrhage in an automobile accident at age 20. ►hemophilia, ►anticoagulation factors, ►Queen Victoria

Good Genes: The expression “good genes” has a double meaning: (i) genes that are advantageous for the individual or for evolution (eugenics), and (ii) genes with good penetrance and expressivity and thus facilitating analysis of their inheritance and function. ►penetrance, ►expressivity

Goodness of Fit Test: ►chi square

Goodpasture Syndrome: An autosomal recessive autoimmune reaction of the basement membrane of the renal glomeruli and the lung. The basic defect is in the α -chain of collagen type 4. Although some cases indicated familial occurrence, most likely they were exposed to similar (viral, bacterial hydrocarbon) environmental factors. ►autoimmune disease, ►collagen, ►basement membrane, ►Wegener granulomatosis; Papiris SA et al 2007 Critical Care 11:213)

GOOSE: *Anser anser*, $2n = 80$.

Gooseberry (*Ribes* spp): Tart berry fruits; $2n = 2x = 16$.

Gopher: Genetic information databases, accessible through INTERNET electronic networks. Software for gopher is free and can be obtained with FTP (file transfer protocol) by gopher@boombox.micro.umn.edu. (The name comes from a ground squirrel).

Gordon Syndrome (PHA2A, 1q31-q42): The Gordon syndrome involves hypertension and high salt concentration in the blood with normal filtration rate in the kidneys. It is also called pseudohypoaldosteronism II. Similar disorders occur at 17q21-q22 and 12p13. ►hypertension, ►pseudohypoaldosteronism, ►Liddle syndrome

Gorilla: ►Pongidae, ►primates

Gorlin-Chaudhry-Moss Syndrome: A very rare autosomal recessive craniofacial dysostosis (head malformation), excessive hairiness, heart and lung defect

(patent ductus), and hypoplasia (reduced growth) of the female external genitalia. ►hypertrichosis, ►craniosynostosis

Gorlin-Goltz Syndrome ►nevroid basal cell carcinoma

Gossypium: (cotton): A member of the *malvaceae* family of plants. Economically the most important are the long staple upland species, *G. hirsutum* ($2n = 4x = 52$) that produces 95% of the cotton fibers, and *G. barbadense*, an extra long staple (Sea Island; Egyptian) cotton (also a tetraploid), contributes about 5% of the world fiber. There are 30 diploid species. *G. herbaceum* and *G. arboreum* carry the *A* genome and are the only diploids with spinnable lint. The *B* genome is represented by North-African and Cape Verde Islands species. The *C* genome occurs in Australian diploids. *D* genome plants occur in Mexico, Peru, Galapagos Islands, and the USA. The *E* genome species occur in North Africa, Arabia, and Pakistan. The *F* genome is represented by a single African species. The new world tetraploids contain the *A* and *D* genomes. Most of the cottons are naturally cross-pollinated but tolerate inbreeding. The various genomes are distinguished primarily on the basis of chiasma frequencies and the number of univalents in the species hybrids, although some chromosome morphological differences also exist. The seed of the plants would be potentially useful for food but it contains the toxic gossypol (terpenoids), which provides protection against herbivorous insects. RNAi technology can disrupt gossypol biosynthesis in cottonseed by interfering with the expression of the δ -cadinene synthase gene during seed development (see Fig. G58). This genetic modification does not affect gossypol level in the leaves but reduces it to apparently safe level in the seeds. (Sunilkumar G et al 2006 Proc Natl Acad Sci USA 103:18504; ►terpene; <http://www.tigr.org/tdb/tgi/>).

Figure G58. Cadinene

Gout: A complex hereditary disorder of the joints leading to arthritis caused by overproduction and/or underexcretion of uric acid. In one autosomal recessive gout, glucose-6-phosphatase is deficient. In the X-linked gout, hypoxanthine-guanine phosphoribosyl transferase deficiency exists (see Fig. G59). Some gout is associated with increased

turnover of nucleic acids. Autosomal dominant and polygenic forms are also known. Gout may be asymptomatic initially but at later stages the joints and the kidney may become permanently injured. (See Fig. G59). The first sign is pain in the great toe but it may spread to other parts of the foot and also to the wrists and other body parts. The prevalence may vary in different populations from 0.2 up to 10%. The serum urate level may vary from 6 to over 9 mg/100 mL serum. Generally, fewer women than men suffer from it, but in women the gout may be more severe and destructive. If the diet is very low in proteins, gout may not appear. The uric acid crystals (urate) activate the Hageman factor in the viscous fluid (synovia) of the joints that in turn sets into motion a series of events leading to inflammation. Uric acid crystals activate the inflammasome (Martinon F et al 2006 Nature [Lond] 440:237). In chickens that lack the Hageman factor or in dogs with suppressed number of leukocytes (leukopenia), the inflammatory reaction fails, indicating the role of these factors in gout attack. After the first attack, the gout symptoms apparently disappear for weeks or many months, only to return with greater strength. The chronic arthritic gout may produce ulcerating tophi (a chalky urate deposit) in the joint and may cause severe deformation of the affected area. Urates may be deposited also in kidneys, cartilage, and bone tissues. Tophi may be present at the fingertips, palms, soles, eyelids, nasal cartilages, and in the eye. Rarely, it is also observed in and on the penis, the aorta, on the heart wall (myocardium), valves, tongue, the entrance of the larynx (epiglottis), and vocal cords. Urate deposits occur in between the vertebral disks and cartilages. There is very little or any urate in the spinal cord or in the nervous system. In the kidney medulla, urate crystals may accumulate and kidney stones may be formed (lithiasis) in 20 to 40% of the affected persons. Gout is frequently associated with obesity, and hyperuricemia is common in case of diabetes mellitus. Hyperlipoproteinemia and high triglyceride levels are common in gout. Alcoholism may aggravate hyperuricemia. Serum urate levels are about the same in people of European origin, in North-American Indians, Hawaiians, Japanese, and Chinese. In some Polynesians and Australian aborigines and South-American Indians, the urate level may be higher. Overproduction of uric acid is correlated to the availability of L-glutamine and phosphoribosyl-1-pyrophosphate that are rate-limiting precursors in purine biosynthesis. Uric acid is dramatically overproduced in case of (partial) deficiency of hypoxanthine-guanine-phosphoribosyl-transferase (HPRT). Glucose-6-phosphatase and glutathione reductase also increase uric acid synthesis.

Exposure to lead may increase the occurrence of gouty arthritis due to inflammation of the kidney (saturnine gout). Starvation, Down's syndrome, and psoriasis (a skin disease causing silvery scaling and plaques) may increase uricemia. Acute attacks of gout may be successfully treated with colchicine and allopurinol, an inhibitor of xanthine oxidase. Both of these compounds may be highly toxic. Gout due to genetically determined factors is called primary gout, the secondary gout is the result of ingestion of certain chemicals and drugs. Many famous historical persons were apparently afflicted by gout: Medici, Newton, Darwin, Luther, Calvin, Benjamin Franklin, Cotton Mather (who reported plant hybrids in America in 1721), and others. Recently by the use of scanning electronmicroscopy in the mummified finger tip of the Holy Roman Emperor Charles V (King Charles I of Spain), uric acid crystals were positively identified after almost a half a millennium, explaining the cause of the illness of this powerful ruler (Ordi J et al 2006 New England J Med 355:516). His seated pose on a special chair, painted by the famous artist Titian, also supports other historical records of his debilitating affliction. ▶[Lesch-Nyhan syndrome](#), ▶[colchicine](#), ▶[antihemophilic factors](#), ▶[Hageman factor](#), ▶[inflammasome](#); Chen SY et al 2001 Metabolism 50:1203.

Figure G59. Gouty fingers

gp: In general, the abbreviation for glycoprotein; the gp is usually followed by a number.

gp: Gene of phage, e.g., the first gene of λ phage entering the capsid is *gpNu*. ▶[lambda phage](#)

GP32 Protein (of phage T4): GP32 protein is required for (i) configuration of the single-strand DNA (ssDNA) to accommodate the replisome, including DNA polymerase, (ii) to melt adventitious secondary structures, (iii) to protect ssDNA from nucleases, and (iv) to facilitate homologous recombination. ▶[replication fork](#), ▶[replisome](#)

gp39: Same as the CD40 ligand.

gp120: The HIV glycoprotein that activates B lymphocytes with receptors carrying variable heavy chain

(V_H3) immunoglobulins. ▶[HIV](#), ▶[immunoglobulins](#), ▶[B lymphocytes](#)

gp130: A ~101-kDa (without glycosylation) subunit of the interleukin 6 family receptors, encoded at 5q21. It is a signal transducer chain for IL-6, IL-11, LIF, OSM, and CNTF. ▶[interleukins](#), ▶[APRF](#); Chow D-c et al 2001 Science 291:2150.

Gp190: A ~121-kDa (without glycosylation) subunit of various cytokine receptors, encoded at 5p12-p13.

GPA: Genes of yeast homologous to G α cDNAs, involved in mammalian G-protein coding. GPA1 protein is 110-, and GPA2 is 83-amino-acid longer at the N termini than the mammalian proteins. GPA1 may be involved in mating signal transduction, GPA2 controls cAMP level. GPA1 (α subunit of G-protein) plays a negative role (growth arrest) in mating signal transduction, whereas the *STE4/STE18* (β , γ subunits) are responsible for a positive transducing signal (enhancement) for mating. ▶[G proteins](#), ▶[cAMP](#), ▶[STE](#), ▶[mating type determination in yeast](#)

GPCR (G protein-linked receptors): ▶[signal transduction](#)

G6PD: The glucose-6-phosphate dehydrogenase deficiency is responsible for one type of hemolytic anemia in humans; it is controlled by a sex-linked recessive gene (map location X28). It catalyzes the reaction $G6P + TPN^+ + H_2O \rightleftharpoons 6\text{-phosphogluconic acid} + TPNH + H^+$. ▶[Zwischenferment](#), ▶[glutathione](#), ▶[glucose-6-phosphate dehydrogenase](#), ▶[malaria](#)

GPI Anchors: Glycosyl-phosphatidylinositol cell surface-membrane proteins.

G1ps: G1 (gap 1) pre-synthetic phase (preceding S phase) of mitosis. ▶[cell cycle](#), ▶[mitosis](#)

GPR: Co-receptors of HIV and SIV. ▶[acquired immunodeficiency syndrome](#)

G-Quadruplexes: Four-stranded guanine-rich structural elements of the telomeres. G-quadruplexes may be directly involved in gene regulation at the level of transcription. In promoter regions of more than 40% of the human genes (1 kb upstream of the transcription start site), one or more quadruplex motifs exist. The promoter quadruplexes are strongly associated with nuclease hypersensitive sites. Regions of the human genome that are both nuclease hypersensitive and within promoters show 230-fold enrichment of quadruplex elements, compared to the rest of the genome (Huppert JL, Balasubramanian S 2007 Nucleic Acids Res 35:406). ▶[telomeres](#), ▶[telomerase](#), ▶[promoter](#), ▶[tetraplex](#); Parkinson GN et al 2002 Nature [Lond] 417:876.

G_q-Protein: A member of the trimeric G-protein family; activates phospholipase C- β and responds to

acetylcholine. ►G-proteins, ►signal transduction, ►phospholipase; ►acetylcholine, ►acetylcholine receptors

Graafian Follicle: Small sac-like structures on the ovary of mammals containing a mature egg (secondary oocyte). The release of the egg is called ovulation and afterwards the follicle is transformed into a corpus luteum. ►luteinization, ►corpus luteum

Gradient Centrifugation: A technique of separation of cells, subcellular organelles, and macromolecules on the basis of their density and shape by centrifugation. High-speed centrifuges may separate the larger particles while for macromolecules ultracentrifuges are used. The medium of separation may be sucrose, percol, cesium salts, etc. The material is placed on the top of the medium, which is made in various concentrations in steps; i.e., first we place in the centrifuge tube 60% sucrose, layer on top of it 40%, then 20% solutions. Alternatively, cesium salts may be used at an average density of the macromolecule. In the latter case, during high-speed centrifugation the medium forms a continuous density gradient. In either case, the material will accumulate either at the top of the step (layer) which has higher density than the substance to be separated or it will accumulate as a band in the medium that corresponds to the density of the macromolecule (DNA, ribosomes, viral particles). ►ultracentrifuge, ►buoyant density, ►DNA density

Grading Up: In the process of grading up an animal breed is repeatedly backcrossed with males of another, more desirable livestock to improve its productivity and/or quality. ►gain

Gradualism: As per gradualism, evolution is supposed to proceed by slow acquisition of adaptive mutations in the Darwinian sense. (See Darwinian evolution; punctuated evolution).

Graeco-Latin Square: An experimental design similar to the Latin Square (see Fig. G60). Three or more variates, e.g., A, B, C, each are tested under three or more different treatments, e.g., 1, 2, and 3, and the results are usually evaluated by analysis of variance. One such arrangement is shown in the box. ►Latin Square, ►analysis of variance, ►factorial experiments

| B ₃ | C ₁ | A ₂ |
| C ₂ | A ₃ | B ₁ |

Figure G60. Layout of simple Graeco-Latin square

Graft: Transplantation of plant or animal tissues by surgical means.

Graft Hybrid: Chimera produced by fusion of two genetically different cells in tissues. The followers of the Mitchurin, Lysenko, and Glushchenko's group of Soviet ideologues postulated non-chimeric type graft hybrids. They referred to them also as vegetative hybrids, and claimed that grafting alters the hereditary material of both graft and scion. These claims were not reproducible by appropriate methods of experimentation, and several of the results were due either to ignorance or deliberate deception. When the mitchurinian experiments were re-examined under well-defined conditions, no acceptable evidence indicated the existence of vegetative hybridization (Stubbe H 1954 Kulturpflanze 2:185; Böhme H 1957 Ztschr Pflanzg 38:37). Certainly, viruses can be transmitted between stock and scion by grafting and this may result in an altered phenotype. But, this can hardly be considered a genetic alteration. Infection of plant (or other cells) by genetic vectors containing foreign genes can result in transgenic individuals because of the transfer of DNA. The "plastic substances" of vegetative hybridizers have no substance in the twenty-first century when all assertions need proof to become acceptable. The assertion (Liu Y 2006 Adv Genet 56:101) that doubts about graft hybridization were "squarely contradicted by a substantial body of reliable experimental evidence (Landman 1963)" is not justified in view of the experiments reviewed and the conclusions of Landman (1963 BioScience 43:696) who does not even mention graft hybridization, although he reviews old and new evidences for inheritance of acquired characters, including "epinucleic inheritance". Liu acknowledges, "Further evidence will be required to elucidate molecular mechanisms underlying graft hybridization". Unfortunately, even the data on graft hybridization are highly questionable. Linnaeus stated already in 1735 "Knowledge... built on opinion only, will not stand". Unsubstantiated findings are not just scientifically unacceptable but may be very detrimental to applications in agriculture or medicine. ►acquired characters

Graft Inheritance: ►cortical inheritance

Graft Rejection (GVHD): The manifestation and result of histoincompatibility between transplanted tissues: host-versus-graft disease. If oocytes of an individual mouse are stimulated to parthenogenetic development, histocompatible tissue can be produced (Kim K et al 2007 Science 315:482). ►cytotoxic T cells, ►HLA, ►MHC, ►mixed lymphocyte reaction, ►microcytotoxicity assay, ►therapeutic cloning, ►graft-versus-host disease, ►stem cells, ►MHC

GVHD (graft versus hoist disease): ►graft rejection

Grafting: Grafting transfers one piece of tissue or an organ from one place to another within the body or to another body. Horticulturists have practiced grafting of plants as a means of propagation. Grafted roses and other ornamentals, as well as fruit trees assure the maintenance of genetic uniformity in the grafts where multiplication by seed would produce a heterogeneous offspring because of heterozygosity at multiple loci. Some grafts are horticulturally advantageous because the rootstock may be resistant to soil-borne pests and can secure crops in more valuable varieties of *Vitis vinifera* grapes. *Vitis rotundifolia*, a wild grape stock, may be 20 fold more resistant to the *Dactylospheera vitifolii* root parasite than the standard varieties. Grafting may be used to propagate inviable plants on appropriate stocks and to study the physiological interactions between scion and stock in such complex processes as flowering response, etc. Macromolecules such as viruses may move from stock to scion through plasmodesmata. mRNA may move through the phloem and mutant phenotype may be expressed in the scion. ▶transplantation, ▶grafting in medicine, ▶graft hybrids; Kim M et al 2001 Science 293:287.

Grafting in Medicine: Grafting is practiced in modern medicine by transplanting skin, kidneys, liver, heart and other organs. Allografts are generally incompatible with the host immune system. The immune response is controlled by a large number of genes that are part of the major histocompatibility gene families. Experimental studies on tissue transplantation are carried out with inbred strains of mice (see congenic resistant). The histocompatibility genes are codominant and F_1 hybrids between different inbred lines may accept graft from both parents, whereas the two parental lines may be incompatible with each other. F_1 hybrid generally accepts grafts also from the offspring from the later generation. The incompatibility is inherited in a Mendelian manner and 3/4 of the F_2 individuals are compatible with one or the other parent and 1/4 are not. If the number of independent histocompatibility loci is (n) , $(3/4)^n$ = the number of histocompatible individuals in F_2 and in a backcross it is $(1/2)^n$. There are some confounding factors, however. Within some highly inbred lines, skin grafts from male to female may be rejected but not from female to male. This may be due to “male-specific” antigens encoded by the Y chromosome. Also, tumor tissues may be rejected when skin grafts are accepted because of tumor-specific antigens. Heterotopically (placed to a non-regular position) transferred hearts and kidneys may be accepted when skin grafts are rejected. Even apparently accepted graft may produce very low level of antibodies. Allogeneic inhibition may also occur, i.e., parental

animals fail to accept transplants from their offspring, but the offspring may accept the transfer from that parent. Most of these principles of grafting were derived from studies on inbred mice strains. Grafts have another interest for medicine with the discovery of the regenerative capacity of stem cells. ▶HLA, ▶allogeneic, ▶mixed lymphocyte reaction, ▶microcytotoxicity assay, ▶therapeutic cloning, ▶stem cells, ▶zoonosis, ▶cell therapy, ▶organ culture; Quisenberry PJ et al 2001 Ann NY Acad Sci 938:54.

Graft-Versus-Host Disease (GvH): GvH may arise when the grafted tissue damages the host because of the immune reaction. GvH may also be beneficial by eradicating the residual leukemia cells though the mediation of T cells and the HLA molecules of the major histocompatibility system. ▶graft rejection, ▶HLA, ▶TIP; Kärre K 2002 Science 295:2029.

GRAIL: A gene locator/annotation program. ▶gene prediction

Gram Molecular Weight: Grams of a compound equal to its molecular weight: mole.

Gram Negative/Gram Positive: Classification of bacteria depending on retention of the Gram stain (gentiana violet after an iodine stain, and then extracted by acetone or alcohol) (see Fig. G61). The outer membrane of the Gram-positive bacteria (stain blue-purple) does not have lipopolysaccharides but these are present in the membrane of Gram-negative bacteria (stain pink-red). The cell wall of Gram-positive bacteria contains peptidoglycans and teichoic acid. *Gram-positive bacteria: Streptococci, Staphylococci, Pneumococci, Corynebacterium, Mycobacterium, Bacillus anthracis, B. cereus, Listeria, Actinomyces, Streptomyces*, etc. *Gram-negative bacteria: Neisseria, Enterobacteriaceae (E. coli, Salmonella, Shigella), Haemophilus, Bordetella, Yersinia, Vibrio cholerae, Pseudomonas, Brucella, Proteus, Campylobacter, Legionella*, etc. ▶peptidoglycan, ▶teichoic acid

Figure G61. Gram-positive cells

Gram Stain: ▶bacteria, ▶Gram negative/Gram positive

Gramene (rice and other grasses database): <http://www.gramene.org>.

Grana (sing. granum): Dark green pile of flattened membrane vesicles (thylakoids) in the chloroplasts (see Fig. G62). ▶chloroplast, ▶chloroplast genetics

Figure G62. Granum

Grandchildless-Knirps Syndrome: In *Drosophila*, maternal effect genes cause embryonic lethality by eliminating pole cells and one or more abdominal segments. ▶morphogenesis, ▶pole cells, ▶maternal effect genes

Granddaughter Design: An analysis of genetic linkage of quantitative loci to (usually) DNA markers among the granddaughters. The markers are identified in grandsires and sons but quantitative analysis is carried on the daughters of sons. ▶QTL, ▶least squares, ▶RFLP, ▶maximum likelihood method applied to recombination; Weller JI et al 1990 J Dairy Sci 73:2525; Cappieters W et al 1998 Genetics 149:1547)

Grande: The wild type cells of yeast in comparison with the petite mitochondrial mutants deficient in respiration. ▶petite, ▶mtDNA

Granin: Calcium-binding acidic proteins (21 to 76-kDa) in the Golgi network. Their function is processing secreted proteins and they are subject to processing by converting into biologically active peptides. The granin consensus bears similarity to breast cancer gene proteins, BRCA1 and 2. ▶Golgi, ▶breast cancer; Rosa P, Gerdes HH 1994 J Endocrinol Invest 17[3]:207.

Grantham's Rule: Highly expressed genes preferentially use, from the synonymous codons, those that have a pyrimidine at the third position of the triplets. ▶genetic code, ▶codon usage, ▶synonymous codons; Grantham R et al 1981 Nucleic Acids Res 9:r43.

Grantham's Classification: Classification of amino acids on the basis of substitution frequencies in proteins, atomic weight ratio of non-C elements in end groups or rings to C atoms in side chains, polarity, and mol volume. Substitution frequencies agree much better with the chemical properties than with

the minimum base differences in their codons. Fixation of mutations involving non-similar amino acids is relatively rare. (See Grantham R 1974 Science 185:862).

Granule Exocytosis: ▶cytotoxic T cells

Granulocyte-

Macrophage Colony Stimulating Growth Factor: GM-CSF (18–30-kDa monomeric glycoprotein, encoded at human chromosome 5q21-q32) activates the cells of the granulocyte pathway. Binding of GM-CSF to its receptor dimerizes the receptor and leads to activation of the Jak-STAT pathway of signal transduction. A small nucleotide, SB 247464, may serve as a non-peptidyl inducer of the oligomerization of the receptor. It may be involved in the maturation or function of special antigen presenting cells. ▶lymphokines, ▶neutropenia, ▶signal transduction, ▶antigen presenting cell; Tian SS et al 1996 Blood 88:4435; Roth MD et al 2000 Cancer Res 60:1934; Trapnell BC, Whitsett JA 2002 Annu Rev Physiol 64:775.

Granulocytes (polymorphonuclear leukocyte): Specialized white blood cells such as neutrophils, eosinophils, and basophils. They contain numerous lysosomes and secretory vesicles (granules) and play an important role in the defense system of the animal body. ▶lysosome, ▶neutrophils, ▶eosinophils, ▶C/EBP

Granulomatous Disease, Chronic (CGD): A group of X-chromosomal (Xp21.1) recessive conditions involving chronic infections, based on defects in NADPH-oxidase subunits of the neutrophils and other phagocytotic leukocytes. If the normal enzyme is activated it generates superoxide that is converted to antimicrobial hydrogen peroxide. The 91-kDa-membrane glycoprotein, a phagocyte oxidase (gp91^{phox}, p47^{phox}, p40^{phox}, p67^{phox}), is a part of the cytochrome b system. The autosomal (16q24) recessive type is deficient in cytochrome b α -subunit (CYBA) and the neutrophil cytosol factor deficiency (NCF1) form is located in chromosome 7q11.23. A third CGD (NCF2) was assigned to 1q25. The Duchenne muscular dystrophy gene may involve CGD and several other genes have bearing on the disease. ▶neutrophil, ▶leukocyte, ▶superoxide dismutase, ▶hydrogen peroxide, ▶McLeod syndrome, ▶muscular dystrophy, ▶contiguous gene syndrome; Grizot S et al 2001 J Biol Chem 276:21627.

Granulolysin: ▶cytotoxic T cell

Granum in Chloroplasts (plural grana): The multilayered thylakoids appear as dark "grains" in the chloroplasts viewed by the light microscope. ▶chloroplasts, ▶chloroplast genetics; see photo at grana.

Granzymes: Cytotoxic T cell serine proteases and perforin responsible for apoptosis by activating the precursor (CPP32) of the protease cleaving poly (ADP-ribose) polymerase. Granzyme B is activated in T cells and in the active form cytolytic CD8⁺ T cells (CTL) destroy infecting particles. Besides Granzyme A and B, perforin is important for the action of CTLs. Granzymes cleave lamins and may be responsible for cytolysis. Granzyme A initiates mitochondrial damage leading to apoptosis (Martinvalet D et al 2005 Immunity 22:355). ▶CTL, ▶ICE, ▶apoptosis, ▶perforin, ▶caspase, ▶cathepsin, ▶lamins; Kam CM et al 2000 Biochim Biophys Acta 1477:307; Zhang D et al 2001 Proc Natl Acad Sci USA 98:5746.

Grapefruit: *Citrus paradisi*, 2n = 18, 27, 36. Grapefruit juice has beneficial dietary value because of high antioxidant content and lowering the level of blood plasma lipids (Gorinstein S et al 2005 J Agric Food Chem 53:3223). Because of furanocoumarin/bergamottin content, it may interfere with or increase intestinal absorption of several drugs (statins, antihistamines, calcium channel blockers, cyclosporin, sildenafil, multidrug transporter P-glycoproteins, etc.) and the fruit and the drugs should not be taken simultaneously or within several hours of each other. ▶bergamottin, ▶drug interaction; Romiti N et al 2004 Life Sci 76:293; Bailey DG, Dresser GK 2004 Am J Cardiovasc Drugs 4(5):281; drug interaction with grapefruit juice: Anonymous 2005 Obstet Gynecol 105(2):429.

Grapes: *Vitis vinifera*, 2n = 38; the *Muscadina* species, 2n = 2x = 40. The condensed tannins/proanthocyanidins, which are a products of the flavonoid pathway in red wines have protective effects against heart disease involving ventricular fibrillation and tachycardia (Pataki T et al 2002 Am J Clin Nutr 75:894). ▶resveratrol; diversity and history of grape wines: This P et al 2006 Trends Genet 22:511; Sandler M, Pinder R (eds) 2002 Wine: A Scientific Exploration. Taylor & Francis, London, UK; <http://mpss.udel.edu/grape/>.

Grapes, Seedless: Normal diploids but a gene prevents the division of the embryo, presumably because of shortage of hormones (stenospermocarp). ▶seedless fruits

Graph Theory: Graph theory represents metabolic or genetic networks as nodes (vertices) connected by links of edges (arcs). The graph theory has many applications, including in biology. ▶networks, ▶genetic networks; Wilson R, Beineke L 2004 Topics In: Algebraic Graph Theory, Cambridge Univ. Press, New York, Solymosi J 2005 Proc Natl Acad Sci USA 102:8075.

Grasses (cultivated for herbage): Blue grass (*Poa pratensis*) 2n = 36–123; Italian ryegrass (*Lolium multiflorum*) 2x = 14; meadow fescue (*Festuca pratensis*) 2x = 14; orchardgrass (*Dactylis glomerata*) 4x = 28; perennial ryegrass (*Lolium perenne*) 2x = 14; smooth brome (*Bromus inermis*) 8x = 56; tall fescue (*Festuca arundinacea*) x = 7, 2n = 42; timothy (*Phleum pratense*) 6x = 42. ▶gramene

Grasshoppers (*Orthoptera*): Grasshoppers are suitable objects of cytological and evolutionary investigations because of the large size and number of chromosomes. (n = 13 to 57 in males that are of XO constitution); *Melanopus differentialis* 2n = 24. The variation in chromosome number is supposed to be due to chromatin reorganization rather than to polyploidy. (See <http://www.haibei.org/brim/grashopp/look.asp>).

Gratuitous Inducer: A substrate analog of an inducible enzyme that may trigger transcription of the gene concerned, such as IPTG (isopropyl thiogalactoside) for the *Lac* operon, although it is not metabolized by the *z* gene of the operon. ▶inducer, ▶*Lac* operon; Horton N et al 1997 J Mol Biol 265:1.

Grazone: A female meiosis regulatory WD type Zinc-finger protein distantly related to Cdc20 that binds to the cortex promoter during meiosis and early embryo development. Meiosis fails when it mutates. ▶WD-40, ▶DNA-binding proteins, ▶CDC20; Harms E et al 2000 Genetics 155:1831; Chu T et al 2001 Genesis 29:141.

Graves Disease (Grave's disease): ▶goiter

Gravitropism: A tendency of plant organs such as roots to grow in the direction of terrestrial gravitation. The mechanism of this response is unclear although amyloplasts and other cytoplasmic characteristics have been suggested as possible receptor sites. ▶statolith, ▶phototropism; Kato T et al 2002 Plant Cell 14:33; Yano D et al 2003 Proc Natl Acad Sci USA 100:8589.

Gravity: Either hypo- or hypergravity may cause chromosomal damage in human cells.

Gray Crescent: A pale area in some amphibian eggs, opposite to the sperm entry; at this point will the dorsal parts be initiated. ▶dorsal

Gray Matter: A butterfly-shaped neuronal tissue of the hippocampus; it is surrounded by the axonal *white matter*. Its anomalies may lead to psychomotor retardation, seizures that are resistant to anticonvulsant therapy. Some of the hereditary infantile seizures respond dramatically to large doses of vitamin B₆ (pyridoxine). Differences in the frontal gray matter of individuals are under genetic control and increased

size appears positively correlated with cognitive abilities. ►[brain human](#), ►[neuron](#); Thompson PM et al 2001 *Nature Neurosci* 4:1253.

Gray Units: Units of ionizing radiations; 1 Gy = 100 rad absorbed dose. ►[R](#), ►[rad](#), ►[rem](#), ►[Sievert](#)

GRB (growth factor receptor-bound protein): A vertebrate adaptor protein with SH2 and SH3 binding domains; it is a downstream receptor kinase. It mediates the activation of guanine nucleotide exchange ($GTP \rightleftharpoons GDP$) on RAS, a homolog of the *Drosophila* protein DRK. ►[DRK](#), ►[signal transduction](#), ►[SH2](#), ►[SH3](#); Jahn T et al 2001 *J Biol Chem* 276:43419; Kessels HWHG et al 2002 *Proc Natl Acad Sci USA* 99:8524.

GRE (glucocorticoid receptor element): GRE is situated upstream from the TATA box gene regulatory tract. ►[backtracking](#), ►[glucocorticoid](#), ►[glucocorticoid response element](#); Herrlich P 2001 *Oncogene* 20:2465.

Greek Alphabet (with Roman counterparts): (see Table G5).

Greek-Key: A protein configuration where β -sheets are connected across the end of a barrel. ►[barrel](#)

Green Beard Effect: An idea that some unique traits are specially favored by the parents' altruistic behavior during evolution. In general, other individuals of the population, irrespective whether they carry it themselves, recognize the "green beard" gene (gene product). ►[gestational drive](#), ►[kin selection](#), ►[altruistic behavior](#); Dawkins R 1976 *The Selfish Gene*, Oxford Univ. Press, New York, Nee S 1989 *J Theor Biol* 141:81; Sinervo B et al 2006 *Proc Natl Acad Sci USA* 103:7372.

Green Processes: Green processes do not have serious environmental impacts.

Green Fluorescent Protein: ►[aequorin](#), ►[Renilla GFP](#), ►[drFP583](#)

Green Revolution: The development of new plant (cereal crop) varieties which, because of the shorter and stronger stems and improved disease resistance, permitted more intensive agricultural practices (use of higher doses of fertilizers, irrigation, etc.) and resulted in 2–3 fold increases in grain yield. (See Khush GS 2000 *Nature Rev Genet* 2:815; Evenson RE, Gollin D 2003 *Science* 300:758).

Greenberg Dysplasia: ►[hydropsectopic calcification–motheaten skeletal dysplasia](#)

Greenhouse Gases: Greenhouse gases are faulted as the main causes of global warming. Carbon dioxide and methane were thought to be primarily responsible.

Table G5. The Greek and corresponding Roman characters

| Greek | | | Roman |
|-----------|--------------------|---------|-------|
| | α | alpha | a |
| | β | beta | b |
| Γ | γ | gamma | G g |
| Δ | δ | delta | D d |
| | ϵ | epsilon | e |
| | ζ | zeta | z |
| | η | eta | e |
| Θ | $\theta \vartheta$ | theta | Th th |
| | ι | iota | i |
| | κ | kappa | k |
| Λ | λ | lambda | L l |
| | μ | mu | m |
| | ν | nu | n |
| Ξ | ξ | xi | X x |
| | \omicron | omicron | o |
| Π | π | pi | P p |
| | ρ | rho | r |
| Σ | σ | sigma | S s |
| | τ | tau | t |
| | υ | upsilon | y |
| Φ | ϕ | phi | F f |
| | χ | chi | ch |
| Ψ | ψ | psi | Ps ps |
| Ω | ω | omega | O o |

Therefore, extended forestation was believed to be able to reduce CO_2 level in the atmosphere. Now it appears that green plants produce large amounts of methane that counteracts the beneficial effects of forestation (Lowe DC 2006 *Nature [Lond]* 439:149; Keppler F et al 2006 *Nature [Lond]* 439:187). Thus, President Ronald Reagan's ridiculed remarks about plants being the cause of warming of the globe appears prescient.

Greig's Cephalopolysyndactyly Syndrome (GCPS): GCPS is dominant in the short arm of human chromosome 7p13. It involves polysyndactyly and malformation of the head without mental defects. Molecular analysis indicates that the anomaly is concerned with GLI3 oncogen, a CREB-binding

protein. The protein product of the *cubitus interruptus* locus of *Drosophila*, involved in the regulation of limb development is also a homolog. ▶[hedgehog](#), ▶[Rubinstein-Taybi syndrome](#), ▶[GLI oncogene](#), ▶[morphogenesis in *Drosophila*](#), ▶[polydactyly](#), ▶[polysyndactyly](#), ▶[Pallister-Hall syndrome](#), ▶[cubitus interruptus](#)

Grey Matter: ▶[gray matter](#)

Grid: A surface evenly lined by parallel horizontal and vertical lines, such as, e.g., in microarray slides.

GRID (general repository for protein interaction database): <http://biodata.mshri.on.ca/grid/>.

Gridding: Aligning spots on a grid. ▶[grid](#)

GRIM (gene associated with interferon-retinoic acid-induced cell mortality): ▶[interferon](#), ▶[retinoic acid](#); Zhang J et al 2003 Proc Natl Acad Sci USA 100:9342.

GRIP (glutamate receptor interacting protein): GRIP contains seven PDZ domains interacts with C end and links AMPA to other proteins. GRIP lacks catalytic functions. ▶[AMPA](#), ▶[CARM](#); van Beeren HC et al 2000 FEBS Lett 481:213.

Griscelli Syndrome: Recessive 15q21 mutation causing anomalous pigmentation and T lymphocyte and macrophage function aberrations (hemophagocytic syndrome). The basic defect is in the RAB27A guanosine triphosphate-binding protein. Defects at the same site may also involve myosin 5a, a motor protein. The former lesion involves immune defects, the latter is concerned with neurological impairment. The hypopigmentation and the immunological problems appear to be related to lysosomal defect. ▶[RAB](#), ▶[lysosomes](#), ▶[Warburg micro syndrome](#); Anikster Y et al 2002 Am J Hum Genet 71:407; Stinchcombe J et al 2004 Science 305:55.

Griseofulvin: Strong inhibitor of fungal mitosis but weak as human spindle microtubule inhibitor and displays relatively low toxicity (see Fig. G63). It has been used against ringworm infections. In human tumor cells, it blocks cell cycle progression at G2/M and can cause apoptosis and it is a potential anti-cancer drug (Panda D et al 2005 Proc Natl Acad Sci USA 102:9878).

Figure G63. Griseofulvin

GRK1 (rhodopsin kinase): GRK1 is involved in the desensitization of G protein-mediated signaling. ▶[rhodopsin](#), ▶[GRK2](#)

GRK2 (G protein-coupled receptor kinase 2): GRK2 controls signaling from activated receptors to downstream effectors. (See for crystal structure: Tesmer VM et al 2005 Science 310:1686).

GRM: General regulator of mating type in yeast in cooperation with PRTF. ▶[mating type determination in yeast](#), ▶[PRTF](#)

gRNA (guide RNA): gRNA has a role in the kinetoplast, mitochondrial DNA of some protozoa. It mediates the pan edited primary RNA transcripts substantially by modified U additions or deletions but some short sequences (50–100 bases) may remain homologous to the primary transcript. These sequences are apparently anchored to the 3'-end and thus pairing may get started. Additional homology may occur in the middle (20–30 bases) and at the 5'-end (ca. 10 bases). These gRNAs may serve as templates for editing. The process requires a series of enzymatic steps. Free uridine triphosphates are the source of the Us inserted and they are added to the 3' ends generated by enzymatic cleavage. ▶[kinetoplast](#), ▶[Trypanosoma](#), ▶[Leishmania](#), ▶[RNA editing](#), ▶[pan editing](#), ▶[mtDNA](#); Müller UF et al 2001 EMBO J 20:1394; Bloom D et al 2001 Nucleic Acid Res 29:2950; Decatur WA, Fournier MJ 2003 J Biol Chem 278:695.

grow: Hamster gene activated by mitogens ▶[KC](#), ▶[N51](#), ▶[MGSA](#)

GRO α : ▶[melanoma growth-stimulating factor](#)

GroEL: A homo-tetradecameric chaperonin, composed of 57 kDa subunits of three functional domains each, arranged as a hollow cylinder of two stacked rings with seven-fold symmetry in *E. coli*. It binds to the smaller GroES molecule. GroEL and GroES are encoded in the same operon of *E. coli* (see Fig. G64). Although the information for folding resides in the primary structure of proteins, the GroEL–GroES complex facilitates the realization of this potential. In *E. coli*, ~250 proteins interact with GroEL but most of these can utilize the upstream chaperone trigger factor and DnaK for folding (Kerner MJ et al 2005 Cell 122:209). ▶[chaperone](#), ▶[chaperonin](#), ▶[protein folding](#), ▶[DnaK](#), ▶[trigger factor](#); Feltham JL, Gierash LM 2000 Cell 100:193; Farr GW et al 2000 Cell 100:561.

Figure G64. GroES and GroEL structure

GroES: A 10-kDa monomer. (See diagram).

G

Groucho: In *Drosophila*, groucho is a somewhat limited in scope corepressor protein responsible for extra bristles and ocelli above the eyes of the flies. It can act with Hairy, Engrailed, and Dorsal although the interacting domains in Hairy and Engrailed are different. Its mammalian homologue is TLE1 and it is structurally and functionally related to Tup1 of yeast. ▶corepressor, ▶ocellus, ▶Tup1, ▶engrailed, ▶hairy [morphogenesis in *Drosophila* {30}], ▶dorsal [morphogenesis in *Drosophila* {3}]

Groundnut (peanut, *Arachis hypogea*): About 40 – 70 species, $2n = 2x = 20$; some have higher ploidy. Some people are allergic to peanut protein that binds immunoglobulin (IgE) in the intestinal mucosa resulting in histamine release, which may cause contraction of the smooth muscles of the airways and anaphylactic reaction. It should be promptly counteracted by epinephrine to prevent serious consequences that may include death. (See Burow MD et al 2001 Genetics 159:823).

Ground State: Stable, normal, not excited form of an atom, molecule, or gene.

Group Selection: Group selection may occur when the behavior of individuals influences their own fitness and the fitness of related individuals and is selected by Nature accordingly. ▶altruistic behavior, ▶kin selection, ▶nepotism

Group Transfer Potential: Ability of a compound to donate an activated group (e.g., phosphate or acyl).

Growth: ▶cell growth, ▶growth curve, ▶exponential growth, ▶invasive growth

Growth Cone: The tip of growing axons. ▶axon

Growth Curve: Cell multiplication may start at an exponential rate under ideal conditions for proliferation, then it reaches a stationary phase (growth flattens) and only maintenance of the cell population takes place (S curve) (see Fig. G65). The exponential growth is named so because an exponent of base 2 can mathematically define the growth. Thus, after 10 divisions of a cell the expected number is 2^{10} . In case

the initial cell number was 100, after exponential growth, the number of cells 10 generations later would be $2^{10} \times 100 = 1024 \times 100$. Alternatively, growth may decline and the level of the population decreases. In higher organisms, such growth curves can be observed only in isolated cell cultures. In differentiated tissues the growth has structural limitations.

Figure G65. Growth curve

Growth Factors: ▶FGF, ▶PDGF, ▶EGF, ▶IGF-I, ▶IL-2, ▶IL-3, ▶NGF, ▶TGF, ▶erythropoietin, ▶cell cycle, ▶growth hormone pituitary, ▶brassinosteroids, ▶epidermis

Growth Hormone, Pituitary: The gene complex for the hormone is in human chromosome 17q23-q24 and encodes a 190 amino acid protein, human growth hormone (hGH), and also the somatotropin, a chorionic growth hormone (191 amino residue with ≈85% homology to hGH), and a growth hormone-like protein (GHL, 22-kDa). The expression of the hormone gene complex is regulated by the 33-kDa growth hormone transcription factor (GHF1) and growth factor response protein (GFRP1). The hGH is released by a 44-amino acid growth hormone-release factor (GHRF) encoded at chromosome 20p12. ▶pituitary dwarfism, ▶pituitary, ▶brain human, ▶secretagogue, ▶ghrelin, ▶Rowley-Rosenberg syndrome, ▶Gapo syndrome, ▶prion

Growth Hormones: Growth hormones and receptors are associated with many cellular proliferative processes and nuclear localization of the growth hormone receptors is associated with various types of cancer (Conway-Campbell BL et al 2007 Proc Natl Acad Sci USA 104:13331). ▶animal hormones, ▶plant hormones, ▶nuclear receptors

Growth Retardation: Reduction in the rate of increase in size, cell multiplication, differentiation and development. ►retardation, ►Rowley-Rosenberg syndrome, ►GAPO syndrome, ►Gombo syndrome

Growth-Associated Kinase: An M-phase histone-1 kinase, functions at its peak in mitotic M phase but its activity ebb at other phases; it is also active during meiosis. ►histones, ►mitosis

GRP: Heat shock glycoproteins of the HSP family. GrpE is itself not a chaperone but as ADP-ATP exchanges factor it is part of the DnaJ-DnaK chaperone complex of prokaryotes and the replication machinery of phage lambda. Its homologs are present in prokaryotes as well as in the mitochondria of yeast, insects, and mammals. The mammalian Grp94 (member of the Hsp90 family of proteins) chaperones are a small number of proteins and are suspected to be involved in antigen presentation and tumor rejection. ►heat-shock proteins, ►HSP, ►DnaK, ►Mge1, ►Droel, ►Hsp90, ►antigen processing and presentation, ►endoplasmic reticulum

GRP: General receptors of phosphoinositides. ►phosphoinositides

Grunstein-Hogness Screening: Grunstein-Hogness screening involves in situ lysis of bacterial colonies on nitrocellulose filters (or other membranes) and non-covalent attachment of the probe DNA to that support medium. ►Benton-Davis plaque hybridization, ►probe; Elvin P et al 1988 Br J Cancer 57:36.

G_s Protein: A stimulatory G protein; when bound to GTP it stimulates the activity of adenylate cyclase, the membrane bound enzyme, which generates cAMP. G_s has α , β and γ subunits, the GTP/GDP binding site being on the α subunit. When GDP is at the nucleotide-binding site, adenylate cyclase activity ceases. Displacement of GDP and replacement by GTP (mediated by the hormone, epinephrine) restores the active form. At this stage, the α sub-unit with bound GTP dissociates from β and γ . ►G-proteins, ►adenylate cyclase, ►signal transduction, ►oogenesis

GSC (genome structure correction): A method to adapt statistical tests to make fewer assumptions about the distribution of features on the genome sequence. This provides a conservative correction to standard tests. ►genome sequence sampling

GSC RT-PCR: ►global single cell reverse transcription-polymerase chain reaction

GSD (genetically significant dose): GSD determines the effectiveness of a mutagenic exposure. ►mutation rate, ►doubling dose, ►genetic hazards, ►genetic load, ►mutation spontaneous

GSEA (gene set enrichment analysis): GSEA detects modest but coordinate expression of groups of functionally related genes. The relevant genes are ranked according to difference in expression between two conditions of interest. The null hypothesis is that the expression is random between the two groups. The alternative hypothesis is that the rank of the affected individuals of the pathway members is associated with the diagnostic criteria used for the characterization. The extent of the association is measured by a non-parametric test. The maximum enrichment score (MES) is evaluated after random permutation of the diagnostic labels between the groups. The actual MES is then compared to the distribution of the enrichment score over all pathways tested. Subramanian A et al (2005 Proc Natl Acad Sci USA 102:15545) described an improved version and the procedure (software) is freely made available. On the basis of microarray information, the genome-wide factors involved in a pathway, e.g., leukemia or lung cancer can be predicted. ►null hypothesis, ►cluster analysis; Mootha VK et al 2003 Nature Genet 34:267.

GSH: Reduced glutathione. ►glutathione

GSK3 (glycogen synthase kinase 3 β): A protein encoded by *Drosophila* gene *zeste white* (z^{W3} , chromosome 1-1); homologous proteins are present in other animals. It is assumed that GSK is mediating a step in the intestinal polyposis carcinogenic pathway. It also regulates global protein synthesis. GSK3 β is involved in the induction of mammalian neurogenesis in embryonic stem cells targeted by 4,6-disubstituted pyrrolopyrimidine (Ding S et al 2003 Proc Natl Acad Sci USA 100:7632). GSK-3 β mediates the establishment and maintenance of neuronal polarity and its inhibitors may be suitable targets to promote the generation of new axons after neural injury (Jiang H et al 2005 Cell 120:123). Therapeutic concentration of lithium (LiCl) inhibits GSK-3 α by interfering with the γ -secretase cleavage of amyloid precursor protein (APP). GSK-3 α also phosphorylates the tau protein, the main component of the neurofibrillary tangles in Alzheimer disease. Thus GSK-3 α may control two steps in the development of Alzheimer disease (Phiel CJ et al 2003 Nature [Lond] 423:435). Levels of Akt-GSK3 β reduction appear to be a factor in schizophrenia (Emamian ES et al 2004 Nature Genet 36:131). AKT-activated GSK also regulates apoptosis. The anti-apoptotic BCL-2 family proteins control the permeabilization of the outer membrane of the mitochondria, whereas the pro-apoptotic BAX and BAK are required for permeabilization. GSK-3 phosphorylates MCL-1 (member of the BCL-2 family of proteins), leading to its degradation by the proteasome and facilitating the release of cytochrome c and apoptosis (Maurer U et al 2006 Mol Cell

21:749). ►polyposis adenomatous intestinal, ►translocation initiation, ►conductin, ►GBP, ►Alzheimer disease, ►tau, ►secretase, ►stem cell, ►AKT oncogene, ►neurogenesis, ►adipocyte, ►apoptosis, ►cleft palate, ►BCL-2, ►BAX, ►BAK, ►epiloia

GSM (genetic sexing mechanism): A method of insect control by producing translocation between the Y chromosome and the X chromosome. The Y translocation serves as a dominant selectable marker and reduces the fertility of the female. ►genetic sterilization, ►autosexing

GSMA (genome search meta-analysis): A linkage analysis procedure based on non-parametric ranking of lod scores or other recombination values. ►lod score, ►non-►parametric tests, ►meta-analysis of linkage, ►affected-sib-pair; Levinson DF et al 2003 Am J Hum Genet 73:17.

gsp: c-oncogene; its product is the α -subunit of G-proteins. ►G-, ►c oncogene

GSP: Gene-specific primer. ►directed mutation, ►c-oncogene

GSS: ►genome sequence sampling

G_{ST}: An index of genetic diversity similar to F_{ST}. (See F; Nei M 1973 Proc Natl Acad Sci USA 70:3321).

GST: ►glutathione-S-transferase

GSTB (Genome Sequence Data Bank): The GSTB maintains nucleotide sequence information on genes and clones ►GenBank; ►NCBI

GT – AG RULE (Chambon's rule): The Chambon's rule states that the first two and the last two nucleotides of introns are GT and AG, respectively; some exceptions are known. ►intron, ►exon

GTL (genome to life): A US Department of Energy project that aims to shed light on the biological mechanisms of microbes and microbial systems under dynamic conditions, in order to use the information for assisting public needs in solving problems of health and the environment. (See <http://DOEGenomesToLife.org/>).

G_t-Protein (transducin): A member of the trimeric G-protein family; it activates cGMP phosphodiesterase in photoreceptors. ►G-proteins; ►rhodopsin

GTBP (G/T mismatch-binding protein): GTBP is encoded in human chromosome 2 and its mutations lead to genetic instability at single nucleotide sites. ►mismatch, ►DNA repair, ►hereditary non-polyposis colorectal cancer

GTF (general transcription factors): Proteins that are required for the initiation of transcription by RNA

polymerase I (TFIs), RNA polymerase II (TFIIs), and RNA polymerase III (TFIIIs). ►transcription factors

GTP: Guanosine triphosphate (see Fig. G66).

Figure G66. GTP

GTPase: ~60 proteins mediating the conversion of GTP into GDP. These enzymes regulate translation, signal transduction, cytoskeletal organization, vesicle transport, nuclear import, and protein translocation across membranes, etc. Two different GTPases may modulate each other's activity. ►RAS, ►RAC, ►RHO, ►RAB, ►RAN, ►RASA, ►dynamins, ►Arf, ►GAP, ►GEF, ►SAR, ►G proteins; Yang Z 2002 Plant Cell 14:S375.

GTPase-Activating Protein (GAP): GAP increases GTP hydrolysis to GDP by several orders of magnitude in signal transduction. ►signal transduction

GTP Binding Protein Superfamily: The GTP binding protein superfamily includes transitional factors, transmembrane signaling proteins, Ras proteins, and tubulins. ►signal transduction, ►E region of GTP-binding proteins

GTP Cyclohydrolase Deficiency (14q22.1-q22.2): The recessive deficiency of guanosine triphosphate cyclohydrolase I results in hyperphenylalaninemia because tetrahydrobiopterin is not converted into dihydroneopterin triphosphate by a process requiring GTP. The disorder involves low urinary pterines, serotonin, and dopamine levels. The afflicted individuals show convulsions, muscular hypotonia of the trunk but hypertonia of the limbs. Oral L-erythro-tetrahydrobiopterin may alleviate some of the symptoms. ►phenylalanine, ►hyperphenylalaninemia, ►pteridines, ►biopterin, ►serotonin, ►dopamine, ►hypotonia, ►hypertonia

Guam Disease: An autosomal dominant complex syndrome displaying the characteristics of amyotrophic lateral sclerosis, Parkinsonism, and dementia, and discovered in Guam. Environmental conditions such as a low calcium and magnesium in the diet and consumption of the Cycas plants seem to favor toxic metal accumulation in the central nervous

system and appears to favor the onset. ►neurodegenerative diseases

Guanidinium Chloride: Guanidinium chloride is used in molecular genetics similarly to guanidinium isothiocyanate for isolation of undegraded RNA. ►RNA extraction

Guanidinium Isothiocyanate: Guanidinium isothiocyanate is used for the isolation of RNA. It breaks up cells, dissociates nucleoproteins, and inactivates tough RNase enzymes (at 4 M solutions) in the presence of the reducing agent β -mercaptoethanol. ►RNA extraction

Guanine: The purine base in DNA and RNA (see Fig. G67). ►glycosylases

Figure G67. Guanine

Guanine Methyltransferase: The guanine methyltransferase methylates the mRNA cap. ►cap

Guanine Nucleotide Binding Protein (16q13, 6q21.3, 20q13.2, 7q21, 22q11.2, 1p13, 3p21, 19p13): The guanine nucleotide binding protein mediates signal transduction on G proteins.

Guanine Nucleotide-Exchange Protein (11p23.3, 19q13.3): The guanine nucleotide-exchange protein catalyze the reaction $GTP \rightleftharpoons GDP$. The large Rho family of G proteins generally contains a Dbl (MCH2) domain and a pleckstrin homology (PH) domain. ►G protein, ►MCH2, ►Rho, ►brefeldin

Guanine Nucleotide Releasing Protein (GNRP, 11q13): GNRP hydrolyzes GTP, bound to G proteins, into GDP. ►signal transduction

Guanosine: The nucleoside of guanine.

Guanosine Tetraphosphate, Guanosine Penta

Phosphate (ppGpp, pppGpp): ppGpp and pppGpp are effectors of the stringent response. ►stringent response; Chatterji D, Ojha AK 2001 Curr Opin Microbiol 4:160.

Guanylate Cyclase: Guanylate cyclase mediates the formation of cyclic guanosine monophosphate, cGMP.

Guanylic Acid: Guanine nucleotide.

Guanylyl Transferase: Guanylyl transferase attaches GTP to the mRNA cap. ►cap, ►GTP

Guard Cell: ►stoma

Guard Hypothesis: The guard hypothesis postulates that the requirement for a specific protein to activate the plant resistance gene when it encounters an avirulence gene of a pathogen and it guards against the suppression of the plant defense mechanism by any bacterial effector.

Guava (*Psidium guajava*): Subtropical, tropical, small, allogamous fruit tree; $2n = 2x = 22$.

Guessmer: Usually 30–7-base long synthetic oligonucleotides representing limited degeneracy and using neutral bases (inosine) at sites of ambiguity. The nucleotide sequence is generated on the basis of information of amino acid sequences in the protein. This label can be used for screening for specific coding sequences (genes). If the codons would be picked at random, the synthetic sequence would represent at least 76% homology by chance, but by considering codon usage of the organism, the homology may be over 90%. The probes are labeled with the aid of polynucleotide kinase or primer extension with the Klenow fragment. ►probe, ►primer extension; O'Farrell PA et al 1997 Biochem Biophys Res Commun 239:810.

Guest Peptide: ►CD tagging

Guest RNA: ►CD-tagging

Guest Tag: ►CD-tagging

Guide RNA: Guide RNA chaperones the alignment of splicing by attaching either to the intron or to the exon sequences of the transcript. ►RNA editing, ►gRNA, ►intron, ►splicing; Kabb AL et al 2001 Nucleic Acids Res 29:2575.

Guillain-Barré Syndrome: A sporadic or familial autosomal dominant. It is a de-myelinating neuropathy arising after infection by *Campylobacter jejuni*. ►Campylobacter

Guillardia: A filamentous alga.

Guinea Pig: *Cavia porcellus*, $2n = 64$ (see Fig. G68).

Figure G68. Guinea pig

Gunther Disease: ►porphyria (erythropoietic porphyria, 10q25.2-q26.3)

GURT: ► **T-GURT**

GUS: The tetrameric glycoprotein acid hydrolase, β -glucuronidase enzyme (gene) is frequently used as a reporter for the in vivo testing of promoters, identifying site-specific expression, or monitoring the excision of transposable elements. Several substrates of the enzyme are useful for releasing a blue color upon activity of GUS. Deficiency of the enzyme in mammals leads to lysosomal storage diseases. ► **lysosomal storage diseases**, ► **gene fusion**, ► **reporter gene**, ► **aging**; Jefferson RA et al 1987 EMBO J 6:3901; Schenk PM et al 2001 Plant Mol Biol 43:399.

Gustatory: “Gustatory” refers to something involving the sensation of taste. ► **taste**

Gustducin: ► **taste**

Gut: The gastrointestinal tract or the developmentally primitive (early) digestive tract composed of fore-, middle-, and hindgut sections. The mammalian gut endoderm forms different ‘buds’ giving rise to the liver, lung, pancreas, thyroid, and gastrointestinal tissues. The developmental fates are determined by the additional growth factors recruited. The microbial flora (10 to 100 trillion microbes/gut) has important function in gastrointestinal health and disease, and substantial variations exist in these populations among individuals (Eckburg PE et al 2005 Science 308:1635; Bäckhead F et al 2005 Science 307:1915). ► **microbiome**, ► **oral bacterial films**

Guthrie Test: Guthrie test detects phenylketonuria because if the blood contains phenylalanine, the analog β -2-thienylalanine does not interfere with the growth of *Bacillus subtilis*. ► **phenylketonuria**, ► **genetic screening**

Guthrie Cards: Guthrie cards are used for genetic testing/screening of newborns—from dry blood samples—for about 30 hereditary disorders.

Gutless/Gutted Vector: Usually a viral vector without nearly any viral gene, which would have been required for viral replication. Such vectors require helpers for trans-complementation and propagation. ► **HDAd**

Guttation: In the process of guttation, water ascending through the xylem vessels of plants may drop from the leaves when relative humidity increases. ► **transpiration**, ► **cohesion-tension**

Guttmacher Syndrome (preaxial deficiency, postaxial polydactyly and hypospadias, 7p15-p14.2): A special hand-foot-genital syndrome, apparently due to mutation in the HOXA13 gene. ► **polydactyly**,

► **hypospadias**, ► **hand-foot-genital syndrome**; Guttmacher AE 1993 Am J Med Genet 46:219.

GVG: A transcription factor constructed of the yeast GAL4 DNA-binding domain, the trans-activation domain of herpes virus VP16, and the hormone-binding domain of the glucocorticoid receptor. ► **galactose utilization**, ► **VP16**, ► **glucocorticoid response elements**, ► **dexamethasone**

GW Body (GWBs): 182-kD proteins characterized by multiple glycine (G)-tryptophan (W) repeats and an RNA recognition motif that binds messenger RNAs and have a role in mRNA degradation (Eystathiou T et al 2003 RNA 9:1171).

GWA (genome-wide association, GWAS): GWAS uses mapping linkage to the level of expression across a genome(s). The analysis may involve various markers, including single-nucleotide polymorphism, and determines the regression of the markers and the trait of interest (Evans DM, Cardon LR 2006 Trends Genet 22:350). Statistical and computer programs are now available for studying the association between known phenotypes and molecular biology markers (Pearson JW et al 2007 Amer J Hum Genet 80:126). This relatively new approach is less expensive for the analysis of complex traits than direct genotyping although it may be adversely affected by microarray-based errors (McGregor S 2007 Eur Hum Genet 15:501). A GWA study of British populations in 2007, including 2,000 individuals for each of seven major diseases and a shared set of 3,000 controls, identified 24 independent association signals at $P < 5 \times 10^{-7}$: one in bipolar disorder, one in coronary artery disease, nine in Crohn’s disease, three in rheumatoid arthritis, seven in type 1 diabetes, and three in type 2 diabetes. The information indicates that this is a new powerful approach for understanding human pathophysiology (Nature [Lond] 447:661). ► **QTL**, ► **genotyping**, ► **microarray hybridization**, ► **human subjects privacy protection**; US federal guidelines concerned with GWA: <http://grants.nih.gov/grants/gwas/index.htm>; privacy protection: Lowrance WW, Collins FS 2007 Science 317:600.

Gy: Gray units of radiation; 1 Gy = 100 rad. ► **rad**

Gy: Billion years of geological time.

Gymnosperm (*Coniferophyta*): Plants with seeds, which are not enclosed in an ovary. Typical representatives are the pine trees ($2n = 24$).

Gymnothecium: The fruiting body of some ascomycetes fungi; it may cause skin infections. ► **perithecium**, ► **cleistothecium**, ► **ascogonium**

Gynander: Same as gynandromorphy, *Drosophila* gynandromorph image from Morgan T et al 1925 Bibliographia Genetica 2:1.

Gynandromorph: Sex mosaic (part male/part female); same as gynander. They are the result of the loss one of the X-chromosomes during development of *Drosophila* and other organisms where the XO chromosomal constitution leads to the development of male phenotypic characteristics (see Fig. G69). The loss of the X-chromosome reveals the recessive alleles present in the remaining homolog. These sex mosaic individuals can be exploited for fate mapping. The right side of the diagram of the fly shows male characteristics and has a ruby eye because the left sector is X0. The left side depicts like female (XX). ▶fate mapping, ▶lyonization, ▶variegation; Szabad J, Fajsz J 1982 Genetics 100:61.

Figure G69. Gynandromorph

Gynecomastia: Increased development of the mammary gland of males caused either by estrogen accumulation and/or reduction of testosterone (see Fig. G70). Deficiency of a gene encoding hydroxysteroid dehydrogenase III (9q22) and increased expression of the cytochrome P450 (CYP, 15q21.2) aromatase subunit may be responsible for pseudohermaphroditism and gynecomastia. X-linked inheritance with male transmission has also been suggested. A transient mild form may not be abnormal during puberty. Several statues of the young pharaoh, Tutankhamen (fourteenth century BC), reveals bilateral gynecomastia and the somewhat bloated stomach suggests the likelihood of celiac disease (see Fig. G71). Gynecomastia can be corrected by plastic surgery (Yavuz M et al 2006 Ann Plast Surg 57 [4]:370). ▶pseudohermaphroditism male, ▶Klinefelter syndrome, ▶Kennedy syndrome, ▶animal hormones, ▶steroid dehydrogenase/ hydroxysteroid dehydrogenase, ▶aromatase; black and white photo showing a young male with gynecomasty on one side of his chest; photo by courtesy of Dr. C. Stern.

Figure G70. Gynecomastia

Figure G71. Tutankhamen

Gynodioecious: A gynodioecious population consists of both hermaphroditic and female individuals, and is generally determined by nuclear and mitochondrial genes. ▶hermaphrodite; Taylor DR et al 2001 Genetics 158:833.

Gynoeceum: The carpels and structures enclosed by them in flowers. ▶fruits; Ferrándiz C et al 1999 Annu Rev Biochem 68:321.

Gynogenesis: Reproduction by parthenogenesis, i. e., the sperm does not fertilize the egg but stimulates the cleavage of the unreduced egg (pseudogamy). Also, embryos developed by transfer of male pronuclei into the egg, and thus diploid are called *gynogenones*, in contrast to *parthenogenones* (gynogenotes), which arise from parthenogenesis. ▶apomixis, ▶parthenogenesis, ▶androgenesis, ▶EP

Gypsy: A somewhat diverse ethnic group migrating from the Indian subcontinent north and southward, presumably before the ninth century, to Asia and to Egypt, and from there to most of the northern hemisphere, although they are now found all over the world. Their Indian origin is asserted by orally transmitted legends. Linguistic evidence indicates Sanskrit roots. Y chromosomal and mtDNA information

support Indian origin. Their ethnic identity has been preserved by cultural and genetic isolation. Haldane JBS (1935) used ABO blood type frequencies to show that the Hungarian Gypsies are more closely related to some Eastern Indian populations than to that of Hungary although some of them lived in that country since the early fifteenth century. They prefer to be called Roma. ► [ethnicity](#); Kalaydjieva L et al 2001 Eur J Hum Genet 9[2]:97; Gresham D et al 2001 Am J Hum Genet 69:1314.

Gypsy Retroposon: ► [copia](#), ► [insulator](#)

Gyrase: A DNA topoisomerase II that reverses the direction of coiling in DNA, resulting in negative supercoiling. ► [DNA replication](#), ► [transcription](#), ► [supercoiling](#), ► [topoisomerase](#); Gellert M et al 1979 Proc Natl Acad Sci USA 76:6289; Kirchhausen T et al 1985 Cell 3:933; Williams NL, Maxwell A 1999 Biochemistry 38:13502.

G

Historical vignettes

“William Curtis, British botanist, described a weed called *Arabidopsis thaliana* as having ‘no particular virtues or uses’. More than 200 years later, he could not have been proved more wrong.”

The Guardian, UK, quoted after Jane Alfred, Editor of Nature Rev. Genet. 2001, 2:86.

Herman N Eisen 2001 in Annu. Rev. Immunol. 19:1

“...the self-correcting character... is inherent in the scientific enterprise. This aspect of science seems at times to be utterly incomprehensible to journalists, politicians, and the public at large—as I was to find out painfully many years later...”

H

H: A heavy chain of a double-stranded DNA.

H1, H2A, H2B, MacroH2A, H3, H4: H1 and H5 are variants of H1 histones. ► [histones](#)

h (Planck constant): An energy quantum of radiation that relates it to the frequency of the oscillator that emitted it. $E = h\nu$ where E is the energy quantum, ν is its frequency, numerically 6.624×10^{-27} erg/sec.

h: Also indicates the human homolog of a gene or protein standing in front of the symbol.

H-2: The major histocompatibility gene cluster in the mouse is located to chromosome 17, proximal to the centromere within a segment of about 1.3 cM consisting of about 2,000 kb DNA. They encode cell surface glycoproteins that have a major role in recognition and immune response to foreign antigens. The gene order in this cluster encoding Class I, Class II and Class III and Class I-like polypeptides is:

K-A-E-C2-Bf-SLP-OH-C4-TNF-D-D2-D3-D4-L-Q-T-T1a-centromere. The transplantation antigens are the Class I proteins coded for by genes K, D and L. The Class II proteins, encoded by genes A and E, occupy the surface of B and T lymphocytes and the macrophages and participate in cell immune responses. The Class III proteins coded for by genes C2, Bf, SLP, OH, and C4 are the complement proteins of the serum involved in the lysis of foreign material after the recognition by the antibody. The Q and T loci determine the so-called differentiation antigens present in the blood cells. TNF is the tumor necrosis factor gene. ► [HLA](#), ► [antibody](#), ► [lymphocytes](#), ► [TNF](#); Fischer K et al 1997 Annu Rev Immunol 15:851.

h²: The symbol of heritability; it is derived historically from Sewall Wright's definition of heritability as the ratio of the standard deviations of the additive and phenotypic variances, $h^2 = V_A/V_P$. Heritability is not a squared entity, and h^2 stands for heritability and not for its square. More at ► [heritability](#), ► [correlation](#), ► [offspring-parent regression](#), ► [intraclass correlation](#), ► [heritability estimation in humans](#)

H Test: An H test defines, statistically, the effect of hitchhiking on the evolution of genomes. H is the average difference between θ_π , which is based on the average frequency of heterozygosity and influenced most by the average intermediate frequency variants, and $\hat{\theta}_H$, which is influenced mainly by the average high-frequency variants. Under neutrality the

expected difference between the two estimators of θ is zero, but following the hitchhiking event $\hat{\theta}_H$ and $\hat{\theta}_w$ (the total number of segregating sites) should be $>\theta_\pi$. ► [hitchhiking](#); Fay JC, Wu C-I 2000 Genetics 155:1405.

H Value Paradox: The H value paradox expresses the tendency of homology across a genome and it may indicate a late specific expansion after losing some of the evolutionarily ancestral genes. ► [C value paradox](#), ► [N value paradox](#); Petrov DA 2001 Trends Genet 17:23.

HA: ► [hemagglutinin](#)

HAART: Stands for highly active antiretroviral therapy.

Habitat: An area in nature where an organism(s) occur(s) naturally. ► [source habitat](#), ► [sink habitat](#)

Habituation (accoutumance à l'auxine, anergie à l'auxine): Plant tissues, after prolonged culture, may dispense of the continued reliance on exogenous auxins for proliferation. This alteration does not involve somatic mutation yet it bears similarity to oncogenic transformation. In animal cells, the SV40 T antigen loss after a period of time still may not cease proliferation in the absence of the oncoprotein. ► [tissue culture](#), ► [somatic mutation](#), ► [transformation oncogenic](#), ► [tumor](#), ► [oncoprotein](#), ► [SV40](#); Gautheret RJ 1955 Rev Gen Bot 62:1.

Habrobracon: ► [wasp](#)

Habsburg Lip: The protruding lower lip and the undershot lower jaw were transmitted among male and female members of this European dynasty up to the twentieth century. The coin shown here represents Maximilian I (1459–1519) (see Fig. H1). (See Thompson EM, Winter RM 1988 J Med Genet 25:838).

Figure H1. The Habsburg lip on a coin of Maximilian I

HAC (hyperpolarization activated channels): ► [I_h](#)

HAC (human artificial chromosome): Critical elements (telomeres, centromeres, and replicator) must be present. HACs can eventually be used to ferry

desirable genes to human cells for medical purposes. A useful human artificial chromosome should be much smaller than the smallest chromosome in the natural genome in order to transfer genes into human cells, yet it should be big enough to carry large human or mammalian genes and some regulatory sequences. Minichromosomes of ~4 Mbp appear stable but those below 2.5 Mbp seem unstable. The useful HAC is expected to be stable through mitosis and possibly even through meiosis. This requires a minimal functional centromere and telomeres. The centromeric DNA (α -satellite) is variable in length in the different human chromosomes but in order to function may have to comprise ~150 kbps. It should not incite an adverse immunological reaction in the recipient cell. For experimental manipulation it is desirable that the HAC be easily transferable to any type of cell, including, e.g., yeast cells. ▶**YAC**, ▶**BAC**, ▶**PAC**, ▶**human artificial chromosome**, ▶**minichromosome**, ▶**MAC**, ▶**HAEC**, ▶ **α -satellite**, ▶**DT40**, ▶**vectors**; Henning KA et al 1999 Proc Natl Acad Sci USA 96:7125; Shen MH et al 2000 Curr Biol 10:31; Csonka E et al 2000 J Cell Sci 113(18):3207; Mejia JE et al 2001 Am J Hum Genet 69:315.

HAC1: A basic leucine zipper protein; is a transcription factor that binds to the UPR element in the promoter of the UPR genes. ▶**unfolded protein response**

H/ACA Box: Nonprotein-coding RNAs, which include small nucleolar RNAs (snoRNAs), small Cajal body-specific RNAs (scaRNAs), and a homologous class of RNAs in archaeal organisms. Typical box H/ACA RNA exhibits a common hairpin-hinge-hairpin-tail secondary structure with the H (ANANNA) motif in the single-stranded hinge region and an ACA triplet located 3 nucleotides upstream of the 3' termini. The majority of known H/ACA RNAs play important roles in the posttranscriptional modification of rRNAs and snRNAs. H/ACA snoRNAs direct the conversion of uridine to pseudouridine at specific residues of eukaryotic ribosomal RNAs and Pol III-transcribed snRNA U6, whereas H/ACA scaRNAs guide the formation of Pol II-transcribed spliceosomal nuclear RNA. Some H/ACA RNAs process ribosomal RNAs. In humans, 100 H/ACA RNAs have been identified, and most of which are located within the introns of protein-encoding genes. Retrotransposition seems to have played a pivotal role in the mobility and diversification of H/ACA RNA genes. In the human genome 202 sequences derived from box H/ACA snoRNAs (Luo Y, Li S 2007 Nucleic Acids Res 35: 559). ▶**noncoding RNA**, ▶**snoRNA**, ▶**Cajal body**, ▶**pseudouridine**

Hae II: A restriction enzyme with recognition site
 $\begin{array}{c} \text{A} \\ \text{G} \end{array} \text{GCGC} \downarrow \begin{array}{c} \text{T} \\ \text{C} \end{array}$

Hae III: A restriction enzyme with recognition site GG↓CC.

HAEC (human artificial episomal chromosome): The HAEC was constructed by using the replicational origin of the Epstein-Barr virus. Such a construct may carry over 300-kb inserts and may be maintained in human cells without integration (as an episome) in the genome. ▶**Epstein-Barr virus**, ▶**episome**; Wade-Martins R et al 2000 Nat Biotechnol 18:1311.

Haem: Iron-porphyrin; occurs in different forms (see Fig. H2). Chlorophyll contains Mg porphyrin. ▶**heme**, ▶**chlorophyll**

Figure H2. Heam

Haematopoietic Growth Factor: ▶**IL-3**

Haematoxinil: ▶**hematoxylin**

Haemochromatosis: ▶**hemochromatosis**

Haemophilus influenzae: Gram-negative bacterium and an early object of genetic transformation. The first free-living organism completely sequenced by 1995. Its genome includes 1,830,137 bp. (See Fleischmann RD et al 1995 Science 269:496).

Hailey-Hailey Disease (HHD, benign pemphigus): An autosomal dominant skin disease involving vesicle formation generally on the neck, groin, and armpits. The benign disease is precipitated by infection by the fungus *Candida albicans*, but antifungal, antibacterial drugs may also initiate it. Mutation in an ATP-powered ion pump sequestering calcium into the Golgi apparatus causes HHD. ▶**skin diseases**, ▶**pemphigus**

Hair: The human hair has a high- and a low-sulfur protein; the former is about 40% of the hair proteins. In some animal hairs a high-tyrosine protein also occurs. Hair develops from multipotent clonogenic keratinocytes, which are similar to multipotent stem cells. Hair follicle progenitor cells are maintained in an undifferentiated state by the transcription factor Lhx2 (Rhee H et al 2006 Science 312:1946). Regeneration of lost hair follicles was considered unlikely. After wounding of mouse skin, in the presence of functional *Wnt* gene de novo follicle formation occurs from epithelial cells (Ito M et al

2007 Nature [Lond] 447:316) promising new approaches to treating hair loss in mammals. ▶hair color, ▶hair whorl, ▶alopecia, ▶hypotrichosis, ▶hypertrichosis, ▶baldness, ▶De Lange syndrome, ▶glomerulonephritis with spare hairs, ▶hairy ears, ▶hairy elbows, ▶hairy nose, ▶hairy palms and soles, ▶hair-brain syndrome, ▶catenins, ▶keratin, ▶widow's peak; Fuchs E et al 2001 Develop Cell 1:13; Jave-Suarez LF et al 2002 J Biol Chem 277:3718; Tumber T et al 2004 Science 303:359; Fuchs E 2007 Nature [Lond] 445:834.

Hair Color in Humans: Strikingly blond and red hair colors (prevalence about 2% or less) appear to be autosomal recessive but the latter may have some expression in the heterozygotes. Red hair is hypostatic to brown and black. Brown hair appears to be autosomal dominant and it is closely linked to green eye color. Dark hair appears to be dominant. The babies' first hair may not be concordant with that of later years. The relative proportions of the reddish pheomelanin and the black eumelanin pigments determine the hair color. Their level is controlled by the melanocyte stimulating hormone (MSH) and its receptor (MC1R). Environmental factors (temperature, sunshine, diseases) may also affect transiently the color. Graying of the hair is usually preceded by aging, however, precocious graying may be determined by dominant genes and it may be a symptom shared by several syndromes such as the Waardenburg and the Werner syndromes; pernicious anemia (a vitamin B12 deficiency) may also cause it. Graying in the aged is caused by defective self-maintenance of the melanocyte stem cells (see Fig. H3). Pax3 and Mitf (positive regulator of tryptophan and tyrosinase transcription) molecules balance melanocyte stem cell maintenance and differentiation (Steingrimsdottir E et al 2005 Cell 121:9). In case of deficiency of the anti-apoptotic Bcl2, the process is greatly accelerated (Nishimura EK et al 2005 Science 307:720).

Figure H3. Hair follicle. The black circles are melanocyte stem cells. The white spots are mature melanocytes. The sebaceous gland lubricates the hair.

Actually, the inheritance of human hair is determined by many loci. In human chromosome 19 alone there are 6 loci homologous to fur color genes of the mouse. ▶pigmentation in animals, ▶forelock white, ▶albinism, ▶melanin, ▶aging, ▶hypostasis, ▶BCL2, ▶Pax; Sturm RA et al 1998 Bioessays 20 (9):712; Flanagan N et al 2000 Hum Mol Genet 9:2531; Healy E et al 2001 Hum Mol Genet 10:2397.

Hair Whorl: May be clockwise, that is autosomal dominant over counterclockwise rotation. Hair pattern is controlled by the *frizzled 6* gene and homologs, which are receptors of the *Wnt* gene. ▶hair, ▶wingless; Guo N et al 2004 Proc Natl Acad Sci USA 101:9277.

Hair-Brain Syndrome (trichothiodystrophy, BIDS): A condition characterized by autosomal recessive brittle hair, low intelligence, short stature, reduced fertility and reduced cystine-rich protein in the hair and nails. ▶hair, ▶stature, ▶trichothiodystrophy

Hairpin: A double-stranded structure in nucleic acids brought about by folding back of palindromes like a hairpin. At the end, where the arrow is pointed → C, the unpaired structure may be digested by S₁ single-strand-specific nuclease. ▶S₁ nuclease, ▶palindrome, ▶pseudohairpin

Hairy Ears: Hairy ears (see Fig. H4) occur primarily in the male humans and have been thought to be due to Y-chromosomal (holandric) gene(s) or to two genes in the homologous segments of the X and Y chromosomes. Most likely it is determined by autosomal dominant factors and sex-influenced inheritance. ▶sex-influenced, ▶holandric genes. [Photo is courtesy Dr. Curt Stern.]

Figure H4. Hairy ear

Hairy Elbow: An autosomal dominant hairiness on the elbows associated with short stature. ▶hair

Hairy Nose: Autosomal dominant (?) hairs on the nose tip; onset after puberty in the male only. ▶hair

Hairy Palms and Soles: Apparently autosomal dominant, male transmitted, site-specific hairiness. hair.

Hageman Factor: A protein (M_r ca. 80,000) present in the blood plasma and serum of the majority of mammals, but absent in dolphins, killer whales and birds. It is involved in the blood coagulation pathway; it also affects vascular permeability, dilates blood vessels, contracts smooth muscles, provokes pain, promotes the migration of leukocytes, induces fibrinolysis (dissolution of fibrin), etc. ▶[antihemophilic factors](#), ▶[Hageman trait](#); Schousboe I et al 1999 Thromb Haemost 82:1041; Gaffney PJ et al 1999 Haemostasis 29:58.

Hageman Trait: The Hageman trait is controlled by an autosomal recessive gene causing deficiency of the Hageman factor in the blood. Normally, the individuals lacking this factor do not show any disease symptom although blood coagulation is slow in the laboratory. No therapy is required, yet, in case of surgery, it is advisable to keep at hand appropriate blood or plasma. ▶[Hageman factor](#)

Haldane's Mapping Function: $(1 - e^{-m}) 0.5 = y$ (recombination fraction), where m is the number of exchanges, e is the base of the natural logarithm. Hence, $(1 - e^{-m}) = 2y$, and $e^{-m} = 1 - 2y$ and $m = -\ln(1 - 2y)$ and the corrected map distance estimate is $x = m/2$ because each exchange produces maximally 50% recombination. This formula does not take into account interference and thus frequently overestimates map distances. The graph (see Fig. H5) permits reading directly the recombination frequencies corrected by Haldane's mapping function.

Different organisms may require different mapping functions (Stahl FW Genetic recombination, Freeman, San Francisco, California). ▶[Kosambi's mapping function](#), ▶[mapping functions](#), ▶[recombination frequencies](#), ▶[mapping genetic](#), ▶[coefficient of coincidence](#)

Haldane-Muller Principle: The seriousness of the consequences of a mutation is not its deleterious effect because a dominant lethal mutation is eliminated immediately, but its probability of death. Thus moderately disadvantageous mutations may be maintained for many generations and in each generation they may adversely affect the fitness and eliminate a number of individuals. ▶[genetic load](#)

Haldane's Rule: When, in the F_1 offspring of two different animal races, one sex is absent, or sterile, that sex is the heterogametic one. The cause is not an imbalance between autosomes and sex-chromosomes, rather it is due to the somewhat general fact that lethality is usually completely recessive whereas deleterious mutations may show a series of less debilitating effects that may also be expressed in heterozygotes. Another interpretation in some species is the "the faster male" theory, i.e., the sex-specific, male fertility genes evolve faster than those responsible for female fertility. It has been suggested that the reduction in the heterogametic class is due to sex transforming genes. This mechanism may play some but apparently insignificant role. Another interpretation pointed to dosage compensation, which may

Figure H5. Read the point of intersection between the recombinant fraction observed (ordinate) line and the solid line curve corresponding to the mapping function and project the point to the bottom line representing map units. For example, 0.3 recombination corresponds to about 45–46 map units. (After Haldane JBS 1919 J Genet 8:299)

break down in crosses between distantly related species. This interpretation is contradicted by the fact that Haldane's rule is observed in the ZW sex determination system albeit dosage compensation is not evident. Furthermore, in mammals, the X chromosome inactivation in the females ►[Lyon hypothesis](#) and the hypoactivation of the X chromosome in the hermaphroditic *Caenorhabditis* are kinds of female dosage compensation. X-Y and Y-Autosome incompatibilities may account, to some extent, for the sterility of species hybrids but not for their viability. Meiotic drive has also been invoked as a possible cause without general acceptance. There are some examples of cytoplasmic effects, independent of heterogamety, although they may affect heterogametic individuals ►[segregation distorter](#), ►[infectious heredity](#). With rare exceptions, Haldane's rule is generally valid. ►[sex-chromosomes](#), ►[sex determination](#), ►[hybrid inviability](#), ►[hybrid sterility](#); Haldane JBS 1922 J Genet 12:101; Laurie CC 1997 Genetics 147:937; Naisbit RE et al 2002 Genetics 161:1517.

Half-Chromatid: A half-chromatid involves only one of the strands of the DNA double helix in the chromatid. The expression of mutation is delayed by one division if it occurs in a half-chromatid and it may result in somatic sectors after replications. chromatid.

Half Conversion: In yeast the tetrad contains 2 *A*, 1 *a* and 1 *A/a* heteroduplex sectorial spores. ►[gene conversion](#)

Half-Life: In general, half-life is the time required for the decay of one half of a compound; the decay, e.g., of a promutagen or procarcinogen may lead to the formation of an even more active mutagen and/or carcinogen. The half-life of H^3 and C^{14} is 12.4 and 53,700 years, respectively, and that of P^{32} 14.3, P^{33} 25.4 and I^{131} 8, I^{125} is 60 days respectively. The half-life $T_{1/2} = 0.693/\lambda$, and λ = the characteristic disintegration constant for the specific isotope. The radioactivity is gradually decreasing by time and the correlation between the number of half-lives passed and the chart (see Fig. [H6](#)) shows the amount of radioactivity still remaining. The mean and median half-life of 3,751 proteins of yeast was ~43 min but in 161 unstable proteins it was only ~4 min (Belle A et al 2006 Proc Natl Acad Sci USA 103:13004).

►[evolutionary clock](#), ►[isotopes](#), ►[radiocarbon dating](#), ►[mRNA](#)

Half-Mutant: Half-mutant is a Hugo de Vries' term for the new types that arose relatively frequently in *Oenotheras* with translocation rings. The half-mutants produced normal (translocation-ring) and sterile progenies due to recombination between the differential segment and its homolog in another chromosome within the ring resulting in smaller rings and other chromosomal changes. When the non-crossover original translocation ring was recovered in the egg and sperm, the offspring was the same as the original complex heterozygotes. ►[complex heterozygote](#)

Half-Sibs: Half-sibs share only one biological parent; they are half-sisters or half-brothers. ►[sibling](#)

Half-Tetrad Analysis: Tetrad analysis is feasible in a limited number of organisms where the four products of meiosis can be separately recovered either as a tetrad or, after a post-meiotic division, as an octad, a phenomenon common in ascomycetous fungi. In *Drosophila*, half-tetrad analysis can be carried out in the presence of attached X chromosomes (See Fig. [H7](#)). In this case, the products of meiosis have either two attached X chromosomes or are nullisomic for the X chromosome. X-chromosomal genes are inherited as a block unless recombination takes place. Flies heterozygous for attached X-chromosomal genes can become homozygous only after crossing over and producing two different nonparental gametes from a single meiocyte. This type of recombination provided the first direct evidence that genetic recombination takes place at the 4-strand stage of meiosis.

Half-tetrad analysis has been adapted to a plant (*Medicago*) case using four RFLP markers in situations when restitution nuclei were observed at a high frequency. Three of the markers were linked (chromosome 1) and the fourth was independent (chromosome 6). The analysis permitted the localization of the centromere. Trisomics may also be used for half-tetrad analysis. Molecular analysis of individual secondary oocytes by PCR may also reveal gene positions. ►[tetrad analysis](#), ►[gene-centromere distance](#), ►[attached X chromosomes](#), ►[restitution nucleus](#), ►[disomic](#); Nullisomic, Zhao H, Speed, T.P. Genetics 150:473.

Figure H6. Half-life. The chart depicting the correlation between the number of half-lives passed and the amount of radioactivity that still remains

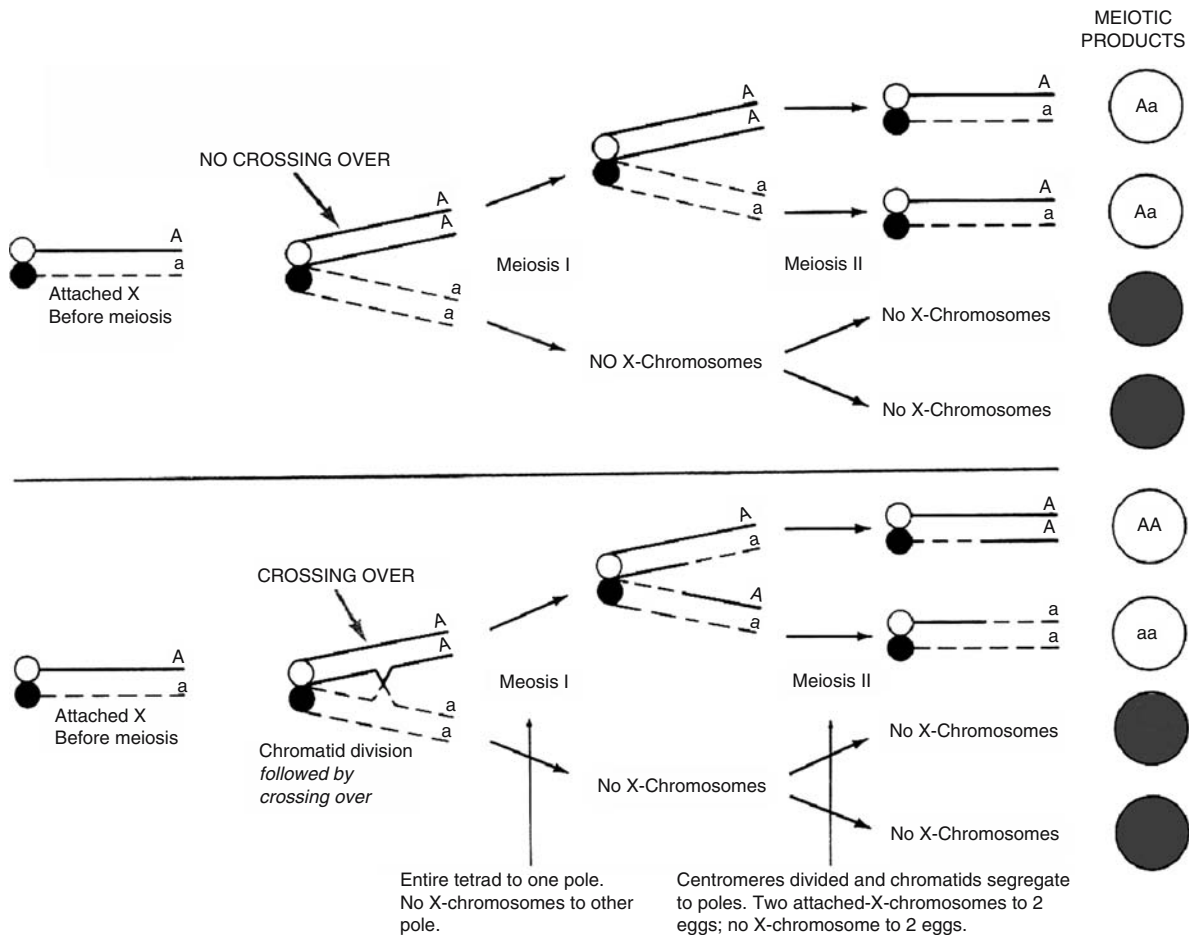

Figure H7. Half-tetrad analysis in *Drosophila*. Because the centromeres of the attached x chromosomes are stably fused, they cannot pass to opposite poles during anaphase I. Segregation of the chromatids is equational at anaphase II. Instead of four viable meiotic products, only two X-disomic and two lethal, nullisomic gametes are formed. If the two attached chromosomes carry different alleles, all the non-crossover gametes will be the same and only the crossovers will be of two nonparental types. (After Shult EE, Lindegren CC 1959 Can J Genet Cytol 1:189)

Half-Translocation: A half-translocation is the half of an original reciprocal translocational event. Such a situation occurs, e.g., when a presumably reciprocal interchange takes place between the proximal region of an X chromosome and the small 4th chromosome of *Drosophila*, but one of the translocated strands is not recovered because it gets lost during segregation of chromosomes into the functional gamete. ▶[translocation chromosomal](#)

Half-Value Layer: The half-value layer reduces the transmission of radiation to half.

Hallermann-Streiff Syndrome: Characteristics include, most likely, an autosomal recessive bird-like face, long, narrow nose, cataracts, sparse hairiness, occasionally

teeth by birth and proportionate dwarfism. ▶[dwarfs](#), ▶[tooth](#)

Hallervorden-Spatz Disease (neuroaxonal dystrophy): Human chromosome 20p12.3-p13 located recessive brain atrophy accompanied by involuntary movement and early death. The brain accumulates iron in the basal ganglia probably due to defects in the panthotenate kinase gene. ▶[Lewy body](#), ▶[synuclein](#), ▶[ferritin](#); Zhou B et al 2001 Nat Genet 28:345.

Halophyte: A salt-tolerant or salt-resistant plant species.

Halo Assay: A substance is placed at a spot to a microbial culture plate and inhibition of growth or reverse mutations appear as a circle around the spot (see Fig. [H8](#)).

Figure H8. Halo assay

Halothane Gene: The halothane gene controls malignant hyperthermia syndrome in pigs (in chromosome 6). Halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) is an anesthetic applied by inhalation. ►PSE

Haltere (singular), **Halteres** (plural): Halteres are balancing organs. *Ultrabithorax* (*Ubx*) controls haltere size by restricting *Decapentaplegic* (*Dpp*) by increasing the amount of *Dpp* receptor, *thickveins* (Crickmore MA, Mann RS 2006 Science 313:63). (See Fig. H9; ►morphogenesis in *Drosophila*).

Figure H9. Haltere

Halvorson 5: A nutrient concentrate for yeast g/L $(\text{NH}_4)_2\text{SO}_4$ 20, K_2HPO_4 43.5, succinic acid 29, $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ 1.99, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 5.11, *trace elements* 5 mL [containing mg/0.5 L $\text{Fe}_2(\text{SO}_4)_3$ 307, MnSO_4 280, $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$], pH 4.7. This medium is usually diluted five times.

HAMA (human anti-mouse antibody): A human antibody response against murine monoclonal antibodies. The HAMA complexes are usually rapidly cleared from the human body and may incite allergic reactions or even anaphylactic shock. Engineered rodent antibodies may overcome the problems. Human antibodies are better because they are compatible with the complement system and ADCC. ►monoclonal antibody, ►complement, ►ADCC, ►humanized antibody

Hamartin: ►epiloia

Hamartoma: A tissue overgrowth (of darker color).

Hamiltonian Path: A directed graph if and only if there is a sequence of a one-way path beginning with *vin* (vertex in) and ending at *vout* and enters every other vertex exactly once. This mathematical method may serve the basis for designing a molecular (DNA)

computer that may assist in developing very complex combinatorial approaches to manipulating macromolecules, e.g., designer enzymes. ►DNA computer, ►RNA computer; Liu Q et al 2000 Nature [Lond] 403:175.

Hamilton's Rule: ►inclusive fitness

Hammerhead: ►ribozymes

HAMP Domains (histidine kinases, adenylyl cyclases, methyl-accepting chemotaxis proteins and phosphatases): HAMP domains are in the C-terminal end of transmembrane segments. HAMP occurs in thousands of proteins connecting extracellular sensing with intracellular signaling. It operates with signal transduction. ►signal transduction; Hulko M et al 2006 Cell 126:929.

Hamster: *Cricetulus griseus* (Chinese [gray] hamster) $2n = 22$; *Mesocricetus auratus* (Syrian [golden] hamster), $2n = 44$.

Hand Clasping: Some authors claimed that it is genetically determined whether the left- or right-hand fingers (the latter more common among females) are on top when hands are clasped. The control may be autosomal dominant or polygenic. ►handedness

Handcuffing: The products of plasmid replication associated with *incA* and *incC* (incompatibility factors of replication) that cause antiparallel pairing of the two DNAs preventing replication until the "handcuffs" are disrupted. (See Chatteraj DK 2000 Mol Microbiol 37:464).

Handedness: About 93% of the human population is right-handed; left-handedness is higher among younger age groups than in the older age groups indicating greater longevity of right-handed individuals. Right-handedness most frequently is associated with clockwise orientation of the hair whorls on the scalp. Lefties and ambidextrous individuals display either clockwise or counterclockwise hair swirls. The inheritance of handedness is unclear; it was attributed to polygenic control (2p12-q11, Francks C et al 2003 Am J Hum Genet 72:499), and it has been suggested that it is due to a homozygous recessive state, the heterozygotes being ambidextrous (able to use both hands with equal facility). In *Arabidopsis*, left-right asymmetry of leaf twisting is controlled by the intradimer interface of α -tubulins 4 and 6 (Thitamadee S et al 2002 Nature [Lond] 417:193). (See Klar AJS 2003 Genetics 165:269).

Hand-Foot-Genital Syndrome (Hand-Foot-Uterus syndrome, HFU, 7p15-p14.2): A rare condition with dominant malformations of hands, feet, fingers, toes, vaginal septum and uterine anomalies in girls, hypospadias in boys, common infections of the

urinary tract, and other variable symptoms. The mutation affects a HOXA13 gene. ►[hypospadias](#), ►[homeotic genes](#), ►[Guttmacher syndrome](#)

Hand-over-Hand Model: One way that motor proteins may move along microtubules. The two-headed kinesin may move ahead by alternative steps of its two heads and thus exchanging leading and trailing roles ►[kinesin](#), ►[motor protein](#), ►[microtubule](#); Asbury CL et al 2003 Science 302:2130.

Hanging Drop Slide: The material to be examined microscopically hangs from the cover slip into the concavity of the slide in a drop of a solution (see Fig. H10).

Figure H10. Hanging drop slide

Hap: A positive control protein of transcription (46 kDa), attached to one or two sites in the DNA. It generally associates with heatshock protein70 (Hsp70). Its murine homolog is BAG-1.

Haplodiploidy: In some social insects (Hymenoptera), the males (drones) are haploid (because they develop from unfertilized eggs) whereas the females (queen and workers) are diploid (because they hatch from fertilized eggs). Consequently, usually full sisters (progeny of a single mating) are more closely related to each other and less closely related to their brothers than to their daughters and sons. In the wasp, *Bracon hebetor*, the females are normally heterozygous for genes of sex determination. Inbreeding in such populations may result in homozygosity of the sex-determining genes and male diploidy. In *Nasonia vitripennis* there is a “selfish” supernumerary chromosome, PSR (paternal sex ratio chromosome). When PSR males produce offspring with normal females only haploid males occur because the paternal chromosome set, except the PSR chromosome, is eliminated. When PSR males mate with triploid females the offspring becomes diploid males. In *Nasonia* females can develop from unfertilized eggs and these are haploid (Beukeboom LW et al 2007 Science 2007 315:206). ►[sex determination](#), ►[complementary sex determination](#); Smith NG 2000 Heredity 84(2):186; Bordenstein; SR et al 2003 Genetics 164:223.

Haplogroup: A group of haplotypes which share some sequence variation. ►[haplotype](#)

Haploid: A haploid contains only a single complete set(s) of chromosomes ►[monoploid](#). The gametes are haploid; the meiotic products of polyploids are often called *polyhaploid*. Many of the fungi are haploid during most of their life cycle, except after fusion of the nuclei in dikaryotes preceding meiosis. ►[meiosis](#), ►[fungal life cycle](#). Haploid individuals among diploids show up spontaneously at low frequency. Haploid lines are very rare in animals *although* haploid frog cell lines have been used in cultures. In the spider mite *Brevipalpus phoenicis* most of the populations are haploid females caused by infection by the bacteria *Cytophaga-Flavobacterium-Bacteroides*. Once antibiotics cure the females of the bacterium they are converted to male individuals (Weeks AR et al 2001 Science 292:2479). The spontaneous frequency of haploids varies among different lines of the same species. A high frequency of haploids occurs in crosses involving the wild barley, *Hordeum bulbosum*, and certain wheat varieties crossed with the grass *Aegilops caudata* (*Triticum dichasians*). Wheat pollinated by maize also yields haploid wheat. In these crosses one of the genomes (e.g., *H. bulbosum*) is eliminated at high frequency. Haploid plants have been obtained in many species in an artificial culture of immature pollen or microspores and anthers. The microspores can be cultured without separation from the anthers, although separation of the pollen sacs may improve their development because the anther walls may contain growth inhibitors. From these haploid cells haploid plants can be regenerated. Successful embryogenesis is generally easier if the cultures are initiated at the uninuclear stage of the microspore. Haploid plants may actually be obtained through two different routes from microspores: either by so called *direct androgenesis* when the haploid male cells are guided through embryogenesis directly or, alternatively, through indirect androgenesis wherein the haploid initial cells can be converted to callus and from the callus plants are generated. The latter procedure is less desirable because during callus growth, spontaneous chromosome doubling and other types of chromosomal anomalies frequently occur. If the microspores are exposed to colchicine or other agents that block the mitotic spindle, chromosome doubling may be induced. Haploid cell cultures have great advantages for mutation studies because all the recessive mutations are detectable without the masking effect of the dominant alleles at the loci. Similar advantages are available in the use of hypoploid animal cell cultures, such as derived from XY males where X-chromosomal genes are present in a single dose or, e.g., in the culture of Chinese hamster ovary cells (CHO) when individual chromosomes are spontaneously be eliminated. Although

effective screening methods are available in animal cells (BUdR, antibiotic, temperature), regeneration of animals from isolated cells cannot be accomplished in culture, except from stem cells or via nuclear transplantation. Haploids may have a great advantage in plant breeding work because by doubling the chromosome numbers, in a single step, 100% homozygosity results. Ordinarily, by self-fertilization or inbreeding 6 to 8 cycles result in only 98 to 99% homozygosity ($0.5^6 \cong 0.0156$ heterozygosity). S.S. Chase developed a successful method for selective isolation of haploid maize. Female flowers, recessive for several markers and easily recognizable in the kernels, are pollinated by the corresponding dominant stocks (*A*, *B*, *Pl*, *R*). Kernels that fail to show the paternal markers in the endosperm are discarded because they originated by unintended selfing. The seedlings displaying the dominant paternal markers are also discarded because they are most likely diploid. The true haploids thus arise from fertilization of the endosperm nucleus by the dominant sperm, but the egg that develops into an embryo without fertilization yields seedlings with maternal traits only (thus haploid). After doubling their chromosome number, homozygotes are obtained. Some caution may be required in critical studies because through spontaneous mutation some variations may arise in these otherwise completely homozygous lines. Haploidy may also be induced by pollination with heavily irradiated pollen or pollen damaged by other means. Some genotypes display a proclivity for spontaneous androgenesis. ►androgenesis, ►apomixis, ►anther culture, ►embryo culture, ►embryogenesis somatic, ►selective medium, ►antibiotic resistance, ►bromouracil, ►conversion, ►doubled haploid, ►sex determination; Hall DW 2000 Genetics 156:893.

Haploidization: The reduction of the chromosome number to the haploid level.

Haploid-Specific Genes: Haploid-specific genes are turned on in response to mating factors (yeast). The responding consensus is 50 bp upstream of the translation initiation site. ►mating type determination in yeast, ►consensus, ►upstream, ►translation

Haplo-Insufficient: The gene in a single dose (such as in hemizygotes) cannot assure its normal function and may even be lethal. Haplo-insufficiency may also lead to tumorigenesis or to disease by reduced ability of tumor suppression or genetic repair. ►Turner syndrome, ►DiGeorge syndrome, ►Waardenburg syndrome, ►familial hypercholesterolemia, ►Chotzen syndrome, ►polycystic kidney disease, ►hemizygous ineffective, ►PCR-mediated gene replacement

Haplontic: During most of its life the organism is haploid. ►haploid

Haplopappus gracilis: A composite plant with only two pairs ($n = 2$) of good-size chromosomes. Due to self-incompatibility genes, its culture is somewhat inefficient.

Haplotype: A set of genes in each chromosome of the genome inherited ordinarily as a block. (The term was most commonly used in immunogenetics.) Originally, it represented the haploid set of genes of the MHC (multiple histocompatibility) antigens. It is generally assumed that individual genes within a haplotype would display collinearity with homologous genes of other haplotypes of the same species. This expectation may not be valid, however, since it has been shown that, e.g., at and around the *bz* locus of maize substantial nucleotide heterogeneity occurs (Fu H, Dooner HK 2002 Proc Natl Acad Sci USA 99:9573). ►HLA, ►SNIPs, ►association test, ►linkage disequilibrium, ►hapmap; Gabriel SB et al 2002 Science 296:2225; <http://www-gene.cimr.cam.ac.uk/clayton/software/>.

Haplotype Analysis: A haplotype analysis infers the relative position of genes and DNA markers by assuming a minimum number of crossing overs along the chromosome. Haplotype analysis may be very useful for the identification of human disease genes. ►crossing over, ►linkage disequilibrium; Daly MJ et al 2001 Nat Genet 29:229; Johnson GC et al 2001 Nat Genet 29:233; Ding C, Cantor CR 2003 Proc Natl Acad Sci USA 100:7449.

Haplotype Blocks: An average of ~5,000 to ~20,000 base pair segments of the genome are preserved by lack of recombination. These blocks display characteristic variations within populations or species groups. About 50% of the haplotype blocks are preserved in the populations of the three main continents (Europe, Asia and Africa). About 72% are shared in Europe and Asia but in Africa 28% of the blocks are limited in occurrence to certain geographic regions.

Human populations in Africa display the greatest and most unique variation. The analyses of the blocks reveal evolutionary and demographic histories. Recombinational hot spots are found at the boundaries of these blocks (Pääbo S 2003 Nature [Lond] 421:409). The linkage disequilibrium is high in the large human haplotype blocks while it is low in the short ones. Using SNP markers their association with disease factors can determine functional polymorphism by appropriate algorithms (Zhang K et al 2003 Am J Hum Genet 73:63). Large human data sets indicate that some regions conform well to the haplotype block concept, others do not because there is an extensive variation in recombination rates across the genome (Wall JD, Pritchard JK. 2003 Am J Hum

Genet 73:502). ►association map, ►HapMap, ►hot spot, ►linkage disequilibrium, ►SNIPs

Haplotyping: Haplotyping is the determination of the genotypic constitution of a haplotype. ►haplotype

HapMap: The HapMap is based on haplotype patterns of SNIPs. The goal is to find connections between single nucleotide polymorphism haplotypes and disease, and possibly a response to therapeutics. There are two approaches: (i) the direct approach which seeks a correlation between the disease and putative variations, and (ii) the indirect approach that wishes to establish an association between particular genomic regions and a particular disease. Approach (ii) is more practical and it detects variants of candidate genes and chromosome regions across the genome. Also, the indirect analysis reveals that most of the variants occurred in, and were preserved from, the ancestral chromosome where the mutation occurred. In the SNIPs (displaying an average frequency of 0.1%), either a C or T most commonly occurs at a particular site. In the human genome at an estimated 10 million sites both of these alleles (C and T) occur at higher than 1% frequency. These common SNIPs constitute 90% of the variations in the human populations. The mutation rate per a particular site is about 10^{-8} . Only about 10^4 generations have elapsed since any two humans separated from the most recent common ancestor and there is a high chance that the neighboring alleles in the ancestral chromosomes are still preserved in this haplotype. Such conservatism is present despite recombination and additional mutations during the course of evolution. As a consequence, few carefully chosen SNIPs (*tag SNIPs*) can identify the most relevant haplotypes. These common SNIPs are apparently older than the rare ones and by virtue of linkage disequilibrium are shared among populations. Such studies will be carried out among different ethnic groups with careful consideration to individual and group sensitivities. HapMap DNA samples can be used to select SNIPs tags for genome-wide association studies in many samples around the world. The tags picked from the HapMap DNA samples capture rather well the variation in other samples too (de Bakker PIW et al 2006 Nature Genet 38:1298). ►haplotype analysis, ►association mapping, ►SNIPs, ►PAF, ►Perlegen Sciences; Carlson CS et al 2003 Nature Genet 33:518; Cardon LR, Abecasis GR 2003 Trends Genet 19:135; The International HapMap Consortium 2005 Nature [Lond] 437:1299; HapMap use for defining human variations: Kruglyak L 2005 Nature Genet 37:1299; Conrad DF et al 2006 Nat Genet 38:1251; <http://www.hapmap.org/>; <http://hapmart.hapmap.org/BioMart/martview>.

Happiness: Happiness is most likely genetically determined because the correlation between monozygotic and dizygotic twins was found to be 0.44 and 0.08, respectively. It has been suggested that happiness may be determined by the D4 dopamine receptor and unhappiness is related to the control of serotonin metabolism. ►dopamine, ►serotonin

HAPPY (haploid genome equivalent and polymerase chain reaction): HAPPY is an in vitro method of mapping DNA fragments. The fragments are generated from genomic DNA by irradiation and classified by size with the aid of pulsed-field gel electrophoresis. The fragments are distributed into a 96-well panel. The panel members are amplified by PCR and then screened for specific new STS markers. LOD scores test co-segregation. The procedure is very efficient. The disadvantage of the methods—which may later be overcome—is that the pre-amplification of the genomic DNA results in new STS markers. These STS markers are flanked by interspersed repeat elements and are thus not identical to known STS markers and reflect the distribution of interspersed repeats rather than the standard maps. (►STS, ►PCR, ►lod score, ►pulsed field gel, ►radiation hybrids; Dear PH, Cook PR 1993 Nucleic Acids Res 21:13; Walter G et al 1993 Nucleic Acids Res 21:4524; Dear PH et al 1998 Genomics 48:232).

Happy Puppet Syndrome: An abandoned, derogatory name of the Angelman syndrome. ►Angelman syndrome

Hapsburg Lip: ►Habsburg lip

Hapten: A small molecule that, in association with a protein (carrier), can act as an antigen. Alone, haptens are only antigenic but not immunogenic. The hapten-carrier is the basis of the immune response to the complex. ►antigen, ►immune system, ►affinity labeling, ►affinity maturation; <http://bioinformatics.charite.de/superhapten/>.

Haptoglobin: A mammalian serum protein composed of two α and two β chains. The $\alpha 1$ chain contains 84 amino acids and differs from the $\alpha 2$ chain which is nearly double in size in the presence of the Hp^2 allele due to a duplication in an intercalary segment, presumably brought about by an unequal crossing over event during its evolution. The $\alpha 2$ chain occurs only in humans and it is thus most likely to be of relatively recent origin. This protein is attached to hemoglobin and has a role in recycling heme. The HP gene was located to human chromosome 16q22. A number of electrophoretic variants have been identified. The frequency of the gene responsible for the $\alpha 1$ chain varies a great deal in ethnic populations.

►globin, ►hemoglobin, ►plasma proteins, ►unequal crossing over

Haptotaxis: The movement of cells is determined by the concentration gradient of a cell adhesion molecule.
►CAM

Hard Disk: A permanently sealed disk of the computer; it operates faster than floppy disks and has a large capacity. ►disk

Hard Heredity: Inheritance determined by permanent genetic material such as DNA and RNA, rather than the diffuse hypothetical gemmules, pangenes, etc., hypothesized before the acceptance of Mendelian genetics. ►Mendelian laws, ►pangenes, ►gemmules, ►soft inheritance

Harderoporphyria: A variant form of coproporphyria where the relative amount of excreted coproporphyrin is less in favor of the other intermediate in heme biosynthesis, harderoporphyrin. ►coproporphyria, ►porphyria; Lamoril J et al 2001 Am J Hum Genet 68:1130.

Hardware: Hardware constitutes physical equipment such as the computer machine. ►software

Hardy-Weinberg Equilibrium: The genotype and gene frequencies remain constant from generation to generation because there is random mating between individuals and neither selection nor mutation or migration affect the composition of the population.
►Hardy-Weinberg theorem

Hardy-Weinberg Theorem: For one allelic pair $p^2 + 2pq + q^2$ where p is the frequency of the dominant and q is the frequency of the recessive allele ($1 - p$). If the genotypic frequencies are available, the allelic frequencies can be derived because the two types of homozygotes have two copies of the alleles concerned whereas the heterozygotes have one of each. In the case of three alleles at a locus, such as in the ABO blood group, the frequency of the i^O recessive allele is $r = \sqrt{\frac{O}{N}}$. Since the combined frequencies of i^O and I^A is $r^2 + 2pr + p^2$ the frequency of the i^A allele is $p = \sqrt{\frac{A+O}{N}} - r$, and therefore the frequency of the allele, by subtraction, becomes $q = 1 - p - r$. O, A, and B are the actually observed numbers of the representatives of the blood groups and N is the population size. In the case of trisomy the various possible genotypes will be given by $(p_1A_1 + p_2A_2)^3$ after the expansion of this binomial. It is often critical for human genetic analysis to estimate accurately the possible deviation from the Hardy-Weinberg equilibrium. An exact stratified test for diallelic markers, such as single-nucleotide polymorphisms (SNPs), and an exact test for homogeneity

of Hardy-Weinberg disequilibrium is available. Applying these methods to data from Perlegen and HapMap—a combined total of more than five million SNP genotypes, with three to four strata and strata sizes ranging from 23 to 60 subjects—this exact stratified test provides more robust and more powerful results than those obtained by either the minimum of exact test P values over strata or approximate stratified tests that sum measures of departure from equilibrium (Schaid DJ et al 2006 Amer J Hum Genet 79:1071). ►allelic frequencies, ►ABO blood group, ►HapMap, ►Perlegen sciences, ►stratification

Hare: *Lepus americanus* $2n = 48$; *Lepus townsendii* $2n = 48$ (see Fig. H11).

Figure H11. *Lepus europaeus*

Harelip: A hereditary cleft of the upper lip (see Fig. H12). The maxilla (upper jaws) and palate (the partition of the oral and nasal cavity) may also be affected. The incidence in the general population varies between 0.04 to 0.08% and the recurrence risk among brothers and sisters is about 0.2%. It is somewhat more common among males than females. Harelip is a sex-influenced trait. Haploinsufficiency for SUMO1 leads to harelip and cleft palate in mouse (Alkuraya FS et al 2006 Science 313:1751). ►cleft palate, ►sex-influenced, ►haploinsufficient, ►SUMO; Van der Woude syndrome, [photo after RJ Gorlin, Univ. Minnesota].

Figure H12. Harelip

Harlequin Fetus: ►Ichthyosis

Harlequin Staining of Chromosomes: The Harlequin staining of chromosomes results in different coloration of sister chromatids as the result of one or two

cycles of replication in the presence of the nucleoside analog 5-bromodeoxyuridine (BrDU). The chromatids replicated in the presence of BrDU absorb less of the fluorescent stain Hoechst 33258 than the chromatid that has replicated in the presence of thymidine. On a black and white photo negative, the chromatid free of BrDU appears lighter and darker in the print than the one that incorporated BrDU. Thus, chromatids containing one, two or no BrDU can be distinguished. Therefore, such a staining permits the detection of sister-chromatid exchange. ▶[sister chromatid exchange](#), ▶[bromouracil](#); Rachel AJ et al 1991 *Mutation Res* 264:71; Jordan R et al 1999 *Biotechniques* 26:532.

H

Hartnup Disease (11q13): An autosomal recessive disorder involving photosensitivity, rash, cerebellar ataxia (impaired muscle coordination by the brain), and aminoaciduria (see Fig. [H13](#)). The uptake of methionine and tryptophan and, to some extent, of other neutral amino acids by the intestines is reduced. It is diagnosed by urine analysis for increase in neutral amino acids. Its prevalence is about 4×10^{-5} . ▶[tryptophan](#), ▶[light-sensitivity diseases](#), ▶[ataxia telangiectasia](#); photograph from Bergsma D ed 1973 *Birth Defects*, March of Dimes Foundation.

Figure H13. Hartnup disease

Harvest Index: The harvest index refers to proportion of the economically and directly usable productivity of crops, e.g., grain versus straw. It has also been defined as the ratio of dry weight of the harvestable organs to the total dry weight.

Harvey Murine Sarcoma Virus (transformation gene): The Harvey Murine sarcoma virus was originally derived from rats and it is found to encode a 21-kDa oncoprotein (p21) or RAS. The human homolog was mapped to chromosome 11p14.1. ▶[RAS](#), ▶[p21](#)

Harvey: A *Drosophila* transposable element (7.2 kb). ▶[transposable elements](#)

Haseman-Elston Regression: A method to study the linkage between QTLs and markers. ▶[QTL](#); Haseman JK, Elston RC 1972 *Behavioral Genet* 2:3.

Hashimoto Thyroiditis: An autoimmune disease of the thyroid gland controlled by several loci; some of them affect Graves disease too. ▶[autoimmune](#)

[disease](#), ▶[goiter](#); Tomer Y et al 2003 *Am J Hum Genet* 73:736.

Hassall Corpuscles: Hassall corpuscles express thymic lymphopoietin in the stroma (TSLP) and activate CD11c-positive dendritic cells to make CD80 and CD86. The active dendrites induce the proliferation and differentiation of CD4⁺ CD8⁻ CD25⁻ thymic T cells into CD4⁺ CD25⁺ FOXP3⁺ regulatory T cells. The induction also requires CD80, CD86, and interleukin-2. The corpuscles thus mediate selection for medium to high affinity self-reactive T cells (Watanabe N et al 2005 *Nature [Lond]* 436:1181). (See terms under separate entries).

Hat: ▶[histone acetyltransferase](#), ▶[nucleosomes](#), ▶[histones](#), ▶[coactivator](#)

HAT Medium: Hat medium of animal cell culture contains hypoxanthine, aminopterin and thymidine. It has been extensively used for the isolation of bromodeoxyuridine and azaguanine resistant mutants and complementary fused cell lines by the rationale outlined in the figure (see Fig. [H14](#)). ▶[selective isolation](#), ▶[bromodeoxyuridine](#), ▶[azaguanine](#), ▶[aminopterin](#)

Hatching Time of Poultry: The eggs of chicken hatch in three weeks; turkey, goose and duck eggs require four weeks incubation.

HAUSP: A herpesvirus-associated ubiquitin-specific protease.

Haustorium (plural haustoria): Those organs of parasites (see Fig. [H15](#)) (e.g., fungi) that penetrate the periplasmic space of the host cells for the purpose of absorbing nutrients. In parasitic plants (*Striga asiatica*) quinone may serve as a signal to the expression of the expansion gene and the cellulose fibers are modified to form haustoria. (See Voegelé RT et al 2001 *Proc Natl Acad Sci USA* 98:8133).

Haw River Syndrome: The same as dentatorubral-pallidolusian atrophy.

Hawkinsinuria (4- α -hydroxyphenylpyruvate hydroxylase deficiency): The hawkinsin is a 2-L-cystein-S-yl-1, 4-dihydroxycyclohex-5-en-1-yl acetic acid. On a restricted phenylalanine and tyrosine diet the dominant condition greatly improves. It is a childhood disease.

Hawthorne Effect: The persons involved in a treatment know about the treatment and their behavior may be thus affected.

Hay Fever: ▶[allergy](#)

Hayflick's Limit: Human cells usually die in culture after 50 to 60 or fewer cell cycles. Cancer cells

Figure H14. Alternative pathways of nucleic acid biosynthesis. The upper *de novo* pathway can be selectively blocked by aminopterin, an inhibitor of dehydrfolate reductase (an enzyme essential for the biosynthesis of thymidylate). In case of such a block, pyrimidines and purines may still be synthesized through the salvage pathway from nucleosides. Tk (thymidine kinase) can make thymidylic acid and hgprt (hypoxanthine guanine phosphoribosyl transferase) can supply guanylic acid. In case *tk* is inactivated by mutation (*tk*⁻), the cells become resistant to 5-bromodeoxyuridine because the cells cannot convert it into a nucleotide analog. Similarly, if hgprt is inactivated (*hgprt*⁻) by mutation the guanine analog, 8-azaguanine cannot be incorporated into DNA and thus the cell will be resistant to it. Therefore, on hat medium, both bromodeoxyuridine and azaguanine resistant mutant cells can selectively be isolated

Headful Rule: Bacteriophages replicate their DNA in concatamers but the phage head (capsid) has a limited storage capacity and, therefore, the molecules have to be cut to “headful” lengths. Bacteriophages, herpesviruses and other large double-stranded DNA viruses pump the DNA into the capsids by molecular motors that generate pressure, ten times in excess of bottled champagne (Lander GC et al 20067 Science 312:1791). ►concatamer, ►lambda phage, ►packaging of phage DNA; ►Droge A, Tavares P 2000 J Mol Biol 296:103; Coren JS, Sternberg N 2001 Gene 264:11.

Hearing Deficits: ►deafness

Heart Disease: Heart disease affects about 1% of the population and only a little less of the newborns; for about 15%, it is lethal. The majority of heart diseases involve either hypertrophy of the heart muscles or ventricular dilation. The myocytes after differentiation do not replicate any more but can increase their size leading to hypertrophy upon stress. Under healthy conditions Ca^{2+} regulates cardiac contraction and relaxation through an elaborate path. The

mammalian heart cannot regenerate in contrast to that of zebrafish that can regenerate when up to 20% is amputated. According to classical developmental ideas, different mammalian heart tissues arise from separate precursor lineages under the control of a unique combination of transcriptional networks. Newer information indicates the LIM homeobox islet gene (*Is/1*) of the mouse determines alternative multipotent progenitor cells that can lead to cardiac, smooth muscle and endothelial cell diversification suggesting a potential for stem cell therapy (Moretti A et al 2006 Cell 127:1151).

Many genes are involved in the development of the heart (see Fig. H18) and platelet-derived growth factors are upregulated during the process (Lien CL et al 2006 Plos Biol 4(8):e260). Congenital heart disease frequently occurs as a component of various syndromes. About 2% of the cases are caused or precipitated by environmental effects and various diseases (alcoholism, lithium, thalidomide, retinoic acid [a derivative of vitamin A]), trimethadione (anticonvulsant drug), viral infections (rubella), maternal diabetes and phenylketonuria, trisomics (21, 8, 13), Turner syndrome, deletions by the DiGeorge syndrome, asplenia, patent ductus, Holt-Oram syndrome, Ellis-van Creveld syndrome, mucopolysaccharidosis, Danon disease, Pompe’s disease, endocardial fibroelastosis, coarctation of the aorta, Noonan syndrome, LEOPARD syndrome, Fallot’s tetralogy, mitral prolapse, myotonic dystrophy, Jervell and Lange-Nielsen syndrome, Opitz-Kaveggia syndrome, etc.

Heartbreaker (*hbr*): A nontranslated, short (314-bp) insertion element in several grasses (maize and other cereals). It is present in ~4,000 copies in the maize genome. It is suspected to be responsible for a significant portion of the polymorphism observed. ►MITE, ►transposable elements plants; Zhang Q et al 2000 *Proc Natl Acad Sci USA* 97:1160.

Heat Repeats: A repeated element first discovered in the following proteins: huntingtin, translation elongation factor EF3, the A subunit in protein phosphatase 2A (PP2A), and TOR1, a target for rapamycin. Similar repeats have since been found in different proteins of several species. ►Huntingtin, ►EF3, ►TOR, ►rapamycin; Andrade MA et al 2001 *J Struct Biol* 134:[2–3]:117.

Heat Shock Elements: ►HSE

Heat-Shock Proteins (hsp): Heat-shock proteins are most commonly molecular chaperones that under heat stress inhibit or prevent denaturation of other proteins by binding to interactive surfaces and thus securing that these chaperoned proteins maintain their structure required under normal, no stress conditions. A heat-shock transcription factor (HSF1), peptide chain elongation factor eEF1A, and heat-shock RNA (HSR1) mediate, primarily, the expression of heat-shock proteins (Shamovsky I et al 2006 *Nature [Lond]* 44):556). The production of heat-shock proteins to this type of stress is very rapid because the hsp70, hsp26, hsp27 genes of *Drosophila* are initiating transcription in anticipation of heat by a halted 20 to 40 nucleotide transcript that can be then readily elongated. Hsp70 (see Fig. H19) is stalled near the promoter under un-induced conditions but,

upon heat shock, RNA polymerase Pol II is readily released by TFIIS and additional Pol II molecules as well as transcription factors are recruited to the initiation site (Adelman K et al 2005 *Mol Cell* 17:103). Some Hsp proteins may have other functions as well. Hsp110 is present in prokaryotes and eukaryotic organelles in response to stress. Hsp90 family members bind ATP and are involved in autophosphorylation, although in animals they are immunophilins (binding to immune-suppressive antibiotics such as cyclosporin). Hsp70 members are made in all types of organisms and their main role is to mediate the folding of nascent proteins. The heptameric hsp60 molecules participate in the molding of proteins using $ATP \rightleftharpoons ADP$ for energy. The hsp40 proteins may be involved in sorting polypeptides. The smaller hsp proteins may form aggregates before acting on other molecules. Prokaryotes do not contain the very smallest hsp proteins. The hsp genes are classified into families on the basis of the molecular weight of the proteins (in kDa) encoded by them.

For the small heat-shock proteins ►sHsp. Under high temperature stress heat-shock proteins may accumulate to 15–20% of the total cellular proteins. Their formation is tightly regulated by both positive and negative controls. In *E. coli* the heat signals activate the $E\sigma^{32}$ RNA polymerase and the *rpoH* operon whereas misfolding activates the $E\sigma^E$ (σ^{24}) operon. Besides elevated temperature (5–10°C above normal), heat-shock responses may also be elicited by toxic chemicals, metabolic inhibitors and analogs, microbial or viral infections, various injuries, cancer, aging and developmental events. During heat shock, normal protein synthesis may be selectively repressed. ►HSE, ►Hsc, ►transcription factors inducible, ► σ , ►chaperone, ►thermal tolerance, ►cold shock, ►HSP, ►Hsp70, ►Hsp90, ►Hsc66, ►DnaJ, ►sHsp, ►elongation factors, ►immunophilin, ►spastic paraplegia; Nagao RT, Gurley WB 1999 In Reynolds PHS (ed) *Inducible gene expression in plants*, CABI, Wallingford, UK, p 97; Macario AJ, Conway-Macario E 2000 *Int J Clin Lab Res* 30[2]:49; Queitsch C et al 2002 *Nature [Lond]* 417:618; Srivastava P 2002 *Annu Rev Immunol* 20:395, <http://www.heatshock.net/>.

Heat Tolerance: Some lower eukaryotes and some prokaryotes can tolerate temperatures close or even above the boiling point of water. Their special ability

Figure H19. Generalized structure of an Hsp-70 protein

enables them to survive under the blazing temperature of the equator or in hot springs. In the warm soil of the Yellowstone National Park the fungus, *Curvularia protuberata*, controls the high temperature tolerance (65°C) of the grass, *Dicanthelium lanuginosum*, when the fungus harbors a double-stranded RNA mycovirus (Márquez LM et al 2007 Science 315:513).

Heavy Chain: ►antibody, ►Watson-Crick model, ►DNA heavy chain

Heavy Chain of DNA: ►DNA heavy chain

Hebbian Mechanism: An old hypothesis proposed by Donald Hebb (1949) for the memory function of the brain as a series of excitations of axons resulting in firing of other nerve cells and resulting in long-term potentiation. ►memory; Rao RP, Sejnowski TJ 2001 Neural Comput 13:2221.

Hec: An 80 –kDa, coiled-coil nuclear protein. It interacts with Smc1 and Smc2 and apparently controls chromosome segregation. ►spindle

HECT: A protein domain present in ubiquitin ligases. ►ubiquitin

Hedgehog: *Erinaceus europaeus*, 2n = 48 (see Fig. H20).

Figure H20. Hedgehog

hedgehog (*hh*, 3–81): A segment polarity type embryonic lethal mutation in *Drosophila*. The product of the wild type allele of *hh* encodes a signaling molecule that is processed by auto-proteolysis into two active species. By the action of the C-terminal domain of the protein it is cleaved into two and the N-terminal signaling domain covalently binds a cholesterol moiety. This binding is required for neutralizing the effects of Patched and Smoothed proteins that would block the signaling pathway. The Cholesteryl-Hedgehog-Patched-Smoothed complex displays differences in tissue distribution and instructs adjacent cells to express the organizing signal encoded by the *decapentaplegic* (*dpp*) locus. The Hh protein is secreted under the control of the *En* (engrailed) protein. The *en* locus is continuously expressed in the posterior part of the embryo. The anterior part of the embryo expresses the *ci* (*cubitus*

interruptus) locus, which encodes a zinc-finger binding protein of the Gli family of transcription factors. If *ci* is not expressed the *hh* gene product shows up and posterior compartment properties appear without the expression of the *en* signal. Increased levels of *ci* products induce the expression of *dpp* independently from *hh*. Expression of the normal *ci* product in the anterior cells results in limb development by limiting the expression of *hh* to posterior cells and mediating the ability to respond to the protein signal of the *hh* locus. *Ci* transduces the Hh signal by activating the *dpp* and *ptc* (*patch*) genes. The Patch gene product and the cyclic AMP-dependent protein kinase A interfere with inappropriate expression of *dpp* if an Hh product is not available. The *ci* product at low level represses *dpp* and at higher concentration appears to be an activator of the same gene. Hh induces both decapentaplegic (dorsal compartment) and wingless (ventral compartment) and these two modulate each other's function to assure normal axial development. The product of the *patched* (*ptc*) gene is the receptor of Hh and *smoothed* (*smo*) is a signaling component of *Ptc*. Hip (hedgehog-interacting protein, ~78 kDa) has a somewhat similar role as *Ptc*. The human gene EXT-1 (and the apparently homologous *Drosophila* gene *Ttv*) seems to regulate the embryonic movement of the *hh* protein. EXT encodes a protein apparently involved in the cell surface glycosaminoglycan (GAG) synthesis. The *hh* gene has at least three homologs in humans and other vertebrates: the Sonic hedgehog (SHH, 7q36, patterns the neural tube, early gut endoderm, posterior limb buds). Indian hedgehog (*Ihh*, 2q33-q35) is expressed primarily in cartilage and Desert hedgehog (*Dhh*, 12q13.1) is expressed primarily in the testes. *Ihh* in mouse mediates progesterone signaling in the uterus (Lee K et al 2006 Nature Genet 38:1204). The *hh* signaling system is present in many invertebrates and vertebrates but it is absent from *Caenorhabditis*. Upon autocatalytic processing, Hh releases a 19-kDa ligand with cholesterol linked to its C-end. It is assumed that Hh works in *Drosophila* as a raft for intracellular transport. Basal cell carcinoma and medulloblastoma cancers are frequently associated with mutation of Hh. An RNAi system applied genome-wide, revealed hundreds of new regulators of Hh (Nybakken K et al 2005 Nature Genet 37:1323). (See more about ►*ptc*; ►*decapentaplegic* under ►nevoid basal cell carcinoma, ►holoprosencephaly; Gli in ►Greig's cephalopolysyndactyly syndrome, ►cubitus interruptus, ►Rubinstein syndrome, ►engrailed in ►morphogenesis in *Drosophila*, ►sonic hedgehog, ►tumor suppressor pathway, ►cholesterol, ►glycosaminoglycan; McMahon AP 2000 Cell 100:185; Kalderon D 2000 Cell 103:371;

Ingham PW 2001 Science 294:1879; Bale AE 2002 Annu Rev Genomics Hum Genet 3:47, review; Lum L, Beachy PA 2004 Science 304:1755, signaling pathway: <http://www.hedgehog.sfsu.edu>.

HEI (hybrid element insertion): The left end of one hybrid dysgenesis-causing P element of *Drosophila* in *trans* position can move with the left end of another P element as a unit and causes viable exchanges or inviable rearrangements. The exchange products may be due also to hybrid excision and single strand repair synthesis (HER). The HEI model may account for male recombination in *Drosophila*. ▶ [male recombination](#), ▶ [hybrid dysgenesis](#), ▶ [DNA repair](#); Tanaka MM et al 1997 Genetics 147:1769.

Heisenberg's Uncertainty Principle: Developed in the 1920s by the German physicist Werner Heisenberg for quantum mechanics. In its simplest form: an atomic particle moves at a *p* momentum (speed) and has a certain *x* position on its track. These properties (*p* and *x*) cannot be measured with certainty because whenever a measurement is made the system is disturbed. Therefore, all measurements are loaded with some errors, some uncertainties. This concept was developed for interpretation of nuclear fission but it may have relevance for studies of biological systems too.

HeLa Cell Line: An immortalized human cancer cell line which originated in 1951 from a highly malignant cervical carcinoma of patient Henrietta Lacks who died the same year. The line, however, is maintained all over the world indefinitely. Many of the HeLa cell lines have been contaminated—by error or by deception—with cells of different origin. Now, with improved forensic laboratory techniques these can be identified by high probability. ▶ [immortalization](#); O'Brien SJ 2001 Proc Natl Acad Sci USA 98:7656; Masters JR 2002 Nat Rev Cancer 2:325.

Helical Twist: The angle between neighboring DNA base pairs; it is within the range of 24° and 51° with a mean of 36.1 ± 5.9.

Helicases: Helicases are enzymes unwinding the double helix of a nucleic acid for replication and transcription, repair, recombination, and in reactions associated with binding and hydrolysis of DNA. About 60 helicases have been identified; some unwind DNA and RNA hybrids. *E. coli* bacterium encodes about 12 different helicases, and all organisms have several types (see Fig. H21).

The activity of a helicase may be coordinated with DNA polymerase and the complex may travel at about 1,000 nucleotide/second. The RecQ family of helicases is implicated in mutator functions and chromosomal rearrangements such as occurring in

Figure H21. Phage T7 hexameric helicase motor protein. (From Waksman, G et al. 2000 Nature Struct. Biol. 7:20)

***Helicobacter pylori*:** A bacterium (strain 26695) with a completely sequenced genome of 1,667,867 bp and 1,590 ORF (Nature 388:539 [1997]). Strain J99 is also sequenced (1,643,831 bp, Nature 397:176 [1999]). The latter has a 24,036-bp smaller genome. The genic difference between the two strains is about 6–7% and half of these are clustered in a hypervariable region. These common pathogens are tolerant to high acidity and are responsible for peptic ulcers and possibly gastric carcinoma but may also be harmless. The *H. pylori* strain causing atrophic acute superficial gastritis (1,596,366 bp) has also been sequenced (Oh JD et al 2006 Proc Natl Acad Sci USA 103:9999). O-glycan of the gastric mucin has an antibiotic effect against the bacterium (Kawakubo M et al 2004 Science 305:1003). The carcinogenic effect may be brought about by increased gastric acidity and interleukin-1. The damaged stomach epithelia may recruit bone marrow cells, which may become

metaplastic and dysplastic (Houghton J et al 2004 Science 306:1568). *H. pylori* can produce an antibacterial peptide (a cecropin), bearing similarity to ribosomal protein RplL1. A protein-protein interaction map using yeast two-hybrid assay has been developed for over 46% of the proteome by 2001. The *H. pylori* antigen-binding adhesin (BabA) has increased affinity for O blood group and this fact explains the increased incidence of gastric inflammation among some Amerindians who have predominantly O blood group (Aspholm-Hurtig M et al 2004 Science 305:319). The Nobel Prize for Physiology and Medicine in 2005 was awarded to BJ Marshall and Robin Warren for the discovery of the role of this bacterium in duodenal and gastric ulcers. Anatomically modern humans were already infected by *H. pylori* before their migrations from Africa and it has remained intimately associated with their human host populations ever since (Linz B et al 2007 Nature [Lond] 445:915). ►ORF, ►*E. coli*, ►antimicrobial peptides, ►ABO blood group, ►adherence reaction, ►dysplasia, ►metaplasia, ►gastric cancer; Rain J-C et al 2001 Nature 409:211; Ernst PB, Gold BD 2000 Annu Rev Microbiol 54:615; Del Giudice G et al 2001 Annu Rev Immunol 19:523; *Helicobacter hepaticus* genome sequence: Suerbaum S et al 2003 Proc Natl Acad Sci USA 100:7901; <http://genolist.pasteur.fr/>.

Helitrons: ►rolling circle

Helix (of macromolecular structure): A coil of a three-dimensional ribbon; the DNA double helix is similar to a staircase with the steps corresponding to the bases and the strings of the staircase representing the sugar-phosphate backbone of the two polynucleotide chains; thus it is not a simple spiral. Besides the commonly seen double-helix structure, a nucleic acid can also assume triple and quadruple helical structures. Telomeric and centromeric DNA can show quadruplex structure in guanine- and cytosine-rich sequences. These sequences have potentials for binding different ligands. RNA quadruplexes offer chances for binding both outside and inside of the groove of the quadruplex. Quadruplexes can also bind each other at the termini and extend their length. RNA quadruplexes can display bulges at the end of the 5' structure and can result in the formation intercalated octaplexes (Pan B et al 2006 Proc Natl Acad Sci USA 103:3130). ►DNA, ►triplex, ►triple helix forming oligonucleotides, ►Watson and Crick model, ►collagen

Helix Bundle Proteins: ►integral membrane protein

Helix Destabilizing Protein (RF-A): A single-strand binding protein instrumental in DNA replication. ►DNA replication, ►binding proteins, ►RF-A

Helix-Loop-Helix: Helix-loop-helix are polypeptides, each with three-partite structures; two of the helices are connected through a loop in each component of the dimer; the third helix of the components is rich in basic amino acids and this end binds to the DNA. The monomers thus appear as HOOC-helix-loop-helix positively charged helix-NH₂. They recognize the CANNTG (E-box) sequence in the DNA. The H-L-H proteins may form dimers and recognize two different neighboring DNA-binding sites. The proteins may saddle into the major groove of the DNA through their positively charged amino acids in the α helix of the NH₂ terminus. Basic helix-loop-helix proteins (>250) control transcription of genes involved in a great variety of cellular functions. ►DNA-binding protein domains, ►regulation of gene activity, ►helix-turn-helix motif; Lodent V, Vervoort M 2001 Genome Res 11:754.

Helix-Turn-Helix Motif: H-T-H motifs are parts of regulatory proteins of prokaryotes and homeodomains of eukaryotes. One α -helix (*recognition helix*) fits into the major groove of the DNA and the other is positioned at a right angle above it and it allows interaction with other proteins. The other monomer of the dimeric structure is binding to the next major groove along the DNA. There are large varieties of these proteins in bacteria and eukaryotes yet they contain a conspicuous symmetrical structure formed of antiparallel β sheets or α -helices separated by a turn of several amino acids. H-T-H motifs occur in the homeodomain proteins, in various repressors (λ *ci* and *cro* proteins, in the *E. coli* catabolite activator [CAP] proteins, etc.). ►DNA-binding protein domains, ►regulation of gene activity, ►lac operon, ►lambda phage, ►DBP, ►monomeric, ►DNA grooves, ►protein structure

Helminthosporium maydis: Fungus is the causative agent of the maize disease, southern corn leaf blight. Plants with the T (Texas) cytoplasmic male sterility are extremely susceptible to the disease and suffer serious damage. ►cytoplasmic male sterility, ►cms

Helper Plasmid: ►binary vector

Helper T Cell: ►T cell

Helper Virus: A helper virus provides the functions that a defective virus particle lacks.

Hemagglutinin: Hemagglutinins are proteins that cause agglutination of the red blood cells such as antibodies, lectins, and certain viruses (influenza, mumps, etc.). Variations in hemagglutinins due to amino acid substitutions are important factors in viral infectivity and the ability of the cells to make antibodies against them. ►fusogenic liposome,

►antibody, ►antigen; Skehel JJ, Wiley DC 2000 *Annu Rev Biochem* 69:531.

Hemangioblast: Mesodermal stem cells giving rise to blood vessels, hematocytoblasts (hemocytoblasts) and endothelial cell lineages. ►angiogenesis, ►blood, ►hematocytoblast; Huber TL et al 2004 *Nature [Lond]* 432:625; Vogeli KM et al 2006 *Nature [Lond]* 433:337.

Hemangioma: Several forms of neoplasias of blood vessels under autosomal recessive gene control in humans. ►angioma, ►Kasabach-Merritt syndrome

Hematocytoblast (hemocytoblast): Totipotent stem cells of blood. ►blood, ►stem cell, ►angiogenesis, ►hemangioblast

Hematopoiesis: The process of blood formation. It is a homeostatic process as new cells are formed and old ones are removed by apoptosis. After a certain age the blood volume does not expand. The major regulatory factors in this process are cytokines. Growth factors include the Kit ligand, the various macrophage factors. Large-scale culture of CD34⁺ produces normal, functional red blood cells from stem cells of peripheral blood and bone marrow (Giarratana M-C et al 2004 *Nature Biotechnol* 23:69). ►G-CSF, ►GM-CSF, ►M-CSF, ►interleukins, etc., ►bone marrow, ►Gleevec, ►PTEN; Metcalf D, 1998 *Stem Cells* 16:314; Christensen JL et al 2004 *PLoS Biol* 2:368; <http://bioinformatics.med.ohio-state.edu/HemoPDB/>.

Hematopoietic Receptors: Hematopoietic receptors bind hormone (GH, PRL, EPO, G-CSF) or cytokine (interleukin) ligands and are involved in cellular signaling. They may be homodimers (α -chain) and or heterooligodimers (α and β chains). (See mentioned items under separate entries).

Hematopoietic Stem Cells (HSC): HSCs can give rise to blood cells. By QTL analysis in mouse, a stem cell proliferation locus (Scp2) was identified in chromosome 11, corresponding to 5q31.1 in humans. The deletion of this region is associated with myelodysplastic syndrome and acute myeloid leukemia. The Scp2 locus is subject to cis- and trans-regulation by several genes and allelic forms. Hematopoietic CD34 human stem cells from bone marrow, when implanted into developing chicken spinal chord, differentiated into neurons (Sigurjonsson OE et al 2005 *Proc Natl Acad Sci USA* 102:5227).

Latexin (*Lxn*, human chromosome 3q25.3; is an endogenous carboxypeptidase inhibitor), is a gene whose differential transcription and expression is associated with the allelic differences in the mouse hematopoietic cell number. Expression is inversely correlated with the number of HSCs. The ectopic

expression of *Lxn* using a retroviral vector decreased stem cell population size. Clusters of SNPs upstream of the *Lxn* transcriptional start site, at least two of which are associated with potential binding sites for transcription factors, regulate stem cells. Thus, promoter polymorphisms between the B6 and D2 alleles may affect *Lxn* gene expression and consequently influence the population size of hematopoietic stem cells (Liang Y et al *Nature Genet* 39:178). Methylated histones H3K4 and acetylated histone AcH3, and unmethylated CpG dinucleotides colocalize across defined regulatory regions of lineage-affiliated genes in HSC and these active epigenetic histone modifications either accumulated or were replaced by increased DNA methylation and H3K27 trimethylation in committed progenitors consistent with gene expression (Attenu JL et al 2007 *Proc Natl Acad Sci USA* 104:12371). ►stem cells, ►QTL, ►cis, ►bone marrow, ►histones; Bystrykh L et al 2005 *Nature Genet* 37:225.

Hematoxylin: A histological and cytological stain in different formulations (Delafield's hematoxylin, Haidenhain hematoxylin, iron hematoxylin, etc.). ►stains

Heme: A iron or magnesium-porphyrin prosthetic group in hemoglobin, cytochromes, and chlorophyll, respectively. The majority of free-living eukaryotes synthesize heme but *Caenorhabditis* and other worms may depend on their food supply for it (Rao AU et al 2005 *Proc Natl Acad Sci USA* 102:4270). ►haem [for structure].

Hemeralopia: ►day blindness

Hemerythrin: A circulatory transport, non-heme iron protein in some non-vertebrates. ►heme, ►hemoglobin, ►hemocyanin Kurtz DM 1992 *Adv Comp Env Physiol* 13:151.

Hemicellulose: A polymer of neutral polysaccharides present in the plant cell wall matrix. (See Dhugga KS et al 2004 *Science* 303:363).

Hemichannels: Hemichannels are open half-gap junctions that permit the flux of ions and <1-kDa molecules. ►channel, ►gap junction

Hemiclonal (hybridogenetic species): *Rana esculenta* (European edible green frog) arises from the hybrid of *Rana ridibunda* x *R. lessonae*. In *R. esculenta*, before meiosis, one of the parental genomes is eliminated before DNA synthesis and after duplication of the remaining genome meiosis takes place. Thus, the gametes are produced from only one of the genomes. Backcrossing to the parental species whose genome was eliminated then reforms the hybrid. In case of exposure to ionizing radiation the *R. esculenta*

individuals may lose up to ~50% of its DNA and thus make it possible to measure the extent of radiation fallout with the aid of flow cytometry. The *Poeciliopsis* fishes and the *Bacillus rossius-grandii* stick-shape insects are also hybridogenetic. The latter may also reproduce by parthenogenesis, gynogenesis, or androgenesis. ▶parthenogenesis, ▶gynogenesis, ▶androgenesis; Giorgi PP 1992 Nature [Lond] 357:444; Vinogradov AE, Chubinshvili AT 1999 Genetics 151:1123.

Hemifusion: A step toward fusion of membranes or viruses. First, the membranes dock and the outer membrane leaflets mix (hemifusion) followed by pore opening and mixing of contents. The entire process may be preceded by trans-SNARE pairing. ▶SNARE; Reese C et al 2005 Nature [Lond] 436:410.

Hemiglobin: ▶methemoglobin

Hemiknot: A means of stabilizing a DNA tract by threading one end of the duplex through another (see Fig. H22). (Diagram modified after Lyubchenko YL et al 2002 Nucleic Acids Res 30:22).

Figure H22. Hemiknot

Hemimetabolous: The insect hatches as a miniature adult and grows to the imago size. ▶imago, ▶holometabolous

Hemimethylated: Only one of the two DNA strands is methylated. ▶methylation of DNA, ▶demethylation

Hemin (ferriprophyrin chloride, $C_{34}H_{32}ClFeN_4O_4$): Hemin is used for the treatment of porphyria and the preparation of rabbit reticulocyte lysate. ▶porphyria, ▶haem, ▶rabbit reticulocyte in vitro translation

Hemin Regulated Inhibitor: ▶HRI

Hemiobiotrophy: For infection the parasite requires live cells but later it can grow on the ones killed.

Hemizygous: Gene(s) present in a single dose in an otherwise diploid cell or organism (e.g., X-chromosome-linked genes in an XY male or XO cells). ▶dosage compensation

Hemizygous Ineffective: A special class of recessive mutations in allopolyploids. These recessive alleles are not expressed in monosomics (hemizygotes) and in case of nullisomics the dominant wild type is expressed for these loci. Their expression requires two doses of these recessive alleles and never displays pseudodominance. Thus, the hemizygous ineffective alleles resemble recessive suppressor mutations in diploids. Recessive mutations in allopolyploids are generally of this type because the homoeologous loci cover up the mutations at the other corresponding genes. ▶allopolyploid, ▶monosomic, ▶nullisomic, ▶pseudodominance, ▶suppressor gene, ▶homoeologous alleles; Sears ER 1972 Symp Biol Hung 12:72.

Hemochromatosis (HFE/HLAH, haemochromatosis): A disease of iron accumulation, accompanied by cirrhosis (fibrous condition) of the liver, diabetes, dark pigmentation of the skin, heart abnormality, and cancer. If diagnosed early by determining plasma iron and ferritin (a red 80,000 M_r serum protein with 2 iron-binding sites to transport iron, also called siderophilin), it is curable by lowering the iron level through venesection (phlebotomy), letting out blood by cutting the vein. The recessive gene HFE is located within the HLA-H complex in human chromosome 6p21.3. The frequency of the gene is about 6 to 10% with an incidence of homozygosity of 2–3 per 1,000 births. The HFE2 locus is at 1q21 and HFE3 is at 7q22 encoding (TFR2) transferrin receptor-2. Neonatal hemochromatosis (8q21.3) has very complex expression due to modifying effects. The solute carrier family member, ferroportin (FPN1, 2q32), may be involved in dominant hemochromatosis. ▶HLA, ▶Menke's disease, ▶Wilson disease, ▶liver cancer, ▶ferritin, ▶ferroportin, ▶transferrin, ▶hepcidin, ▶anemia, ▶metal metabolism and disease; Njajou OT et al 2001 Nature Genet 28:213; Muckenthaler M et al 2003 Nature Genet 34:102.

Hemocyanin: A copper-containing protein in several invertebrates that is used to bind O_2 in a way similar to hemoglobin. ▶keyhole limpet hemocyanin, ▶hemoglobin, ▶hemerythrin; van Holde KE et al 2001 J Biol Chem 276:15563.

Hemocyte: The collective name of blood cells in higher animals or the lymph of insects.

Hemocytometer: A special microscope slide with compartments (see Fig. H23) of known exact volume when a coverglass is laid over. It is used for the

microscopic counting of the number of blood cells, or any other suspended cells, or protoplasts in a certain volume.

Figure H23. Compartments of hemocytometer

Hemodialysis: The removal of certain components of the blood in a machine through a semipermeable membrane by virtue of their differential rate of diffusion. ► **plasmaphoresis**

Hemoglobin: Oxygen-transporting heme proteins (M_r 64,500) in the red blood cells. The four polypeptide chains are attached to four heme prosthetic groups (Fe_2^+ state). The human adult hemoglobin consists of two α (141 amino acids) and two β (146 amino acids) polypeptide chains, whereas in the early embryo the polypeptide composition is $\zeta\zeta\epsilon\epsilon$. The ζ (zeta) is α -like, the ϵ (epsilon) is β -like. By the eighth week of gestation the embryonal hemoglobin is replaced by fetal hemoglobin with a structure $\alpha\alpha\text{G}\gamma\text{A}\gamma$; (the latter ones are β -like). Just before birth these two γ chains are replaced by β - and δ -globin chains. By the age of six months after birth 97–98% of hemoglobin A (HbA) is $\alpha\alpha\beta\beta$ and about 2% is $\alpha\alpha\delta\delta$ (HbA₂), and a very small amount is still fetal hemoglobin (HbF). Thus, there are two gradual developmental switches in the β -like genes but only one in the α -like genes. These changes are programed as the sites of the synthesis shift from the yolk sac of the embryo to the liver, spleen and bone marrow of the fetus and finally to the bone marrow in adults. The two gene families, α and β , of hemoglobin include α , γ , ζ and θ (θ , theta, unknown function) were located to human chromosome 16p13, and β , δ , ϵ and γ are at chromosome 11p15.5.

Both the α family of genes ($\rightarrow \zeta, \psi\zeta, \psi\alpha, \psi\alpha, \alpha 2, \alpha 1, \theta$) and the β family ($\rightarrow \epsilon, \text{G}\gamma, \text{A}\gamma, \psi\beta, \delta, \beta$) include pseudogenes (ψ) and are transcribed in the order as shown by the arrow. Hundreds of different amino acid substitutions and deletions are known in the globin chains and some of them lead to hemoglobinopathies, or blood diseases. One of the most famous among them is a substitution of valine for glutamic acid at residue 6 of the β chain (Hemoglobin S). This is responsible for a hydrophobic change on its surface resulting in an abnormal quaternary association of the subunits. When the oxygen level is reduced, the subunits polymerize into a linear array of fibers that alters the normally doughnut-shaped red blood cells to assume a sickle shape and therefore it is called *sickle cell anemia* in a homozygous condition. In

a heterozygous state it is called the *sickle cell trait*. The sickling erythrocytes are inefficient in oxygen transport. In the arteries, normal hemoglobin is 95% saturated with oxygen, in the venous blood—on the return to the lung—the saturation is about a third less.

Over 3 million Americans carry this abnormal HbB gene and there are many millions more all over the tropical and subtropical regions of the world where malaria is common. The heterozygotes are apparently at a selective advantage when infested with the *Anopheles* mosquito that spreads the causative protozoon, *Plasmodium falciparum*. A milder form of sickling, expressed only in the homozygotes, is caused by another mutation called hemoglobin C (HbC, $\beta 6\text{Glu} \rightarrow \text{Lys}$). HbC also protects against falciparum malaria. Other variants are HbD and HbE. Many other amino acid substitutions that have been identified on the basis of altered electrophoretic mobility or amino acid substitutions at precisely identified residue sites in either of the chains may not involve a disease. In the M hemoglobins, the oxygenated molecule has hereditary deficiencies of NADH-methemoglobin reductase activity and remains largely charged with oxygen. The stability of the hemoglobin molecules depends mainly on the close fit of the hemes to the globin chains that would be thermolabile at 50 °C. Mutations affecting the tight fit of the heme pocket may cause the formation of methemoglobin or the loss of the heme. Such unstable hemoglobins are, e.g., the Hb Zürich in which at β -chain residue 63 His changed to Arg. Hb Köln β 98 has a Val \rightarrow Met substitution. The increase in positive charge (e.g., Hb Zürich) favors the loss of heme. In case of Hb Hammersmith β 42, Phe \rightarrow Ser substitution, there is no change in charge yet instability occurs. Instabilities were associated with α chain substitutions too, e.g., in Hb Boston 58 His \rightarrow Tyr. Other anomalies include *hereditary persistence of high fetal hemoglobin* (HPFH). In the latter case, numerous types of variations exist. It appears that deletions involving a regulatory region of 3.5 kb at 5' to the δ gene may be a very important factor for the high expression of fetal hemoglobin. In one form, all the cells are equally affected whereas in the *heterocellular* hereditary persistence of fetal hemoglobin (HHPFH), only some of the cells display this anomaly. Certain point mutations in the γ -globin gene promoter are capable of maintaining the expression of this gene during adult erythropoiesis, a condition called *non-deletion hereditary persistence of fetal hemoglobin*. Among these, the British form of HPFH carrying a T \rightarrow C point mutation at position -198 of the A-globin gene promoter results in 4–10% fetal hemoglobin in heterozygotes. HPFH -198 bind specifically to DNMT1 (DNA methyltransferase 1), RAP74 (the largest subunit of the general transcription factor (TFIIF), the coactivator p52, nuclear matrix

protein SNEV, and a CDC5-like protein. Sp1 was not found among the proteins identified (Olave AI et al 2007 J Biol Chem 282:853)

In the Lepore hemoglobins $\delta\beta$ or $\beta\delta$ fusion products were observed, indicating the possibility of unequal crossing over between these DNA sites. Another type of hemoglobin anomalies involves the slow rate or lack of synthesis of one or the other hemoglobin chains resulting in thalassemias. The HBA gene is located to human chromosome 16p13.33-p13.11 whereas the HBB, HBD and HBG genes are in 11p15.5. Senescent or damaged erythrocytes are disposed of by macrophages in the bone marrow to protect from the oxidative and toxic effects of heme. Heme is converted into bilirubin and iron.

H

Hemoglobins are ubiquitous in animals and are highly variable. In humans, hemoglobin occurs in muscle cells, but in the carp it is found also in the brain. A different type (truncated) of hemoglobin also occurs in prokaryotes, protozoa, algae and higher plants, but is absent in archaea or metazoa. ►globin, ►methemoglobin, ►thalassemia, ►anemia, ►sickle cell anemia; Hardison RC 1996 Proc Natl Acad Sci USA 93:5675; Watts RA et al 2001 Proc Natl Acad Sci USA 98:10119; Modiano D et al 2001 Nature [Lond] 414:305; Wittenberg JB et al 2002 J Biol Chem 277:871; <http://globin.cse.psu.edu>.

relatively easily. Over 90% of the soluble proteins in blood plasma are globins. The still nucleated erythrocytes and the reticulocytes mainly synthesize globin mRNA. Amino acid sequence variants were detected in these proteins at the beginning of protein sequencing. Since globin genes occur both in animals and in plants, evolutionary studies became attractive. The number of amino acids in globins of plants as well in animals is fairly close: soybean leghemoglobin 143, seal myoglobin 153, human α 141, human β 146. Also, there are sequence homologies in the primary structure of the chains that with aid of estimated average replacement data the evolutionary time could also be quantitated. In vertebrates the globin genes have two introns at around the 30th amino acid-coding region and another around the 100th. In plants there are 3 introns, two at about the same location and a third near the middle in between. The size of the introns varies substantially from 99 triplets of the middle intron of the leghemoglobin, to 4,800 of the first intron in seal myoglobin. In vertebrates the heme binding is in the second exon, closer to the 3'-end. The residues required for tetramer association are in exon 3. (See Fig. H24; ►globin, ►hemoglobin, ►leghemoglobin, ►myoglobin, ►evolutionary clock, ►evolutionary tree; Hardison R 1998 J Exp Biol 201 [pt 8]:1099).

Hemoglobin Evolution: Molecular genetics which evolved from the early studies (late 1940s) has shown that globin genes could be obtained in pure forms

Hemoglobin, Fetal, Persistence of: The condition may be restricted to some of the cells (heterocellular) or it may involve all the cells (pancellular). Fetal

Figure H24. Evolution of hemoglobins. The numbers at each node indicate the numbers of the presumed nucleotide replacements in the genetic code during evolution. The time of divergence is estimated on average amino acid replacement data and evolutionary clocks. (After Fitch WM, Margoliash E 1970 Evol. Biol 4:67)

hemoglobin is a normal protein, only its persistence is a disorder. It may have point mutations or various types of deletions. The DNA may have either the G- γ gene without the presence of A- γ , - δ , - β , or it may retain the G- γ gene and also the A- γ , - δ , - β , or it may have the G- γ and the A- γ but the δ and β are missing. The phenotype depends primarily on the genes present than on the missing ones. ►hemoglobin, ►GATA; Ikunomi P et al 2000 Gene 261:277.

Hemoglobin Switching: During development various different hemoglobin genes are activated resulting in the formation of the different fetal and eventually adult types. ►hemoglobin; Ristaldi MS et al 2001 EMBO J 20:5242.

Hemoglobinopathies: Hemoglobinopathies are diseases that involve hemoglobins. ►hemoglobin, ►methemoglobin, ►thalassemia, ►anemia, ►hemophilia, ►paroxysmal nocturnal hemoglobinuria, ►sickle cell anemia, ►hemophiliacs, ►hemoglobin, ►fetal, ►persistence of

Hemolin: An immunoglobulin-like molecule in insects. ►immunoglobulins

Hemolymph: Blood-like fluids in insects and other invertebrates. It also has a role in defending against pathogens by dispersing to the sites of infection the secreted antimicrobial peptides and melanin. ►antimicrobial peptides; Vierstraete E et al 2004 Proc Natl Acad Sci USA 101:470.

Hemolysins: Hemolysins are proteins secreted by pathogenic bacteria. They cause the formation of pores in the mammalian cell membranes and dissolve red blood cell membranes. ►erythrocyte, ►lysin

Hemolysis: The disruption of the membranes of erythrocytes by antibodies, the hemolysin enzyme, and chemicals. ►hemolytic disease

Hemolytic Anemia: A disease may have several causes such as emphysema, sensitivity to high temperature, Rh blood type, and other autoimmune diseases, etc. ►anemia, ►hemolysis, ►phosphohexose isomerase, ►glutathione synthetase deficiency, ►glutathione peroxidase, ►glutathione reductase, ►pyruvate kinase deficiency, ►autoimmune diseases, ►hexokinase deficiency

Hemolytic Disease: ►erythroblastosis fetalis, ►Rh blood type, ►Su blood type

Hemolytic Uremic Syndrome (HUS): Hemolytic anemia, hypertension, and acute kidney failure are the main

clinical symptoms. In the dominant form (1q32), the complement factor H is defective. ►complement

Hemophagocytotic Lymphohistiocytosis, Familial: ►histiocytosis

Hemophillias: Hemophillias are hereditary bleeding diseases caused by a deficiency of one or another antihemophilic blood-clotting protein factors. The classic *hemophilia A* (deficiency of antihemophilic factor VIII, encoded at Xq28) has a prevalence of about 1/10,000. The estimated mutation rate is about $2-3 \times 10^{-5}$. Somatic mosaicism may occur in 25% of the patients (Leuer M et al 2001 Am J Hum Genet 69:75). The most famous case of hemophilia involved the descendants of Queen Victoria of England (see Fig. H25). She was heterozygous for the gene (probably through a new mutation) and transmitted it through marriage to the Russian, German, and Spanish royal families. ►pedigree chart

The inept handling of Russia's social problems by Tzar Nicholas II of Russia has been attributed partly to his preoccupation with, and worries about, the affliction of his son Tzarevitch Alexis by hemophilia. Thus, a single recessive gene might have had contributed indirectly to the largest upheaval in the social order of the world. The so-called *Christmas disease* (named after the family Christmas [deficiency of antihemophilic factor IX]), hemophilia B is also an X-chromosome linked disease (Xq27.1-q27.2).

The latter defect is about 1/5 to 1/10 as frequent as the classic hemophilia. These diseases are generally expressed in the males (because of X-chromosomal hemizygosity). Heterozygotes also have generally lower amounts of the proteins responsible for the condition, and thus the carriers can be identified in most cases. The estimated average mutation rate for hemophilia B is $\mu = 7.73$, for males $\nu = 18.8$, and for females $u = 2.18$ per gamete per generation, $\times 10^{-6}$ (Green PP et al 1999 Am J Hum Genet 65:1572). Transitions were 7.3×10^{-9} , transversions 6.9×10^{-9} , deletions/insertions 3.2×10^{-10} (Gianelli F et al 1999 Am J Hum Genet 65:1580). The temporarily effective therapy involves treatment with an antihemophilic factor. For gene therapy—using Moloney retroviral or adenovirus vectors—the B domain of Factor VIII is deleted from the cDNA and only a 170-kDa section is used of the total of 293-kDa. The transcription of the Factor VIII sequences may be repressed presumably by MAR action. Transplantation of embryonic day 42 pig spleen tissue into hemophilic mice model (SCID) led to complete alleviation of hemophilia within two to three months after transplant, as demonstrated by tail bleeding and by assays for factor VIII blood levels. These results provide proof of principle to the concept that transplantation of

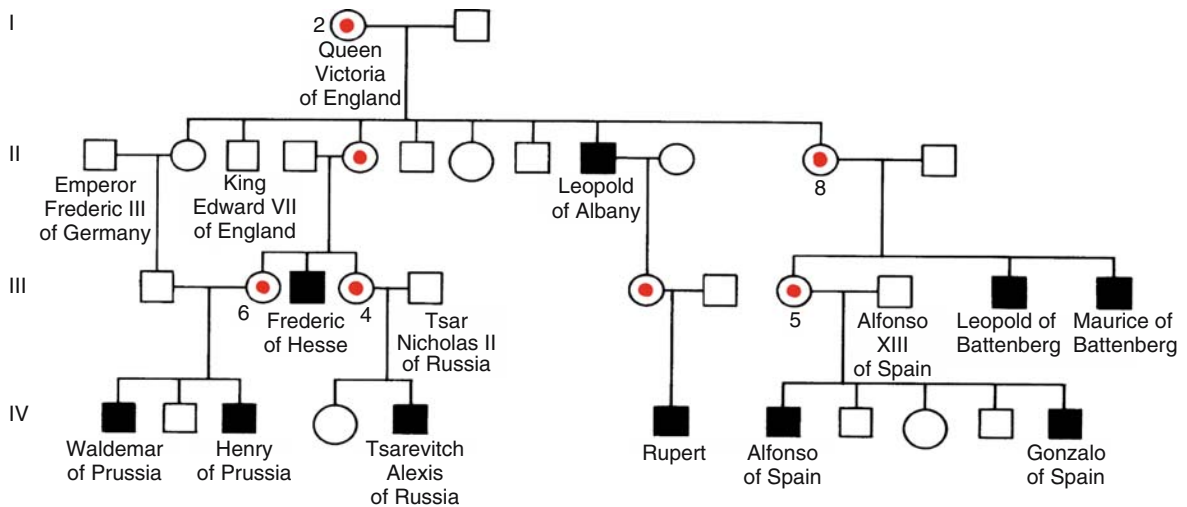

Figure H25. Descendants of Queen Victoria. The family of Queen Victoria of England. Hemophiliac male descendants are represented by black squares. The circles, with a dot inside, stand for the carrier females, 8: Beatrice, 7: Alice, 6: Irene, 5: Victoria, 4: Alexandra, 3: granddaughter Alice

a fetal spleen, obtained from a developmental stage before the appearance of T cells, could provide a novel treatment modality for genetic deficiencies of an enzyme or a factor that can be replaced by the growing spleen tissue (Aronovich A et al 2006 Proc Natl Acad Sci USA 103:19075).

Gene therapy has also been explored for factor IX (Christmas disease); the adeno-associated vector carrying the factor IX gene into skeletal muscles had beneficial effects and no toxicity in phase I clinical trials. The latter has the advantage for being a much smaller protein (454 amino acids). In certain cases the therapy is difficult because the patients may produce significant amounts of the so-called circulating anticoagulant (IgG type antigen) that counteracts the beneficial effects of the clinically transfused blood or the supplied blood factors. Prenatal diagnosis is potentially feasible after 10 weeks by DNA analysis and physical mapping or blood samples can be studied for factor VIII. ▶**antihemophilic factors**, ▶**blood clotting pathways**, ▶**X-chromosomal linkage**, ▶**Hageman trait**, ▶**PTA deficiency**, ▶**prothrombin deficiency**, ▶**Stuart factor**, ▶**vitamin K-dependent clotting factors**, ▶**coumarin-like drug resistance**, ▶**MAR**, ▶**parahemophilia**, ▶**afibrinogenemia**, ▶**dysfibrinogenemia**, ▶**fibrin-stabilizing factors**, ▶**von Willebrand's disease**, ▶**Glanzmann's disease**, ▶**thrombopathic purpura**, ▶**thrombopathia**, ▶**hemostasis**, ▶**platelet abnormalities**, ▶**pseudohemophilia**, ▶**transversion**, ▶**retroviral vectors**, ▶**adenovirus**, ▶**gene therapy**, ▶**clinical trials**, ▶**adeno-associated virus**; New England J Med 2001 345[14].

Hemopoiesis: Same as hematopoiesis.

Hemorrhage: Bleeding.

Hemostasis: The checking or arrest of blood flow. Hereditary diseases involved in hemostasis are the hemophilias, platelet abnormalities, the Nishimura factor, Tatsumi factor, Fletcher factor, Dynia factor, Flood factor, thrombocytopenia, May-Hegglin anomaly, and another number of bleeding anomalies that are characterized by abnormal bleeding such as the Fanconi disease, Meekrin-Ehlers-Danlos syndrome, von Willebrand disease, osteogenesis imperfecta, telangiectasia hereditary hemorrhagic, Osler-Rendu-Weber syndrome, pseudohemophilia, and stroke. (See the mentioned items under separate entries; ▶**venom**; McEver RP 2001 Thromb Haemost 86:746).

Hemp: ▶*Cannabis sativa*

Henbane: *Hyoscyamus niger* (2n = 33, 34); a member of the *Solanaceae* family of plants requiring both vernalization and long photoperiods for flowering (see Fig. H26). It is a source of the hyoscyamine and scopolamine alkaloids (ca. 0.04% in the leaves). The Egyptian henbane, *Hyoscyamus muticus*, has higher alkaloid content (0.5%) and also contains hyoscyperin and choline. These alkaloids are used as a smooth muscle relaxant and a sedative. Hyoscyamine (synonym atropine) has a low lethal oral dose of 5 mg/kg in humans, LD50 intravenously in mice is 95 mg/kg. ▶**alkaloids**, ▶**vernalization**

Figure H26. Henbane leaf and flower

Henden's Node (primitive knot): A group of cells in the primitive streak, contributing to the formation of head, notochord, and endoderm of the embryo. ▶ [primitive streak](#), ▶ [organizer](#), ▶ [notochord](#), ▶ [endoderm](#); Shilo BZ 2001 Cell 106:17.

Henderson-Hasselbalch Equation: $\text{pH} = \text{pK} + \log[(\text{A}^-)/(\text{HA})]$, where pH is the hydrogen ion concentration, pK is an equilibrium constant (1/K), (A^-) is a proton acceptor and HA is a proton donor. This equation expresses the relations between pH and ratio of acid to base in a solution.

Hennigian Cladistics: Basically, a version of the parsimony method of analyzing evolutionary pathways. ▶ [maximum parsimony](#), ▶ [parsimony](#), ▶ [cladistics](#); Mishler BD 1994 Am J Phys Anthropol 94:143.

Henrietta Lacks: ▶ [HeLa cell line](#)

Henry of Prussia: The great-grandson of Queen Victoria of England. Henry of Prussia was afflicted with hemophilia. ▶ [hemophilia](#)

HEPA Filter (high-efficiency particulate air): A HEPA filter traps particles, notably microbes, of the air.

Hepadnavirus (hepatotropic DNA virus): Liver-targeting viruses (~3 kb) that replicate via an RNA intermediate. ▶ [hepatitis](#)

Heparan Sulfate: Repeated disaccharide units composed of glucosamine linked to uronic acid or either to (sulfated) glucuronic acid or (sulfated) L-iduronic acid. Heparan sulfates may be present in mucopolysaccharides and thus in the extracellular matrix. Heparan sulfate proteoglycans are coreceptors in cell adhesion, motility, proliferation, differentiation and morphogenesis, and regulate tumor growth and metastasis. Bacteria, viruses, and parasitic protozoa

bind to the cell-surface heparan sulfate proteoglycans (HSPG). Heparan sulfate proteoglycans may serve as receptors for viral surface fibers and mediate the uptake of the RNA or DNA of the transformation vector. The enzyme heparanase can break down the heparan sulfate meshwork and facilitate the metastasis of cancer cells. In addition, it aids angiogenesis. Heparanase inhibitors are therefore expected to interfere with the development and invasiveness of cancer (see Fig. H27). ▶ [iduronic acid](#), ▶ [glucuronic acid](#), ▶ [mucopolysaccharidosis](#), ▶ [exostosis](#), ▶ [angiogenesis](#), ▶ [metastasis](#), ▶ [Wingless](#), ▶ [syndecan](#), ▶ [glypican](#), ▶ [exostosis](#), ▶ [Simpson-Golabi-Behmel syndrome](#); Bernfield M et al 1999 Annu Rev Biochem 68:729; Liu D et al 2002 Proc Natl Acad Sci USA 99:568; Kramer KL. Yost HJ 2003 Annu Rev Genet 37:461.

Heparin: A mucopolysaccharide consisting of repeated units of uronic acid (glucosamine) and glucuronic acid disulfate. It is secreted into the bloodstream primarily by the liver and it has anticoagulant effects. It is employed as an anticoagulant medicine, and in the molecular biology laboratory it is used (with or without dextran) for in situ hybridization. In Southern hybridization it is used as a blocking agent on nitrocellulose (but usually not on nylon) membranes. Heparin may inhibit metastasis of cancer cells. ▶ [in situ hybridization](#), ▶ [Southern hybridization](#), ▶ [heparan sulphate](#), ▶ [metastasis](#)

Heparin Cofactor II (HCF2, 22q11): Several cofactors facilitate the anticoagulant function of heparin. ▶ [thrombophilia](#)

Heparinemia: The accumulation of heparin in the blood often causing problems in blood clotting and thus bleeding. ▶ [hemostasis](#), ▶ [platelet anomalies](#), ▶ [blood clotting pathways](#)

Hepatitis: The neonatal giant cell hepatitis (8q21.3) is a hemochromatosis due to deficiency in steroid biosynthesis. ▶ [steroid dehydrogenase](#), ▶ [hemochromatosis](#)

Hepatitis B Virus (HBV): A member of the hepadnavirus family. The double-stranded DNA genome is ~3.2 kb. The double-layered mature infectious form

Figure H27. Non-sulphated heparin

is called Dane particle. HBV is replicated through a process of reverse transcription: DNA \Rightarrow RNA \rightarrow single-strand DNA \Rightarrow partially double-strand DNA. The viral DNA may be episomal or it may integrate into the cellular DNA of the host cell by random non-homologous recombination. The virus does not kill the cell upon integration, rather it causes a stable transformation and replicates along with the chromosomes. Infection may increase liver cancer development 5 to 30-fold or more. It is endemic in South-East Asia, tropical Africa and along the Amazon River in South America. Transmission is through body fluids (oral ingestion, blood transfusion, sexual contact, nursing) of the infected persons. The incubation period is one to six months. The disease caused involves fever, vomiting, jaundice, arthritis, etc. Some individuals recover completely but remain carriers and may have a high chance of developing cirrhosis or liver cancer. There are about 350 million chronic HBV carriers worldwide and about one million die annually from complications caused by the infection. The development of effective DNA immunization seems to be a desirable goal. Currently, vaccines based on viral subunits are being used. The HAV and the HCV virus are single-stranded RNA viruses. ►liver carcinoma, ►immunization genetic, ►retroid virus; Ganem D, Schneider RJ 2001 In: Knipe DM, Howlery PM (eds) *Fundamental Virology*, Lippincott Williams & Wilkins, Philadelphia, gene expression, pp 1285; Uprichard SL et al 2003 *Proc Natl Acad Sci USA* 100:1310; particle organizations: Gilbert RJC et al 2005 *Proc Natl Acad Sci USA* 102:14783; http://www.hpa-bioinfodatabases.org.uk/hepatitis_open/main.php.

Hepatitis C Virus (HCV): A member of the Flaviviridae family. HCV infects only humans and chimpanzees; there are no small animal disease models. Its positive-strand RNA genome of ~9.5-kb nucleotides, encodes a polyprotein of 3010–3033 residues. A serine protease processes its polyprotein and this is required for its replication. Inhibition of the protease may be a means for defense (Lamarre D et al 2003 *Nature [Lond]* 426:186). Unfortunately, in a single infected individual about a trillion virus particles are produced daily and each of them may be different from the template strand by one mutation. An estimated 1–3% of the world population is infected by it and chronic infection may lead to liver diseases and cancer. Hepatitis B and C viruses seem to be responsible for 50 to 70% of the cases of hepatocellular carcinomas. Immunization is not available because of the great variety of mutant forms present in the infected individuals. Currently, interferons (IF) are used as a medication but many isolates are resistant to it because the E2 viral coat protein can inhibit the

RNA-inducible protein kinase (PKR). Interferon and ribavirin combination improves treatment effectiveness (Dixit NF et al 2004 *Nature [Lond]* 432:922). IF normally activates PKR that would block the translation initiation factor eIF2 α . R. De Francesco G Migliaccio (2005 *Nature [Lond]* 436:953); Houghton and M Abrignani S 2005 (*Nature [Lond]* 436:961) have summarized newer therapies. Thus, E2 conveys resistance to interferon by facilitating protein synthesis in the cell in the presence of IF. Other pathways of resistance may also exist. HCV can replicate in cell cultures when adaptive mutation(s) occur. Inhibition of geranylation of several host proteins disrupts HCV replication and may promise therapeutic use (Ye J et al 2003 *Proc Natl Acad Sci USA* 100:15865). Although replication in cell cultures of subgenomic particles was earlier known, the complete replication of the full-length genomes in cell cultures has now become known (Lindenbach BD et al 2005 *Science* 309:623; Lindenbach BD et al 2006 *Proc Natl Acad Sci USA* 103:3805). The feasibility of in vitro culture appears to be an important step toward overcoming the debilitating human disease. Recombinant HCV-like particles (HCV-LPs) containing HCV structural proteins (core, E1, and E2) (see Fig. H28), produced in insect cells, resembled the putative HCV virions and were capable of inducing strong and broad humoral and cellular immune responses in mice and baboons in small-scale experiments (Elmowalid GA et al 2007 *Proc Natl Acad Sci USA* 104:8427). ►positive-strand virus, ►eIF2 α , ►PKR, ►claudin; WHO 1999 *J Viral Hepat* 6:35; Barbato G et al 2000 *EMBO J* 19:1195; *Nature* Insight summary of current information: *Nature [Lond]* 436:930–978; interferon pathway targeting by HCV: Meylan E et al 2005 *Nature [Lond]* 437:1167; sequence and immunology database: <http://hcv.lanl.gov/content/hcv-db/index>; European Hepatitis C: <http://euhcvdb.ibccp.fr>.

Hepatitis Delta Virus (HDV): The hepatitis delta virus has a closed circular RNA genome of 1.7 kb packaged into folded and base-paired rods. It codes for two proteins that are edited from a single RNA transcript. The editing is carried out by a double-stranded-RNA-adenosine deaminase. This virus cannot be packaged without the hepatitis B virus. ►hepatitis B virus

Hepatocerebral: Involves the liver and brain

Hepatocyte: A type of liver cell; they are arranged in folded sheets, facing blood-filled spaces (sinusoids). The hepatocytes are responsible for synthesis, degradation, and storage of many substances. The detoxification in the hepatocytes, with the assistance of cytochrome P450, may also produce ultimate mutagens and carcinogens as part of the process.

H

Figure H28. Hepatitis C Virus map. (Redrawn after Lindenbach & Rice 2005 Nature [Lond] 436:933)

Hepatocytes also secrete the bile that mediates the absorption of fats. The forkhead transcription factors, Foxa1/Foxa2, are required for competence within the foregut endoderm for the onset of liver development (Lee CS et al 2005 Nature [Lond] 435:944). Partially hepatoectomized rodent livers are induced to regeneration (Huang W et al 2006 Science 312:233) by increase in bile acid supply and the farnesoid X-activated nuclear bile acid receptor FXR (human chromosome 12q). Severely immunodeficient fumarylacetoacetate hydrolase (Fah)-deficient mice have been constructed which, after pretreatment with a urokinase-expressing adenovirus, could be very successfully engrafted (up to 90%) with human hepatocytes from multiple sources, including liver biopsies. The human cells could then be serially transplanted from primary donors and made to repopulate the liver for at least four sequential rounds. The expanded cells displayed typical human drug metabolism and appear to be a promising model for the study of human liver diseases (Azuma H et al 2007 Nature Biotechnol 29 July doi:10.1038/nbt1326).
 ►hepatoma, ►scatter factor, ►farnesoid X receptor

Hepatocyte Growth Factor (HGF): A mitogen and morphogen, it controls processes in the liver and placental development. Its receptor is a heterodimeric transmembrane protein tyrosine kinase. It has numerous functions such as organ regeneration, angiogenesis, and metastasis of tumors. Also, it is a “scatter factor” because it dissociates epithelial cells and stimulates cell motility. ►scatter factor, ►mitogen, ►morphogen, ►metastasis, ►MET oncogene; Cao B et al 2001 Proc Natl Acad Sci USA 98:7443.

Hepatoma: A liver tumor; originally, it is the transition stage between the generally benign adenoma and the

malignant carcinoma of the liver. Ovarian hormones suppress hepatoma development and therefore male mice and men show five-fold higher incidence of hepatocarcinomas. Myc-induced hepatocarcinoma displays sustained regression and normal-appearing differentiation upon inactivation of Myc, but upon reactivation of the oncogene cancerous growth returns (Schachaf CM et al 2004 Nature [Lond] 431:1112). ►liver cancer, ►chi elements

Hepatomegaly (enlargement of the liver): ►glycogen storage diseases, ►lipodystrophy

Hepatotoxicity: Toxicity to the liver.

Hepcidin (HAMP, 19q13): An antimicrobial peptide of 84 amino acids that processed into mature cysteine-rich peptides of 20, 22, and 25 amino acids. Its deficiency leads to hemochromatosis because of its regulatory role in iron intake. Hepcidin synthesis is stimulated most importantly by IL-6, but IL-1 is also effective (Lee P et al 2005 Proc Natl Acad Sci USA 102:1906). Hemojuvelin, a bone morphogenetic protein coreceptor, regulates hepcidin levels (Babbitt JL et al 2006 Nature Genet 38:531). ►hemochromatosis, ►ferroportin, ►IL-6, ►IL-1, ►bone morphogenetic protein; Roetto A et al 2003 Nature Genet 33:21.

HEPES (N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid): HEPES is used for the preparation of buffers in the pH range 7.2–8.2.

Heptamer: ►immunoglobulins

HER (hybrid excision and repair): ►HEI

her: A mutation that converts X0 *Caenorhabditis* males into females.

HER2: Synonymous with ERBB2 (avian erythroblastosis leukemia viral oncogen homolog, 17q21.2); ►**ERBB1**. The HER2 gene may be amplified by 25% in breast cancer (Meng S et al 2004 Proc Natl Acad Sci USA 101:9393). HER2-mediated metastasis is upregulated by receptor CXCR4 and the inhibition of this receptor suppresses metastasis (Li YM et al 2004 Cancer Cell 6:459). Also HER2/ERBB2 protein tyrosine kinase associated in breast cancer with the kinase CHK/MATK (19p13.3). The HER2 gene also encodes the autoinhibitor herstatin. Fatty acid synthase (FAS) inhibition suppresses HER2 overexpression in cancer (Menendez JA et al 2004 Proc Natl Acad Sci USA 101:10715). ►**tumor-associated antigen**, ►**ETS**, ►**EGFR**, ►**CXCR4**, ►**breast cancer**, ►**metastasis**; Tzahar E et al 1997 EMBO J 16:4938.

H

HER3 (c-Erb-b3): HER3 and other HER proteins are human epidermal growth factor receptor tyrosine kinases and can drive cancer growth (Singer E et al 2001 J Biol Chem 276:44242). When HER2 is inactivated HER3 may take over the role of HER2 (Sergina NV et al 2007 Nature [Lond] 455:437).

Herbaceous: Plant tissue without woody components.

Herbal: Old books with descriptions of plants considered mainly for spice or medicinal use.

Herbarium: A museum collection of dried plant specimens, classified, identified, and described.

Herbicides: Herbicides are chemicals that regulate plant growth. The first herbicides were synthetic auxins (dichlorodiphenyl trichloroacetic acid, 2,4-D). Some of the general type weed killers, e.g., 3-amino triazole, were very potent human carcinogens although they did not respond as positive in the majority of short-term mutagen-carcinogen assay systems. Some herbicides kill plants as germination inhibitors (pre-emergence weed killers such as atrazine). Atrazine interferes with electron transport in photosystem II (photosynthesis) and may disrupt sex hormones. About 20 species of weeds have developed resistance to atrazine since its introduction in agricultural practice in the 1950s. Recently, atrazine was replaced by glyphosate (ROUNDUP), an inhibitor of the biosynthesis of aromatic amino acids by blocking enol-pyruvylshikimate-3-phosphate synthase (EPSP). Glyphosate tolerance is controlled by glyphosate N-acetyl transferase (Castle LA et al 2004 Science 304:1151). Few plant species have yet to develop a resistance to glyphosate.

DICAMBA (3,6-Dichloro-2-methoxybenzoic acid; toxic and carcinogenic) (see Fig. H29) is effective as

glyphosate and other widely used herbicides. The genetically engineered bacterial gene DMO (dicamba monooxygenase) is capable of inactivating dicamba when expressed from either the nuclear genome or chloroplast genome of transgenic plants. The enzyme inactivates the herbicide before toxic levels are reached in treated transgenic crop plants (Behrens MR et al 2007 Science 316:1185).

Figure H29. Dicamba

In glyphosate resistance wheat showed pre- and post-infestation relief against leaf rust (*Puccinia striiformis* and *Puccinia triticina*) and also suppressed Asian soybean rust (*Phacopsora pachyrhizi*) in limited trials (Feng PCC et al 2005 Proc Natl Acad Sci USA 102:17290). (Glyphosate is also effective against some protozoa, e.g., *Plasmodium falciparum*.) Sulfonylureas are selective herbicides of dicotyledonous plants—non-toxic to animals—and they inhibit the acetolactate synthase/acetohydroxyacid synthase enzyme (ALS) in the branched pathway of leucine, valine, and isoleucine (McCourt JA et al 2006 Proc Natl Acad Sci USA 103:569). By a highly selective isolation system resistant mutants were obtained. Resistance under field conditions can be a serious problem. The non-selective herbicide glufosinate-ammonium (phosphinothricin, BASTA) specifically inhibits the glutamine synthetase enzyme (GS). The plants accumulate highly toxic levels of ammonia. The dinitroanilin herbicides (trifluralin, oryzalin) depolarize cytoskeletal tubulins. Three base mutations in its host target molecule results in resistance against this herbicide. Herbicide research took advantage of transformation techniques by developing bacterial EPSP transgenic crop plants (cotton, sorghum, maize, alfalfa, canola, tomato, sugar beet) to make them resistant to glyphosate while the weeds are eliminated. Even greater resistance to glyphosate can be assured by introducing, into crop plants, the *Bacillus licheniformis* gene encoding glyphosate N-acetyltransferase (GAT). The resistance of cultivated plants against sulfonylureas could also be enhanced four-fold by insertion of the ALS gene. The high level of activity of these enzymes permits the transgenic plants to escape death. BASTA resistance was engineered into plants using a gene from *Streptomyces* bacteria that inactivates the

herbicide by acetylation, and, as a consequence, toxic levels of ammonia do not accumulate. Hydantocidin, a spironucleoside, binds to the regulation site of adenylosuccinate synthetase and thus blocks purine biosynthesis in the cells. The overexpression of an ATP-binding cassette efflux protein and apyrase facilitates multiherbicide (and some other chemicals) detoxification and thus generates resistance (Windsor B et al 2003 *Nature Biotechnol* 21:428). Acetyl-CoA carboxylase (ACCase)-inhibiting herbicide resistance for grass weeds was correlated with any of the following five amino acid replacements in the plastids: Ile-1,781-Leu, Trp-1,999-Cys, Trp-2,027-Cys, Ile-2,041-Asn, and Asp-2,078-Gly. Some of the same replacements conferred resistance to aryloxyphenoxypyrone (APP) and cyclohexanedione herbicides in oats and wheat (Liu W et al 2007 *Proc Natl Acad Sci USA* 104:3627).

There is always the possibility that the herbicide-resistance transgene escapes from the crop plants to related weed species by cross-fertilization through the pollen. This risk can be greatly reduced if the resistance transgene is inserted into chloroplast DNA. The large majority of plants do not transmit plastids through the pollen. Another potential advantage of chloroplast transformation is the increased number of transgene copies per cell. Transformation of chloroplasts and mitochondria (by biolistic methods) is somewhat more difficult than introducing foreign genes by agrobacterial vectors into the plant cell nucleus. ▶bialaphos, ▶spironucleoside, ▶transformation, ▶biolistic transformation, ▶transformation of organelles, ▶intein, ▶*Agrobacterium*, ▶vectors, ▶tubulins, ▶acetyl-CoA carboxylase; molecular basis of Roundup resistance: Funke T et al 2006 *Proc Natl Acad Sci USA* 103:13010; Palumbi SR 2001 *Science* 293:1786; herbicide resistance: Gressel J, Levy AA et al 2006 *Proc Natl Acad Sci USA* 103:12215; <http://www.dnr.state.wi.us/org/land/er/invasive/info/herbicides.htm>.

Herbivore: An organism feeding on plants. Insects or higher animal herbivores may cause economic damage. One study indicates that koalas do not like eucalyptus trees with high concentrations of formylated phloroglucinol compounds (see Fig. H30) or low concentrations of nitrogen (Moore BD, Foley WJ 2005 *Nature [Lond]* 435:488). ▶insect resistance, ▶koala

Figure H30. Phloroglucinol

Herceptin (ERBB2, Trastuzumab): An anti-HER2 antibody to control the development of breast cancer and other cancers. It is commonly used with conjugates such as Paclitaxel (a taxol derivative). ▶HER2, ▶breast cancer, ▶ERBB, ▶taxol

Hereditary: Hereditary means being biologically inherited because of the genetic constitution of the family. Being hereditary does not imply perfect transmission to, and expression in, the progeny. The phenotype observed depends on the gene concerned and the environmental factors modifying their expression. The gene(s) responsible for a phenotype may be transmitted without expression under some conditions(s) and the condition still may be hereditary. ▶familial, ▶congenital, ▶reaction norm, ▶heritability, ▶penetrance, ▶expressivity, ▶epigenesis

Hereditary Nonpolyposis Colorectal Cancer (Lynch syndrome, HNPCC, MSH2 chromosome 2p16 and in MLH1 chromosome 3p21, MSH6 in 2p15): HNPCC is accompanied by a high rate of mutation in microsatellite sequences. The mutability is caused by deficiency in mismatch repair controlled by four loci, MSH2, MSH6, GTBP, MLH1, and to a lesser extent by PMS1 and PMS2 (7p22), homologous to microbial enzymes, MutS and MutL. Hypermethylation of the human MLH1 promoter is a frequent cause of insufficient repair. In a family in three successive generations germline allele-specific and mosaic hypermethylation of the *MSH2* gene was detected, without evidence of DNA mismatch repair gene mutation. Three siblings carrying the germline methylation developed early-onset colorectal or endometrial cancers, all with microsatellite instability and MSH2 protein loss. Pyrosequencing showed different methylation levels in different somatic tissues, with the highest level recorded in rectal mucosa and colon cancer tissue, and the lowest in blood leukocytes. Detection of transmission of this condition failed earlier indicating that this case was a hereditary epimutation (Chan TL et al 2006 *Nature Genet* 38:1178). Its prevalence is about 2×10^{-3} . The hereditary nature of HNPCC is determined by the Amsterdam criteria. ▶colorectal cancer, ▶microsatellite, ▶polyposis, ▶Amsterdam criteria, ▶mismatch repair, ▶epimutation, ▶trinucleotide, ▶Gardner syndrome, ▶gastric cancer, ▶histone deacetylase, ▶Muir-Torre syndrome, ▶Turcot syndrome; de la Chapelle A, Peltomäki P 1995 *Annu Rev Genet* 29:329; Scott RJ 2001 *Am J Hum Genet* 68:118; Wagner A et al 2003 *Am J Hum Genet* 72:1088.

Heredity: The study of the storage, transmission, and expression of genetic information. ► [inheritance](#), ► [genetics](#), ► [reverse genetics](#)

Heregulins (glial growth factor/neuroglin differentiation factor/NDGF): Heregulins are transmembrane protein tyrosine kinase receptor ligands (44 kDa, encoded at human chromosome 8p22-p11) present in breast carcinoma and fibrosarcoma cell lines. They bind to the NEU/ERBB2 oncogene. ► [ERBB1](#), ► [\[ERBB2\]](#), ► [oncolytic virus](#); Lee H et al 2001 *Cancer Res* 61:4467.

Herfindahl Index: The Herfindahl index is “the sum of squares of the patent shares (in percentage terms) of each patent assignee (range 0 to 10,000), where 10,000 represent “monopolist” with 100% of patents owned by assignee and low numbers represent more fragmentations” (Jensen K, Murray F 2005 *Science* 310:239). ► [patent](#)

HERG: A human, inward rectifying K⁺ ion channel, responsible for the LQT2 syndrome, encoded in chromosome 7q35–36. HERG is also a regulator of tumorigenesis and apoptosis. ► [ion channels](#), ► [LQT1](#), ► [LQT3](#), ► [Jervell and Lange-Nielsen syndrome](#); Wang H et al 2002 *Cancer Res* 62:4843.

Heritability (h^2): Heritability is generally defined as the ratio of the additive genetic variance and the phenotypic variance (narrow-sense heritability). In some cases only the ratio of the total genetic variance and the phenotypic variance can be determined (broad-sense heritability). Heritability can be estimated by offspring-parent regression, intraclass

correlation and by special methods in humans. Heritability below 0.25 is considered low and above 0.75, high (see Table H1). Generally, heritability of genes barely affecting fitness (e.g., spotting of the fur coat) is higher than for those traits that are important for reproductive success (fertility). The broad-sense heritability of intelligence displays variations during development. In children it may be 40–50%, but by adolescence it may climb to 60–70% or above. The estimates of heritability are valid only for the population that provided the information. In different populations different sets of polygenes may exist and they may provide different heritability estimates. In experimental animals and plants, generally, the narrow sense heritability is used because that is much more predictive.

► h^2 , ► [heritability in the broad sense](#), ► [heritability in the narrow sense](#), ► [correlation](#), ► [intraclass correlation](#), ► [heritability estimation in humans](#), ► [realized heritability](#), ► [QTL](#), ► [behavior genetics](#); <http://www.sfbr.org/solar/index.html>; human variation: www.hgvs.org/; sequence variation database: www.ebi.ac.uk/mutations/.

Heritability, Broad Sense: The total, genetically determined fraction of the phenotypic variance. ► [variance](#), ► [genetic variances](#)

Heritability Estimation in Humans: This may be important in the study of various anthropometric traits, and other polygenically determined conditions such as weight, height, behavior, various types of mental illness, epilepsy, heart disease, diabetes, etc. Since monozygotic twins are expected to be identical

Table H1. Selected heritability estimates in various animals and plants

| HUMANS | | CATTLE | | MAIZE | |
|------------------|------|-----------------|------|---------------|------|
| schizophrenia | 0.75 | white spots | 0.95 | plant height | 0.51 |
| epilepsy | 0.50 | milk production | 0.43 | kernel number | 0.40 |
| MOUSE | | conception rate | 0.03 | yield | 0.29 |
| tail length | 0.60 | SWINE | | ear number | 0.20 |
| litter size | 0.15 | litter number | 0.20 | SOYBEAN | |
| DROSOPHILA | | weaning weight | 0.10 | maturity | 0.75 |
| abdomen bristles | 0.50 | CHICKEN | | plant height | 0.62 |
| egg number | 0.20 | egg weight | 0.75 | oil percent | 0.55 |
| SHEEP | | egg number | 0.25 | seed weight | 0.54 |
| wool length | 0.55 | viability | 0.10 | | |

genetically, any variation between them is supposed to be environmental. Dizygotic twins are of the same age exactly but genetically as different as any other sibs. Thus, heritability (h^2) is calculated frequently as:

$$\frac{\text{variance of dizygotics} - \text{variance of monozygotics}}{\text{variance of dizygotics}} = h^2$$

or

$$\frac{\text{percent monozygotic concordance} - \text{percent dizygotic concordance}}{100 - \text{dizygotic concordance}} = h^2$$

or using the correlation coefficients (r) of monozygotic twins reared together (r_{mzt}) and reared apart (r_{mza}):

$$\frac{(r_{mzt}) - (r_{mza})}{1 - (r_{mza})} = h^2$$

The interpretation in all of these cases has some limitations. The estimate is valid only if the variance is of the additive type because direct estimation, in the absence of controlled matings, cannot be carried out. In the presence of dominance variance, the genetic determination will be underestimated in the two formulas given above. Because the common assortative matings in human populations leads to positive correlation between the parents it thus overestimates heritability. The heritability estimates may be biased if major genes are also involved. Furthermore, environmental variation may not be the same for monozygotic (identical) twins as for dizygotic ones. Generally, it has been difficult to find large enough numbers of twins for precise comparisons. Also, it must be kept in mind that in humans, just as in other organisms, heritability measured in one population, even for the same trait, may not be valid for another population. It would be of great interest to know the heritability of human diseases. Unfortunately, many complicating, nongenetic factors are involved in the development of complex diseases such as cancer (Hemminki K et al 2006 *Nature Rev Genet* 7:958). ▶correlation, ▶intraclass correlation, ▶ h^2 , ▶monozygotic twins, ▶heritability in the broad sense, ▶heritability in the narrow sense, ▶variance, ▶confidence interval, ▶standard error, ▶heritability of some human polygenic disease susceptibility such as blood pressure, ▶lipids, ▶glycemia; pulmonary functions: <http://www.nhlbi.nih.gov/about/framingham/policies/pagetwelve.htm>.

Heritability, Narrow Sense: Narrow-sense heritability is the genetically determined fraction of the phenotypic variance, excluding nonfixable interactions such as due to overdominance. ▶heritability, ▶heritability broad sense

Heritable Translocation Tests as Bioassays in Genetic

Toxicology: Animals exposed to mutagens are tested for sterility or semi-sterility and also examined cytologically for multivalent association during diakinesis to metaphase I in the spermatocytes. Since many of these translocations are transmitted to the progeny, this procedure permits an assessment of how much particular mutagenic agents increase the genetic load of mammals, and potentially of humans too. ▶chromosome breakage in bioassays for genetic toxicology

Hermansky-Pudlak Syndrome: A rare, recessive, human chromosome 10q23 disease, although in some endemic populations (Puerto Rico, Switzerland) its prevalence is $5-6 \times 10^{-4}$. Another locus is at 3q24. In the mouse about 16 loci are involved with the HP syndrome. It involves pigmentation defects (ocular albinism, freckles but the inability to get tanned), predisposition to bruising and bleeding, ceroid storage defects, large and abnormal melanocytes, lower platelet count, and defective lysosomes. Survival is usually limited to 20–25 years. The defect seems to involve a transmembrane protein and lysosomal secretion defect may be involved. This syndrome bears similarities to the Chádiak-Higashi syndrome. ▶Chádiak-Higashi syndrome, ▶albinism, ▶melanocyte, ▶pigmentation of animals, ▶platelet, ▶lysosome, ▶ceroid, ▶lysosomal storage diseases; Anikster Y et al 2001 *Nature Genet* 28:376; Huizing M et al 2001 *Am J Hum Genet* 69:1022.

Hermaphrodite: Both male and female sex organs are present in the same individual. If the same plant bears both male and female flowers but individual flowers are either male (pollen producer) or female (egg producer), it is called monoecious. Hermaphroditism is the most common form of sexual differentiation in plants, but normally it is very limited in the animal kingdom (to flatworms, nematodes, some annelids and crustaceans, etc.) (see Fig. H31). In true hermaphroditism the same individual develops both ovarian and testicular structures. Its frequency is low in mammals, including humans. The majority of human true hermaphrodites have a 46XX constitution and about $\frac{1}{4}$, 46XY; the remaining groups have sex chromosomal mosaicism and are considered to be males by appearance until puberty. In the majority of cases pseudohermaphroditism is observed, i.e., the sex chromosomal constitution does not match the gonadal phenotype. The chromosomally XY individual appears feminine in many ways or the XX individual appears virile. Pseudohermaphroditism may arise by mutation in, or by translocation of, the SRY gene, mutation in the Müllerian duct inhibitor substance gene, defects in the androgen receptor or deficiency in the testosterone 5 α -reductase.

Herpes: A family of double-stranded (linear) DNA (see Fig. H32) viruses with 120–250-kbp genetic material (HSV-1; ca. 75 genes); the capsid is made of about 30 polypeptides. The viruses replicate in the cell nucleus that protrudes through the nuclear membrane into the endoplasmic reticulum. HSV-1 evades the host immune system by the expression of the gE-gI Fc receptor and binds to the Fc region of immunoglobulin G. HSV-1 gE-gI is a heterodimer. gE is a 530 residue protein including a ~401 residue portion followed by a single transmembrane helix and a ~94-residue C-terminal tail. gI has ~370 residues including a ~248 residue extracellular followed a single transmembrane helix and a ~94-residue tail.

The C-terminal CgE ectodomain of gE binds to the $C_H^2-C_H^3$ region of the mammalian antibody's Fc region. The binding is bipolar, i.e., gE-GI is bound to Fc and to a specific gC or gD viral antigen. The bipolar binding at neutral or slightly acid pH protects and helps the spreading of the virus (Sprague ER et al 2006 PLoS Biol 4(6):e148).

There are more than 100 types of herpes viruses and many are serious pathogens; some benign forms are also common in humans. The herpes virus associated with Kaposi sarcoma encodes a chemokine (vMIP-II) that binds to a broad spectrum of chemokine receptors and can thereby block the entry of other viruses (e.g., HIV) into the cells. Most humans harbor latent herpes viruses from early infections during their life. These latent forms rarely erupt in infection again. Latent infection of mouse with viruses similar to the Epstein-Barr virus and cytomegalovirus become resistant to *Listeria monocytogenes* and *Yersinia pestis* bacteria through the continued production of the antiviral interferon- γ (Barton ES et al 2007 Nature [Lond] 447:326).

Herpes Type 1 is responsible for cold sores and Type 2 for obnoxious and painful eruptions in the genital area. The Epstein-Barr virus, a member of the family, is held responsible for nasopharyngeal (nose-throat) carcinoma. The cytomegalovirus, which usually causes mild symptoms, is also a herpes virus, as are also equine and gallid herpes (the latter is responsible for the Marek's disease of poultry [discovered by József Marek, Hungarian veterinary professor]). The herpes simplex virus 1 (HSV-1, 152 kbp) is used as a therapeutic genetic vector to deliver and express genes in the central nervous system, selective destruction of cancer cells, and for prophylaxis against

Figure H32. Ribbon diagram of the CgE structure of HSV-1. β -strand D, E, B, B' and A are light blue, strands A', G, F, C, C' and C'' are dark blue, strands CI', CI and I'' are pink. α -helices are gray. Disulphide bonds are yellow and the three CDR loops (as defined in Ig V domine structures) are red. At right CgE topology. β -strands are shown as arrows and colored as at left. α -helices are gray cylinders. Cysteines are yellow circles with disulphide bonds by yellow lines between paired cysteines. (From Sprague ER, Wang C, Baker D & Bjorkman PJ 2006 PLoS Biol 4(6):e148)

HSV and other infectious agents. The carrying capacity of the HSV vector is about 15–30 kb DNA. The *E. coli* origin of replication permits its propagation in bacteria. For successful propagation in eukaryotic cells, helper HSV-1 is used but it contains either mutations or deletions to avoid its lethal cytotoxic effects. Nevertheless, reversions may occur but in the best helper stocks back mutation is in the 10^{-6} to 10^{-7} range. pHSV amplicon may also be propagated with the assistance of cosmid vectors, which may contain all the essential genes of the virus in fragments but lack the packaging signal. Therefore, lethal infectious virions cannot be reconstituted yet they assure the propagation of the pHSV vector (see Fig. H33) in various types of cells. The newer types of pHSVs may accommodate several genes although generally passengers larger than 15 kb are undesirable. Also, several cell-specific promoters have been employed to facilitate more precise targeting. Another version of the pHSV carries a functional IE3 gene required for the production of the ICP protein (infected cell protein) regulators of transcription and translation. This gene is deleted in the helper virus and it can propagate only by complementation with pHSV. As a consequence, a higher proportion of pHSV is obtained after transfection. Yet another construct of pHSV also contains the inverted terminal repeats (ITR) of the adeno-associated virus (AAV) as well as the AAV *rep* gene. Such a construct integrates specifically into the human chromosome at site 19q13 and behaves there as a stable provirus without disrupting any essential function of the human genome.

Figure H33. Outline of herpes simplex vector, pHSV

Several herpes viruses of the varicella virus group evade cytotoxic T cells by interfering with TAP, a heterodimer of ATP-binding cassette transporter. Normally, MHC class I- β_2 -microglobulin is involved in antigen-presentation to the T lymphocytes and in

the absence of the transport, the MHC I molecules are not loaded with peptide antigen. Herpes simplex virus 1 and 2 encode a cytoplasmic protein, IPC47, that competes effectively with peptide binding to the TAP heterodimer and the transport system ultimately ubiquitinated. Human cytomegalovirus relies on an endoplasmic reticulum-resident type I membrane protein, US6, for the inhibition of TAP by conformational alteration of the transporter complex and that prevents translocation. The murine γ -herpesvirus 68-encoded K3 protein destabilizes MHC class I molecules, TAP and tapasin, and eventually degrades the system. The bovine herpesvirus, the pseudorabies virus and the equine herpesvirus encode the glycoprotein, UL49.5, which evades the killer lymphocytes by impeding the TAP-driven peptide import into the endoplasmic reticulum. Thus all these viruses save their invading ability by different proteins and basically by the same principle, by preventing effective antigen-presentation to killer lymphocytes (Koppers-Lalic D et al 2005 Proc Natl Acad Sci USA 102:5144). ▶Epstein-Barr virus, ▶Marek's disease, ▶cytomegalovirus, ▶gene therapy, ▶Kaposi sarcoma, ▶shingles, ▶chemokines, ▶VP16, ▶LAT, ▶viral vectors, ▶adeno-associated virus, ▶amplicon, ▶TAP, ▶MHC, ▶antigen presenting cell, ▶antibody, ▶killer cell, ▶ubiquitin, ▶tapasin, ▶HVEM, ▶cleft palate; Boehmer PE and Lehman IR 1997 Annu Rev Biochem 66:347; Brune W et al 2000 Trends Genet 16:254; Albà MM et al 2001 Genome Res 11:43; Wolfe D et al 2004 Methods Mol Biol 246:339.

Hers Disease: ▶glycogen storage diseases Type VI

Hershey-Chase Experiment: This experiment demonstrated that only the T2 phage DNA uptake was necessary to reproduce phage in *E. coli* and the phage coat protein was not required. It thus proved that DNA is the genetic material of this bacteriophage (Hershey AD, Chase M 1952 J Gen Physiol 36:39).

Hershey Circle: A nicked phage λ DNA circle in the bacterial host. ▶nick

Hertz (Hz): The unit of the number of cycles in alternating electric currents. In the USA the standard is 60 Hz. 1 megahertz (MHz) is 1 million pulses/second. Modern personal computers employ 300–600 or even much higher MHz microprocessors.

HERV (human endogenous retrovirus): ▶endogenous virus; <http://herv.img.cas.cz>.

Hesitation, Transcriptional: ▶pausing transcriptional

He-T Sequences: Repetitive DNA in the heterochromatin and near the telomeres of *Drosophila*. ▶heterochromatin, ▶telomere

HeT-A: Polyadenylated 6-kb retroposons (no LTR) specific for the telomeres of *Drosophila*, belonging to the family of LINE elements. The 2.8-kb open-reading frame encodes a zinc-finger protein but no reverse transcriptase. Thus, for transposition, it is expected to depend on this function, coded elsewhere in the genome. ▶telomere, ▶retroposon, ▶LINE, ▶zinc finger, ▶TART

Heteradelphian: Conjoined twins or other rare teratological anomalies such as extra limbs without hereditary basis.

Heteroalleles: Nonidentical alleles, which may recombine (involve different nucleotide sites in a cistron). ▶allele, ▶cistron

Heterobrachial: When the two arms of the chromosomes are not identical in length (see Fig. H34). ▶chromosome arm, ▶isobrachial, ▶chromosome morphology

Figure H34. Heterobrachial chromosome

Heterocaryon: ▶heterokaryon (the desirable spelling).

Heterocatalysis: A catalytic process resulting in a product different from the starting material, e.g., the function of enzymes yields a compound different from the substrate or the enzyme. ▶autocatalytic function

Heterocellular: A body or tissue made up of different cells.

Heterochromatin: Parts of the chromosome that stain dark even during interphase (heteropycnotic). The *constitutive heterochromatin* remains in a highly condensed state in all the cells of an organism. Heterochromatin usually reduces recombination and transposon insertion and may affect the expression of adjacent genes (position effect). It contains repetitive and methylated DNA that is usually not transcribed and translated; it is assumed to contain monotonous satellite DNA that is generally rich in AT sequences. It is frequently localized to both sides of the centromeres and to the telomeres. The centromeric heterochromatin of *Drosophila* contains blocks of satellite DNA interrupted at 20- to 200-kb middle-repetitive sequences and by single complete transposable elements. Certain chromosomal regions,

such as most of the Y chromosomes and the B – chromosomes, are heterochromatic. The constitutive heterochromatin can be seen as distinctly and characteristically located cross bands of the chromosomes after stained with Giemsa or other stains. Facultative heterochromatin may be in a relaxed state when it is expressing some information in some cells at certain developmental stages but not under other conditions. The mammalian X chromosome, displaying dosage compensation, becomes heteropycnotic in the additional copies, e.g., in the normal females one of the two X chromosomes is heterochromatic although both of the X chromosomes can be expressed in the males when they are present in a single dose (XY) or in the XO females the single X chromosome is not heteropycnotic. In XXX trisomic individuals two are heteropycnotic and in XXXX superfemales three are heteropycnotic and show two or three Barr bodies, respectively, when in the normal females (XX) there is only one Barr body. The facultative heterochromatinization in the two X chromosomes permits the expression of one or the other alleles of a gene associated with these chromosomes and this results in a variegation called lyonization. The function of heterochromatin has been investigated since the 1930s but no general function could be assigned to it, probably because there are different functional properties of this material, collectively identified as heterochromatin. Most commonly, regulatory and structural roles were attributed to heterochromatin. Lyonization proves some regulatory role. The position effect shows that genes transferred to heterochromatic regions can be silenced. This silencing may be permanent in a stable position effect; presumably the transposed gene lacks the appropriate environment (promoter) for transcription. A multi-enzyme complex (SHREC) with a core of four proteins mediates transcriptional gene silencing of heterochromatin (Sugiyama T et al 2007 Cell 128:491). In case of variegation type position effect (PEV), it was assumed that some binding proteins functioning between the homologous chromosomes have a trans-sensing role in the phenomenon. Both strands of the heterochromatin DNA can be transcribed but one of them may be processed into siRNA and amplified by RdRP and recruited the RITS pathway (Lippman Z, Martienssen R 2004 Nature [Lond] 431:364). RNA polymerase II seems to be required for RNAi-dependent heterochromatin assembly (Kato H et al 2005 Science 309:467). The role of heterochromatin in crossing over remains confusing because both enhancing and suppressing effects on the phenomenon have been observed. Heterochromatin being the site of polygenes has been suggested but not demonstrated

conclusively, unless it is accepted on the basis that some of the redundant genes are heterochromatinized. It came to light recently that centromeric heterochromatin (but not the telomeric) has a role in the disjunction of achiasmate chromosomes. The GAGA transcription factor has been implicated in stimulating variegation type position effect of heterochromatin. The *kl*, *k* and *cry* fertility genes of *Drosophila* seem to be in the Y-chromosomal heterochromatin and the ribosomal gene repeats, *bb* (bobbed), can be found in both the X and Y chromosomes. The enhancer of the second chromosomal (2–54) segregation distorter (*Sd*) locus (*Esd*) and also the activator of *Sd*, responder (*Rp*, 2–56.61), were localized in the heterochromatin. The euchromatic abnormal ovule (*abo*, 2–44) mutations can be normalized by the *ABO* heterochromatic repeats in the X and Y chromosomes. (Hoskins RA et al 2002 Genome Biology 3(12): research0085.16) reported 297 protein-coding genes and six non-protein coding genes in the heterochromatin of *Drosophila*. These genes are different from other *Drosophila* genes in as much that they contain clusters of transposable elements and very large introns (Tulin A et al 2002 Genes Dev 16:2108; Reugels AM et al 2000 Genetics 154:759). The heterochromatic regions generally enclose several transposons and retrotransposons. ATPase DDM1 (decrease in DNA methylation) controls the transposable elements, and the methylation is guided by siRNAs (small interfering RNA). Typically, euchromatin is associated with acetylated histones and with histone H3 dimethylation on lysine 4. In heterochromatin, histone H3 is dimethylated on lysine 9. The transitions between these two states control, epigenetically, the development (Lippmann Z et al 2004 Nature [Lond] 430:471). In rice plants a chromosome 8 that suffered a misdivision contains much reduced repetitive DNA tracts and facilitates the sequencing of this heterochromatic region usually refractory to this procedure. In this region the CENH3 (a generally centromere-specific H3 histone protein gene) as well as several other active genes have been revealed (Nagaki K et al 2004 Nature Genet 36:138). The best-known component of heterochromatin is the heterochromatin-associated protein (HP1), which assists the expression of other heterochromatin genes. Trimethylation of histone H3 lysine 9 creates a binding site for HP1 and contributes to gene silencing by the recruitment of histone methylase (Nakayama J-i et al 2001 Science 292:110). HP1 exists in the isoforms α , β and γ and these are released from chromatin during the mitotic cycles after phosphorylation of histone H3 at Ser¹⁰. However, in the pericentromeric region HP1 α is partly retained. Aurora B kinase is responsible for the serine 10

phosphorylation and the release of HP1 (Fischle W et al 2005 Nature [Lond] 438:1116; Hirota T et al 2005 Nature [Lond] 438:1176).

At the amino end of histone methylase there is about a 50-amino acid sequence (*chromodomain*), a reminder of the Polycomb protein of *Drosophila*. The chromo-ATPase/helicase-DNA-binding proteins (CHD) of humans have two chromodomains to bind to the H3-lysine-4-methylated tails (Flanagan JF et al 2005 Nature [Lond] 438:1181). The chromoshadow domain is located at the C-terminus that is apparently involved in the organization of heterochromatic complexes. Heterochromatin formation requires the deposition of histone in nucleosomes of the newly synthesized DNA (see Fig. H35). The chromatin assembly factor (CAF) and anti-silencing factor (Asf1p), RttP and other proteins serve as chaperones for histones but the PCNA replication factor also controls silencing (Huang S et al 2005 Proc Natl Acad Sci USA 102:13410). ▶satellite DNA, ▶Barr body, ▶lyonization, ▶knob, ▶banding, ▶position effect, ▶silencer, ▶telomeric silencing, ▶*Su(var)*, ▶RAP polygenes, ▶achiasmate, ▶locus control region, ▶GAGA, ▶position effect, ▶PEV, ▶RIGS, ▶histone deacetylase, ▶nucleosome, ▶chromodomain, ▶Aurora, ▶bromodomain, ▶SET, ▶Sbfl, ▶pro-chromosome, ▶centromere, ▶cohesin, ▶boundary elements, ▶CAF, ▶ASF1, ▶PCNA, ▶RITS, ▶histone methyltransferases, ▶insulator, ▶misdivision, ▶epigenesis, ▶RNAi, ▶RITS; McCombie WR et al 2000 Cell 100:377; Hennig W 2000 Chromosoma 108:1; Henikoff S 2000 Biochim Biophys Acta 1470:1; Nielsen AL et al 2001 Mol Cell 7:729; Grewal SI, Elgin SC 2002 Current Opin Genet Dev 12:178; RNAi and heterochromatin: Lippman Z, Martienssen R 2004 Nature [Lond] 431:364; Matzke MA, Birchler JA 2005 Nature Rev Genet 6:24; Grewal SI, Jia S 2007 Nature Rev Genet 8:35; formation of heterochromatin review: Shiv S et al 2007 Nature [Lond] 447:399; annotated sequence of 24 Mb *Drosophila* heterochromatin: Smith CD et al 2007 Science 316:1586; 200 coding and non-coding genes in non-satellite and pericentromeric heterochromatin of *Drosophila*: Hoskins RA 2007 Science 316:1625.

Figure H35. Heterochromatinization

Heterochromia Iridis: (see Fig. H36) ►eye color

Figure H36. Heterochromia iridis

Heterochromosomal Recombination: Involves segmental exchange between repeats within non-homologous chromosomes. ►homologous recombination, ►illegitimate recombination

Heterochronic Expression: The heterochronic expression of genes controls the timing of developmental events.

Heterochronic Mutant: A heterochronic mutant expresses its genetic information with a timing pattern different from that of the wild type, or it regulates development by a (+) or (−) control. Heterochrony has both developmental and evolutionary significance. Heterochrony also bears resemblance to homeotic mutations affecting spatial morphology rather than temporal changes. Heterochronic mutations may orchestrate cell lineage patterns, timing of hormone production, and/or the phasing of the developmental program(s). By studying heterochrony of development the evolutionary pattern in different species can be revealed. ►homeotic genes, ►cell lineages; Pasquinelli AE, Ruvkun G 2002 Annu Rev Cell Dev Biol 18:495.

Heterochronic RNA: Regulates the transition from one developmental phase to another. These RNAs occur in the majority of species with some exceptions, e.g., *E. coli*, *Saccharomyces cerevisiae*, and *Arabidopsis*. In *Caenorhabditis*, the 22-nucleotide *lin-4* RNA controls the transition from the first to the second larval stage. For the progress from the late larval stage to adult cell the 21-nucleotide *let-7* RNA is required. These two RNAs are not homologous to each other but they are complementary to the 3' untranslated sequences of protein-coding genes and negatively affect their expression. These RNAs have single or multiple homologous sequences in humans, *Drosophila*, zebrafish, etc. ►RNAi; Pasquinelli AE et al 2000 Nature [Lond] 408:86.

Heteroclitic Antibody: A heteroclitic antibody binds to an antigen that is different but similar to the one which induced its formation.

Heterocyclic Amines: Heterocyclic amines include mutagens and carcinogens. Some are formed during high-temperature cooking and frying of meat and fish.

Heterocyst: A terminally differentiated cell, e.g., the nitrogenase protecting cells of filamentous cyanobacteria. ►nitrogen fixation; Wolk CP 1996 Annu RevGenet 30:59.

Heterodimer: A protein with two different polypeptide subunits.

Heterodisomy: ►uniparental disomy

Heterodox Chromosomes: The special structures such as polytenic, lampbrush, sex, etc., chromosomes.

Heteroduplex: Base-paired polynucleotide chains with the two strands of different origins; they may not be entirely complementary (see Fig. H37). In case the heteroduplex area includes different alleles, post-meiotic segregation may occur resulting in aberrant ascospore octads or sectorial colonies from single (haploid) spores. ►Meselson-Radding model of recombination

Figure H37. Heteroduplex

Heteroduplex Analysis (heteroduplex tracking, HTA, HMA, QHTA): A method of mutation detection. DNA sequences containing even a single mismatch may move more slowly in the electrophoretic gel when compared with a corresponding homoduplex. ►mismatch, ►electrophoresis, ►mutation detection, ►SNIP

Heteroduplex Rejection: The differences in base composition between recipient and donor decrease the formation of stable transformants.

Heteroencapsidation (transencapsidation): Heteroencapsidation occurs when the viral coat and the enclosing genetic material do not match by origin.

Heterofertilization: Heterofertilization occurs when genetically different sperms fertilize the polar nucleus and egg of plants and, therefore, the egg and the endosperm become non-concordant ►gametophyte, ►embryosac

Heterogametic Sex: Heterogametic sex produces both X (Z) and Y (W) chromosome-containing gametes, or

gametes with X and without X if the diploid has the chromosomal constitution XO. ▶sex determination, ▶MR

Heterogamy: Heterogamy is disassortative mating; it is also the alternation between sexual and parthenogenetic modes of reproduction. ▶disassortative mating, ▶parthenogenesis, ▶homogamy

Heterogeneity: A population or family is segregating for genes of one or more loci. The appearance of phenocopies may confound genetic conclusions. Genetic heterogeneity may be due to mutation in different genes controlling the same developmental or biochemical pathways and resulting in similar phenotype although caused by different molecular mechanisms. Several human diseases (syndromes) are based on mutations in different genes. ▶phenocopy, ▶context genetic, ▶syndrome

Heterogeneous Nuclear RNA: ▶hnRNA

Heterogenote: ▶endogenote

Heterograft: The donor and recipient of the graft are different species. ▶graft, ▶allograft, ▶isograft, ▶grafting in medicine

Heterohybrid DNA: One of the annealed strands is methylated, the other is not.

Heterohybridoma (trioma): Heterohybridoma is obtained by fusing a human lymphoid tumor cell with a mouse myeloma cell. The purpose of generating such a cell is to obtain cell lines which produce more and more stable antibodies than the lines obtained by fusion with rodent cells alone. The production of human monoclonal antibodies may have several problems. There are ethical obstacles which come in the way of immunizing humans with disease markers. It is difficult to harvest appropriate immune cells from the spleen or lymph nodes, and when peripheral blood is used it contains relatively few B lymphocytes. Furthermore, the blood B cells carry IgM on their surface and therefore display low affinity IgM antibodies. In addition, the human myeloma cells proliferate slowly and may express their own immunoglobulins and therefore make purification difficult too. Using murine myeloma cells may be only a partial solution although they may not secrete their own antibody, but they may cause the loss of human chromosomes resulting in the inability of human antibody production. ▶monoclonal antibody, ▶hybridoma, ▶Epstein-Barr virus, ▶lymphocytes, ▶immunoglobulins, ▶myeloma, ▶somatic cell hybrids, ▶hybrid hybridoma; Jessup CF et al 2000 J Immunol Meth 246:187.

Heteroimmune: When a lysogenic bacterium has a normal prophage and the λ dgal transductant, and

the two have different repressors, the transduction is heteroimmune. One species of animals was immunized by another species or the antigen (of any type) used evokes a pathological change. ▶lambda, ▶ λ dgal, ▶specialized transduction, ▶HFT; Yoshida Y, Mise K 1984 Microbiol Immunol 28[4]:415.

Heterokaryon: A cell with more than one nucleus per cell of more than one type. This is of common occurrence in fungi when two different haploid cells undergo plasmogamy or when somatic cells of other organisms fuse and the cell fusion is not followed by fusion of the nuclei (see Fig. H38). ▶dikaryon, ▶homokaryon, ▶fungal life cycle, ▶somatic cell hybrids; Beadle GW, Coonradt VL 1944 Genetics 29:291.

Figure H38. Heterokaryotic cell

Heterokaryon Incompatibility: Heterokaryon incompatibility results when the fusion of opposite mating-type (A and a) vegetative hyphae results in growth inhibition or cell death. ▶incompatibility, ▶fungal incompatibility, ▶hypha, ▶heterokaryon

Heterokaryon Test: When two marked cells are fused and subsequently uninucleate cells are selected. If the nuclei are not fused and recombined, yet the uninucleate progeny still carry both parental markers, the markers must be carried by the cytoplasm.

Heterolabel: A sister chromatid exchange can be identified if the two sister chromatids are different by harlequin staining. ▶sister chromatid exchange, ▶harlequin staining of chromosomes

Heterologous Gene Expression: The transcription/translation or regulation of a gene(s) introduced from another source, e.g., in gene therapy or metabolic engineering.

Heterologous Probe: A heterologous probe is used for the identification, localization, isolation, and cloning of specific genes in an organism by employing a labeled (radioactive, fluorescent) nucleotide sequence of presumably similar structure and function, from another species. ▶probe

Heteromorphic Bivalent: Morphologically distinguishable members of a homologous chromosome pair (see Fig. H39). ▶bivalent

Figure H39. Heteromorphic bivalents

Heteromultimeric: Proteins with nonidentical subunits, encoded by different genes.

Heteroplasmy: The extranuclear genetic material within a eukaryotic cell is not homogeneous but contains genetically different components in analogy to heterozygosis (see Fig. H40). Pathogenic mutations in the mtDNA occurred at a frequency of $\sim 1.3 \times 10^{-4}$ in England. Heteroplasmy, to the extent of 1% or more, was detected in 13.8% of a sample of 253 human individuals and some individuals displayed triplasm, i.e., had three types of mtDNA in the hypervariable region of the mtDNA populations (Tully LA et al 2000 Am J Hum Genet 67:432). Cell fusion, microinjection of somatic mitochondria into pronucleus-stage embryos and nuclear transfer may generate heteroplasmy that may be transient or persistent (Steinborn R et al 2002 Genetics 162:823). Selection would be expected to eliminate inferior mitochondria yet some variation (neutral?) seems to be maintained, although in the majority of cells or bodies homoplasmy seems prevalent. Mitochondrial mutations are subject to genetic drift (Brown DT et al 2001 Am J Hum Genet 68:533) because, during oogenesis, only very few mitochondria are transmitted. Heteroplasmy for mitochondrial encephalopathy was detectable in 87% of the affected tissue (skeletal muscles) but only 0.7% in the unaffected blood. Deletions of the mtDNA are rarely transmitted to the offspring but point mutations (MELAS) reappear by random drift. The exhumed remains of Tsar Nicholas of Russia and his brother Georgij Romanov's

mitochondria displayed two populations of mtDNA with both C and T at position 16,169, respectively. Heteroplasmy may involve differences between individuals and groups but even within different organs of the same individual. Heteroplasmy may involve a single base or several. Human diseases involving defective mitochondria in heteroplasmic state may potentially be temporarily remedied by selective destruction of the defective mtDNA using a specific restriction enzyme. ▶mitochondria, ▶chloroplast, ▶Romanovs, ▶DNA fingerprinting, ▶homoplasmy, ▶paternal leakage, ▶mitochondrial diseases in humans; Chinnery PF et al 2000 Trends Genet 16:500; Brown DT et al 2001 Am J Hum Genet 68:533; Srivastava S, Moraes CT 2001 Hum Mol Genet 10:3093; Schwartz M, Vissing J 2002 New England J Med 347:576.

Heteroplastic: When within the same cell more than one type of chloroplasts exist as a consequence of mutation in the ctDNA or cell fusion. ▶chloroplast genetics, ▶ctDNA

Heteroploid: The chromosome number deviates from the normal.

Heteropolymer: A synthetic polynucleotide containing more than a single type of bases.

Heteropolysaccharide: A heteropolysaccharide contains more than one kind of monosaccharide.

Heteropycnosis: One chromosome or part of it is darkly stained when the rest of the chromosome(s) absorb(s) little or no stain at a particular stage. Dark staining at interphase is an indication of tight coiling and being in an inactive state. ▶heterochromatin, ▶Barr body, ▶pycnosis; Zaccharias H 1990 Chromosoma 99:24.

Heteroscedasticity: Heterogeneity (inequality) of the variances in a group of samples.

Heteroselection: In a population, selection for heterozygotes may prevail and improve its ability to respond to new environmental challenges. ▶selection, ▶homoselection

Heterosis: Heterosis is frequently defined as the superiority of the F_1 hybrids over the mid-parent value (see Fig. H41). This definition expresses heterosis as Σdy^2 where d is the dominance effect at all loci and y is the difference of gene frequency between the two parental populations. This mathematical definition assumes that only dominant genes are responsible for heterosis. In agricultural practice, the breeders and growers require that the hybrids surpass in performance any known parental types and overdominance and epistasis may also be involved ▶hybrid vigor. There is no unanimity in the literature in interpreting the biological basis of heterosis.

Figure H40. Heteroplasmy

Figure H41. Heterosis

Perhaps the majority favors the dominance or epistasis interpretation; there is incontrovertible evidence also for monogenic or overdominant mechanism. Large-scale introgression analysis of tomato species led to the conclusion that overdominance is prevalent in quantitative trait loci for yield and fitness (Semel Y et al 2006 Proc Natl Acad Sci USA 103:12981). Heterosis was known for ages and was systematically exploited in agricultural practice by cross-pollination between open pollinated, distinct varieties of maize. Since the second decade of this century inbred lines of maize were used for the production of single-cross hybrids. A single-cross is the F1 generation of two inbreds. Inbreeding reduces the vigor of the inbreds but the single-cross may surpass not just the parental inbred lines but also the open-pollinated varieties from which the inbreds were isolated by several years of selfing in plants or brother-sister mating in animals. During the process of inbreeding, a progressive increase toward homozygosity takes place. Also, the different inbreds become homozygous for different alleles of the population. Therefore, not all inbreds are capable of contributing valuable genes to show heterosis. The breeders must select for inbred lines that produce superior hybrids, i.e., they have good combining ability. The *specific combining ability* means that a certain inbred contributes to valuable hybrids only with a particular, and other, inbred line. *General combining ability* implies that an inbred yields high in combination with many other inbreds. Heterosis was most successfully exploited in maize breeding where it was practically difficult and expensive to use F1 hybrids for commercial production. In the late 1910s it was discovered that *double-crosses* were also very productive and it is much more economical to generate seeds in large quantities for agronomic production. A double-cross is the intercross of two F1 lines such as (A x B) x (C x D). In order to obtain 100% hybrid seeds, first the plants had to be

detasseled, the male inflorescence, the tassel, had to be cut off before shedding pollen and when the female inflorescence (silks) were receptive, they had to be pollinated. This manual operation was very inefficient and costly. When cytoplasmic male sterility and fertility restorer genes were discovered, cross-pollination could be carried out economically at a large scale. Before hybrid corn was introduced into commercial production the yield per hectare in the USA was about 1,400 kg. By the time the use of hybrid corn became practically universal, the yield increased from five- to ten-fold. Heterosis is now exploited in many other plant species, including some autogamous species such as tomatoes. Hybrid vigor is also commercially utilized in the poultry and pork industries. Both positive and negative heterosis of molecules has also been revealed. Generally, negative heterosis is hybrid inviability in inter-species or laboratory-bred offspring. The latter has been exploited for genetic sterilization of pests. Large-scale (13,999) cDNA analyzed by microarray hybridization indicated that additive, dominance, and overdominance all could contribute to hybrid performance in maize (Swanson-Wagner SA et al 2006 Proc Natl Acad Sci USA 103:6805). ▶inbreeding, ▶maize, ▶cytoplasmic male sterility, ▶hybrid vigor, ▶overdominance and fitness, ▶tassel, ▶genetic sterilization; Gowen JW (ed) 1952 Heterosis, Iowa State College Press, Ames IA; Li SL, Rédei GP 1969 Theor Appl Genet 39:68; Rhodes D et al 1992 Plant Breed Revs 10:53; Comings DE, MacMurray JP 2000 Mol Genet Metab 71:19; Lippman ZB, Zamir D 2007 Trends Genet 23:60.

Heterospecific: Belonging to another species.

Heterosporic: Produces both micro- and macrospores.
▶microspore, ▶macrospore

Heterostyly: The anthers in a flower are at a height different (generally lower) from that of the stigma in order to avoid self-pollination (inbreeding). ▶incompatibility alleles

Heterotachy: The pattern of variation at a molecular site through time of evolution.

Heterotaxy (heterotaxia): Partial asymmetries in the placement (situs) of single visceral organs, e.g., different organs are oriented independently. ▶isomerism, ▶situs inversus viscerum, ▶connexin; Aylsworth AS 2001 Am J Med Genet 101:345.

Heterothallism: Heterothallism in lower eukaryotes (fungi) is comparable to dioecy in higher plants, or bisexuality in animals, i.e., the plus and minus mating type spores are carried by different individuals (thalli, colonies). This definition does not require that the species would have sexual organs (that many fungi

lack), nor are these spores immediate meiotic products. In case of relative heterothallism the union of genetically different nuclei is favored. ► [homothallism](#), ► [pseudohomothallism](#)

Heterotopia: The misplaced location of a tissue or organ. Hereditary nodular, periventricular heterotopia (Xq28) in the cerebral cortex is a serious health problem that results in epilepsy. The basic defect is in filamin-A synthesis. ► [filamins](#)

Heterotopic Graft: A piece of tissue is transplanted to a location different from its original site. ► [graft](#)

Heterotrophs: Heterotrophs cannot meet all their requirements from inorganic nutrients.

Heterotropic: An allosteric enzyme needs more than its substrate for modulation. ► [allostery](#), ► [modulation](#)

Heterozygosity, Average: Heterozygosity varies in an outbreeding population in *Drosophila* as well as in man; many genes are homozygous whereas heterozygosity at some other loci may vary from 0.10 to over 0.70. In a random mating population heterozygosity (H) for a locus can be estimated: $H = 1 - \sum_{i=1}^k x_i^2$

where x_i = frequency of the i^{th} allele, k = the number of alleles, e.g., if the frequencies of the alleles A1 (0.4), A2 (0.2), A3 (0.3) and A4 (0.1) then $H = 1 - (0.4^2 + 0.2^2 + 0.3^2 + 0.1^2) = 1 - 0.3 = 0.70$. In case the size of the population is very small the following formula may give somewhat better estimate: $H = 2n / (2n - 1)(1 - \sum \hat{x}_i^2)$ where \hat{x}_i = the frequency of the i^{th} allele and n = the number of alleles studied. ► [utility index of polymorphic loci in genetic counseling](#), ► [counseling genetic](#)

Heterozygosity-Fitness Correlation: This model assumes that heterozygosity is a major contributor to fitness in a population. An opposing assumption is that fitness is due to the association between certain marker genes and selectively advantageous loci. ► [fitness](#); David P 1998 *Heredity* 80:531.

Heterozygote: An individual with different alleles at one or more gene loci. Segregation identifies it genetically. From the frequency of the heterozygotes, carriers of a recessive disease allele, the approximate frequency of the afflicted (homozygous recessive) can be predicted on the basis of the Hardy-Weinberg theorem; e.g., if a population 1/50 ($2pq = 0.02$) is a carrier the expected approximate frequency of the disease is about 10^{-4} . DNA sequencing may identify it molecularly. ► [homozygote](#), ► [Hardy-Weinberg theorem](#)

Heterozygote Advantage: ► [hybrid vigor](#), ► [heterosis](#), ► [selection coefficient](#), ► [fitness](#), ► [inbreeding coefficient](#)

Heterozygote Proportions: In the F_2 of a monofactorial cross the genotypic proportions are 1AA:2Aa:1aa. If propagation is continued by selfing, the frequency of homozygotes will increase (inbreeding) and that of the heterozygotes will decrease as discovered by Mendel. The proportion of each homozygote (AA or aa) relative to the heterozygotes (Aa) will be in compliance with the formula: $[(2^{n-1}) - 1]:[2]$ where n stands for the number of filial generations. Apply this formula to F_2 : $[(2^{2-1}) - 1]:[2] = 1:2$ and by F_6 : $[(2^{6-1}) - 1]:[2] = 31:2$. (Note that the F_1 was not produced by selfing.) The proportion of both types of homozygotes combined relative to the heterozygotes will be 2:64 at one locus. The same results can also be obtained another way: 0.5^{n-1} , thus, the frequency of heterozygotes at a single locus, in F_6 , will be $0.5^{6-1} = 0.03125$ that is the same as 2/64 obtained above. In case the average effective population size (N_e) is known the heterozygosity remaining after n generations can be determined as $[1 - 1/(2N_e)]^n$. ► [inbreeding](#), ► [inbreeding progress of](#), ► [effective population size](#)

Heterozygous: In a diploid or polyploid the alleles at a locus are not identical; a similar condition may exist in haploids (merozygotes) carrying duplication or a plasmid with the same locus. ► [homozygous](#), ► [Mendelian segregation](#)

HETS: Stands for heterozygotes.

Heuristic Search: A sequential estimation of the shortest branches of an evolutionary tree starting with a single individual and then choosing others. It is carried out usually with the PAUP computer program. ► [PAUP](#), ► [evolutionary tree](#), ► [exhaustive search](#)

Hevea brasiliensis (rubber plant): A major source of latex in plants grown mainly in Asia and West Africa for the production of natural rubber (a polymer of cis-1,4 polyisoprene $[C_5H_8]_n$). The origin of the plant is South America. The basic chromosome number $x = 18$ but 9 has also been suggested. Some of the species are either diploid, $2n = 36$ or triploid, $2n = 54$.

Hexaploid: A hexaploid has six basic sets of chromosomes (genomes) in its cells (chromosome number = $6x$). Hexaploids are generally allohexaploids, i.e., each pair of the sets are of different evolutionary origin. For example, in the somatic cells of the common bread wheat (*Triticum aestivum*) $2n = 42$ contain 6 x 7 chromosomes of the AABBDD genomic composition. In the allohexaploid wheat the three genomes each synthesize benzoxazinones. Their products are not exactly the same, however, and

they correspond to the original progenitors, indicating that these genes evolved before the polyploidy series were formed (Nomura T et al 2005 Proc Natl Acad Sci USA 102:16490). Autohexaploids would have problems with multivalent association, unequal disjunction and consequently with sterility. ►polyploidy, ►allopolyploid, ►*Triticum*

Hexasomic: When one particular chromosome is present in six copies within a cell. ►aneuploid

Hexokinase: A hexokinase phosphorylates glucose to glucose-6-phosphate using an ATP donor. HK1, HK2, and HK3 genes are in human chromosomes 10q22, 2p12, and 5q35.2, respectively. HK deficiency may lead to hemolytic anemia. ►AKT

Hexon: A capsomer with six neighbors in the viral capsid. ►capsomer, ►penton

Hexosaminidase A and B: Hexosaminidase A and B are lysosomal enzymes involved in the breakdown of ganglioside sphingolipids forming about 6% of the membrane lipids in the gray matter of the brain and present in smaller amounts in other tissues. ►gangliosides, ►Tay-Sachs disease, ►Sandhoff's disease, ►lysosome

Hexose: A hexose is a sugar with a 6-carbon backbone, e.g., glucose galactose or fructose. ►galactose

Hexose Monophosphate Shunt: ►pentose phosphate pathway

Hfr: The high-frequency recombination strain of a bacterium. The sex element (F plasmid) is integrated into the bacterial chromosome resulting in about a thousand-fold more efficient transfer of the bacterial chromosome with the integrated F⁺ element into the F⁻ recipient cell. The transfer of the chromosome makes recombination possible but, unlike in eukaryotic crossing over, only one of the recombinant strands is recovered.

The sex factor and the bacterial chromosome are transferred in a unidirectional manner. The F element can be integrated into the bacterial chromosome at different map positions and it may be transferred either clockwise or counterclockwise (see Fig. H42). The transfer involves a process of a rolling circle type of replication. The genes closest to the point of the initiation of transfer are transferred first in proportion to their distance from that point. The transfer point is generally in the middle of the sex element, so for the recipient cell to receive the intact F requires the transfer of the entire Hfr plasmid. The rate of transfer depends also on the nature of a particular Hfr element. The complete transfer of the entire bacterial genome, plus the F element, is about 4,700,000 nucleotides and requires about 90–100 minutes. (See also the

diagram; ►rolling circle, ►replication, ►mob, ►conjugation, ►conjugation mapping, ►bacterial recombination frequency, ►F plasmid; Hayes W 1953 Cold Spring Harbor Symp Quant Biol 18:75).

Figure H42. Two different Hfr groups, 13 and 15. The arrows on the dots indicate the direction of the transfer and the gene first transferred. The open circles show the position of the markers last transferred. In *E. coli* more than two dozen Hfr strains are known

H

HFS Cells: HFS cells are human fibroblast cells transformed by replication/transcription origin deficient SV40 DNA. They produce T antigen (Tag) and thus can provide helper functions for replication to high copy number minireplicons containing only viral replicational origins. ►SV40, ►replicon

HFT: A high frequency transducing lysate. Normal lambda phage and the defective λdgal phage can transduce bacteria. Upon induction both λdgal and normal phages can be released at about equal frequencies because the wild type phage can provide the information missing in the defective λ DNA. The two types of particles can be separated by CsCl density centrifugation because the density of the wild type particles is about 1.7 g/cm³, whereas that of the defective may be as low as 1.3. ►specialized transduction, ►LFT, ►lambda phage, ►high-frequency lysate

HGF (hybridoma growth factor; hepatocyte growth factor): The HGF receptor is the product of the Met oncogene. The hepatocyte growth factor may interfere with the neoplastic activity of the c-myc oncogene in mouse. ►signal transduction, ►hybridoma, ►hepatocyte, ►macrophage-stimulating factor, ►Met, ►hepatocyte growth factor, ►Ron, ►HNF

HGI (Human Gene Index): Gene indexing, <http://www.tigr.org/tdb/hgi/index.html>.

HGMD (human gene mutation database): See <http://www.hgmd.cf.ac.uk/ac/index.php>.

HGP (human genome project): ►genome projects; <http://www.ncbi.nlm.nih.gov/genome/guide>.

HGPRT: ►hypoxanthine-guanine phosphoribosyltransferase; the same as HPRT.

Hhal: A restriction enzyme that has the same recognition site as CfoI: GCG↓C.

HHV8 (KSHV): The human herpes virus 8 (~165 kb); it is consistently associated with Kaposi sarcoma. It has no in vitro transmission. It may inactivate the complement, induce IL-6, MIP-1 α , β , RANTES, BCL2, Cyclin D2, and inhibit interferon signaling. ►Kaposi sarcoma, ►Cd21/CR2, ►IL6, ►MIP-1, ►RANTES, ►BCL2, ►cyclin D, ►interferon, ►interferon receptor, ►Jak-Stat, ►signal transduction

Hibernation: Hibernation in mammals involves decreased metabolic rate and survival up to ~6 months without food and low body temperature of close to 0° C. In ground squirrel (*Spermophilus*) the heartbeat may be lowered to just a couple percent of the rate of that during aroused state and oxygen consumption becomes ~1/40th of normal. The activity of the genes controlling pyruvate dehydrogenation is turned down and the activity of pancreatic triacylglycerol kinase is turned on to switch to energy source of adipose tissues rather than from carbohydrates. (See Andrews MT 2004 Biochem Soc Trans 32 (6):1021). In nonhibernating mammals (mouse) a similar state (torpor) may also be evoked by long circadian dark cycles (Zhang J et al 2006 Nature [Lond] 439:340). A hibernation protein complex in the brain controls seasonal (circannual) hibernation rather than by body temperature and it actually protects the animals from the harmful effects of low body temperature (Kondo N et al 2006 Cell 125:161).

HIC (hypermethylated in cancer, 17p13.3): A zinc-finger protein regulating embryogenesis and differentiation. It is deleted in the Miller-Dieker syndrome. ►Miller-Dieker syndrome

Hickory (*Carya* spp.): A hardwood forest and shade trees, 2n = 32, 36.

Hidden Markov Model (HMM): A probabilistic model for a protein or RNA family. In a HMM graph the nodes are “states” and the edges are “transitions”. The total probability is the sum over all paths. ►Markov chain statistics

Hide-and-Release Variation: The decrease in function of the heatshock protein Hsp90 capacitates the expression of silent mutation in genes chaperoned by Hsp90 (Queitsch C et al 2003 Nature [Lond] 417:618).

Hieracium: A genus of the Compositae family with many weedy species in America and Europe (see Fig. H43). Several of them have a euploid chromosome number (e.g., *H. japonicum* 2n = 18). The apomicts have chromosome numbers 2n = 27, 36 and 45. Apomixis in *Hieracium caespitosum* is controlled at two principal loci, one of which regulates events

associated with the avoidance of meiosis (apomeiosis) and the other, an unlinked locus that controls events associated with the avoidance of fertilization (parthenogenesis). AFLP bands identified as central to both loci were isolated, sequenced, and used to develop sequence-characterized amplified region (SCAR) markers (Catanach AS et al 2006 Proc Natl Acad Sci USA 103:18650). These apomicts, studied by Gregor Mendel, upon the recommendation of Carl Nägeli, Professor of Botany at the University of Munich, caused great worries to Mendel concerning the validity of his discoveries about inheritance because the apomicts failed to segregate as expected. Thus Nägeli, despite his great fame, almost thwarted the development of genetics with plants as he also argued against the existence of hard heredity in bacteria by advocating his theory of pleomorphism, meaning that these organisms lacked fixed genetic material and vary freely. If Nägeli's theory had been accepted, it would have also foiled the development of bacteriology and medicine. ►Mendel's laws, ►pleomorphism, ►AFLP, ►parthenogenesis

Figure H43. *Hieracium auranticum* herbal illustration

Hierarchical Cluster Analysis: Compares pair-wise large sets of data to determine similarities and homogeneity in genetic-metabolic information. ►cluster analysis; Eisen MB et al 1998 Proc Natl Acad Sci USA 95:14863.

Hierarchical Shotgun Sequencing: This procedure is based on mapped clones generated by BACs. The main advantage of this conservative approach versus the whole genome shotgun procedure is that several laboratories can work simultaneously on the project. The International Human Genome Sequencing Consortium relied on it. ►shotgun sequencing

HIF (hypoxia-inducible factor): A transcription factor binding to the 5'-ACGTG-3' element and it is

involved in oxygen homeostasis under anoxic (low-oxygen) conditions by inducing glycolysis, erythropoiesis, and angiogenesis. HIF-1 regulates cytochrome oxidase subunits (Fukuda R et al 2007 Cell 129:111). Blocking the interaction between HIP and its transcriptional coactivator CREB binding protein, p300, disrupts HIF activity (Kung AL et al 2004 Cancer Cell 6:33). The HIF1A α subunit is encoded in humans at 14q21-q24, the HIF2 (EPAS1) α subunit is at 2p21-p16. In the presence of the wild type allele of HIF, hypoxia and hypoglycemia reduce cell proliferation controlled by p53, p21 and Bcl-2 proteins, but the inactivated HIF genes do not affect p27 and GADD153. Prolyl hydroxylase domain (PHD) enzymes regulate HIF by proteasome-dependent degradation of E3 ubiquitin ligases, Siah 1a/2 enzymes (Nakayama K et al 2004 Cell 117:941). Prolyl hydroxylation generates ubiquitin ligase binding sites in the von Hippel-Lindau tumor suppressor protein, resulting in the decay of HIF α . Some tumors containing HIF display reduced apoptosis and increased proliferation under anoxia because of the different response of genes to the homeostatic effect of HIF (Moeller BJ et al 2006 Cancer Cell 8:99). In contrast, HIF-2 α increased angiogenesis and yet enhanced apoptosis in rat gliomas; the net effect was tumor suppression. Therefore, HIF inhibitors may not be advisable for cancer therapeutic strategies (Acker T et al 2005 Cancer Cell 8:131). [►homeostasis](#), [►glycolysis](#), [►erythropoiesis](#), [►hypoglycemia](#), [►p53](#), [►p21](#), [►p27](#), [►GADD153](#), [►Bcl-2](#), [►apoptosis](#), [►CBP](#), [►hypoxia](#), [►von Hippel-Lindau syndrome](#); Wenger RH 2000 J Exp Biol 203:1253; Ramírez-Bergeron DL, Simon MC 2001 Stem Cells 19:279; Semenza GL 2001 Cell 107:1; Kaelin WG Jr 2005 Annu Rev Biochem 74:115; Pouyssegur J et al 2006 Nature [Lond] 441:437; review: Keith B, Simon MC 2007 Cell 129:465.

High-Content Screening: High-content screening bears similarity to high-throughput analysis but the properties of the tested compounds is tested by cell cultures, which register reactions by multiple biological criteria and not only by chemical reactivity. [►high-throughput analysis](#); Dove A 2003 Nature Biotechnol 21:859.

High-Density Lipoprotein (HDL): High-density lipoprotein is located in particles rich in various proteins and relatively low in cholesterol and cholesteryl esters. HDL is the benign lipoprotein; atherosclerosis is inversely related to the concentration of HDL. Lipoprotein lipase and endothelial lipase mutations may result in lower levels of HDL. The SR-BI scavenger receptor controls the amount of HDL and the concentration of cholesterol in the bile cells. The familial high-density lipoprotein deficiency syndrome

(FHA, 9q22-q31) is characterized by a susceptibility to coronary heart disease because of the low level of HDL cholesterol in the blood. The ABC transporters are apparently responsible for the normal balance between cholesterol export and LDL import. It is assumed that HDL promotes and facilitates the process of reverse cholesterol transport (RCT), whereby excess macrophage cholesterol is channeled to HDL and ultimately returned to the liver for excretion in the bile and feces (Lewis GF, Rader DJ 2005 Circulation Res 96:1221). Mutation of the ABC1 transporter accounts also for the Tangier disease. [►cholesterol](#), [►apolipoproteins](#), [►lipids](#), [►lipase deficiency](#), [►Tangier disease](#), [►LDL](#), [►hypertension](#), [►atherosclerosis](#), [►ABC transporters](#), [►SR-BI](#); Sacco RL et al 2001 JAMA 285:2729.

High Dose/Refuge Strategy: A high dose/refuge strategy has been designed to prevent the development of resistance in insect populations against toxins synthesized by transgenic plants for their protection against insects. The resistance gene is engineered to a high degree of resistance and dominant inheritance. Any mutation for countering the resistance is expected to be recessive and thus not selected effectively because in the heterozygotes the recessive allele is not expressed. Or, even if the counter-resistance is intermediate the high toxin level is expected to be lethal or deleterious to them. The refuge strategy is expected to reduce the genetic survival (fitness) of the counter-resistance. The refuge is the presence of nontoxic plants that allow the reproduction of the susceptible insects. When there are substantial numbers of susceptible insects, the rare recessive counter-resistant individuals will mate with them and there is a reduced probability for mating between two counter-resistant individuals. Therefore, the counter-resistant phenotypes will not be propagated and will eventually be eliminated. This strategy is very attractive theoretically yet under the conditions of the natural environment it may have limitations. (See Rauscher MD 2001 Nature [Lond] 411:857; [►insect resistance in plants](#), [►genetic sterilization](#), [►Cochliomya hominivorax](#)).

High-Energy Bond: Upon hydrolysis the covalent linkage liberates large amounts of free energy, e.g., the phosphodiester bond of ATP, thioester linkage in acetyl Coenzyme A. [►phosphodiester](#), [►thioester](#)

High-Frequency Lysate: When a temperate bacteriophage excises from the bacterial chromosome it may pick up an adjacent site. For example, bacteriophage λ may gain, from *E. coli* map position 17, a *galactose* gene, but because of the reciprocal recombination a piece of its own genetic material, required for lysogeny, may be left behind. Thus, the new phage

becomes *λdgal* (lambda-deficient-galactose). Such a phage particle may multiply vegetatively but its infecting ability is reduced. When a helper phage is inserted into the bacterial chromosome next to *λdgal*, the wild type phage gene may compensate for the defect and a *double lysogenic bacterium* is produced. Upon induction (to liberate phage), a *high-frequency lysate* containing the two types of the phages is produced with high transducing ability. ▶ [specialized transduction](#), ▶ [lambda phage](#); Hartman PE 1963 in: *Methodology in Basic Genetics*, Burdette BJ (ed) Holden-Day, San Francisco, CA, pp 103.

High-Frequency Transducing Lysate: HFT.

H

High-Lysine Corn: The seed proteins of cereals are composed of four major fractions in variable but frequently in closely equal amounts: prolamine (zein in maize, gliadin in wheat), glutenin, albumin, and globulin. In maize, the genetically determined lysine content is highly variable and subject to increase and decrease by selection for high or low zein content, respectively. Two families of genes *opaq* (*o*) and *floury* (*f*) scattered over the maize map are particularly influential in reducing the low-lysine protein fractions with the concomitant increase (doubling or more) of the percentage of this essential amino acid and that of tryptophan as well. In some *f12* lines the level of methionine is also substantially higher. Particularly beneficial effects are due to genes *o2*, *o7*, *f12*, and *f13*. In wheat, in mol/10⁵ g protein the lysine contents are: ca. gliadin 5.0, glutenin 17.6, albumin 78.4, and globulin 98.0. The *o2* maize itself also has a disadvantage, namely, the liability of the kernel to physical damage. In the Quality Protein Maize (QPM), genetic modifications make the kernels vitreous and more damage resistant. One genetic modifier is near the terminus of the long arm of chromosome 7 and it encodes a 27-kDa γ-zein, which is present in two- to three-fold amounts in QPM. The kernel structure—among other factors—is modified also by altered branching of amylopectin (Gibbon BC et al 2003 *Proc Natl Acad Sci USA* 100:15329). Cereals with improved nutritional values are desirable for feeding of animals and more importantly for the production of cereal food for human populations suffering from malnutrition as a result of protein deficiency in the diet (kwashiorkor). ▶ [essential amino acids](#), ▶ [kwashiorkor](#), ▶ [amylopectin](#), ▶ [zein](#); Coleman CE et al 1995 *Proc Natl Acad Sci USA* 92:6828; O'Quinn PR et al 2000 *J Anim Sci* 78:2144; Zarkadas CG et al 2000 *J Agric Food Chem* 48:5351.

High-Mobility Group of Proteins (HMG): This group of proteins is associated with functionally active chromatin and renders the genes more sensitive to DNase and probably to RNase II. HMGs also

promote the elongation of the RNA transcripts. They are regulated by cell-cycle-dependent phosphorylation, affecting their ability to bind to DNA. HMG proteins are important for growth and development. A large number of transcription factors contain HMG-like domains. The specificity of these proteins varies but a common feature is that they distort the DNA structure and have an affinity for distorted DNA structures. The change in DNA electrophoretic mobility is correlated with this altered structure. Thus, HMGs have both regulatory and structural functions. Recurrent rearrangements of the HMGI-C group were detected in some benign tumors (lipomas). There are three groups of these proteins: HMGI-C (12q15), HMGI, and HMGI(Y) encoded at 6p21. ▶ [chromatin](#), ▶ [nonhistone proteins](#), ▶ [cell cycle](#), ▶ [coactivator](#), ▶ [transcription factors](#), ▶ [FACT](#), ▶ [SOX](#), ▶ [DNA bending](#), ▶ [elongation factors](#), ▶ [lipomatosis](#); Bustin M 1999 *Mol Cell Biol* 19:5237; Reeves R et al 2001 *Mol Cell Biol* 21:575; in inflammation: Jiang W, Pisetzky DS 2007 *Nat Clin Rheumatol* 3:52.

High-Performance Liquid Chromatography (HPLC): A mixture of compounds is applied to chromatographic columns with strong ion exchange resins. The solvent is forced through the resin under pressure for rapid and sharp separation of the components of the mixture. The eluates are electronically scanned and identified. Denaturing high-performance liquid chromatography can be used to detect structural differences between mutant and wild type molecules. ▶ [chromatography](#)

High-Quality Sequence: A (final) stage of the contiguously sequenced genome that has an error rate of only ~10⁻⁴. ▶ [first-draft sequence](#), ▶ [genome projects](#)

High-Throughput Analysis: High-throughput analysis permits the study of large amounts of facts by the use of (generally) automated equipment, using the tools of bioinformatics, and working on the basis of combinatorial chemistry. ▶ [combinatorial chemistry](#), ▶ [high content screening](#)

Highly Repetitive DNA: Such DNA contains a high degree of redundancy and reassociates very rapidly after denaturation. ▶ [SINE](#), ▶ [LINE](#), ▶ [annealing](#), ▶ [C₀t value](#)

Hill Reaction: The Hill reaction occurs when illuminated chloroplasts evolve oxygen and reduce an artificial electron acceptor (ferricyanide → ferrocyanide). It was an important tool to study the mechanism of photosynthesis, namely, that the evolved oxygen comes from water rather than from CO₂ and it demonstrated that isolated chloroplasts can perform part of the reactions. It also

revealed the light-activated transfer of an electron from one substance to another against a chemical-potential gradient. ► [photosynthesis](#)

Hill-Robertson Effect (interference): The selection at one locus may hinder the choice of a favorable allele at another linked gene in a population in the absence of recombination. ► [hitchhiking](#), ► [genetic drag](#); Hill WG, Robertson A 1966 Genet Res 8:269.

Hilum: A depression or pit where vessels and nerves enter an organ; the place (↓) where the plant seed (see Fig. H44) is connected to its stalk in the fruit.

Figure H44. Hilum

him: A high incidence of male mutation in *Caenorhabditis* has a high level of nondisjunction in XX hermaphrodites and thus produces XO males. ► [nondisjunction](#), ► [chromosomal sex determination](#), ► [Caenorhabditis](#)

Himalayan Rabbit: The Himalayan rabbit carries temperature-sensitive tyrosinase genes controlling pigmentation.

The extremities, paws, ears, and tail having lower blood circulation and concomitant lower body temperature develop darker pigmentation (see Fig. H45). A similar pattern of pigmentation occurs in other rodents and in Siamese cats. Tyrosinase is a copper enzyme (also called polyphenol oxydase) and is involved in the formation of 3,4-dihydroxyphenylalanine (DOPA) that is responsible for the production of melanin in the hair and skin and darkening of wounded fruits and other plant tissues. ► [albinism](#), ► [piebaldism](#), ► [Siamese cat](#), ► [pigmentation of animals](#), ► [temperature-sensitive mutation](#)

HindIII: A restriction enzyme with recognition site shown at A↓AGCTT.

H-InvDB: An integrative annotation of human genes, description of gene structures, details of novel alternative splicing isoforms, non-protein-coding RNAs, functional domains, subcellular localizations, metabolic pathways, predictions of protein three-dimensional structure, mapping of known single nucleotide polymorphisms (SNPs), identification of polymorphic microsatellite repeats within human genes, and comparative results with mouse full-length cDNAs. (See Imanishi T et al 2004 PloS Biol 2(6):e162; <http://www.h-invitational.jp/>).

Hindbrain (rhombencephalon): The caudal part of the brain. It includes the cerebellum, pons (metencephalon), and the medulla oblongata (myelencephalon). ► [brain human](#)

HiNF (histone nuclear factor): A 48-K M_r protein, identical to interferon regulatory factor IRF-2. ► [IRF-2](#), ► [histones](#)

Hinge: ► [antibody](#)

Hinny: She-ass (2n = 62) x stallion (2n = 64) hybrid. The reciprocal (mare x jackass) is called mule (see Fig. H46). Mules are easier to produce because the jackass willingly mates with the mare but the stallion mates with the she-ass only under special circumstances (blindfolded). The hybrids' body resembles more closely the female parent as an apparent cytoplasmic influence. These sterile hybrids—known since the beginning of human civilization—may retain some sexual drive and occasionally fertility has been reported in backcrosses with either the jackass or the stallion. The jackass backcrosses are entirely sterile but the backcrosses with stallions appear more normal. Nuclear transplantation using horse oocytes and mule embryonal fibroblast nuclei has resulted in apparently normal offspring after normal gestation (Woods GL et al 2003 Science 301:1063). The advantages of the mule and hinny are that they are stronger and yet as resistant to stressful conditions as the donkey, and they can thrive on much less feed than the horse. The adults are generally

Figure H46. Hinny (left), mule (right)

healthier than the horse and well adapted to work under primitive conditions. These hybrids do not require iron hoof plates (horseshoes). They are more obstinate than the horse although they are shrewd and better self-disciplined under conditions scary to horses. ► [mule](#), ► [animal species hybrids](#), ► [nuclear transplantation](#); Rong R et al 1988 Cytogenet Cell Genet 47[3]:134.

HINT: An autoproteolysis and protein-splicing domain. (See Kroiher M et al 2000 Gene 241:317).

Hip: A 41.3-kDa cytosolic protein interacting with Hsc70; it is homologous with DnaJ. ► [Hsc](#), ► [DnaK](#), ► [molecular chaperone interacting complex](#), ► [huntingtin](#)

H

Hip Dislocation, Congenital: An autosomal dominant complex with a prevalence of about 0.001/live births. Generally involves laxity of joints.

Hippel-Lindau Syndrome: ► [von Hippel-Lindau syndrome](#)

Hippocampus: A seahorse-shaped, ventral-temporal gray matter part of the brain including seven layers of tissues. It is the presumed site of memory-amnesia-learning deficit, etc. During mouse hippocampal development, 1,926 genes displayed dynamic changes—by microarray analysis—and seem to be involved in neuronal proliferation, differentiation, and synapse formation. ► [brain human](#), ► [memory](#), ► [microarray hybridization](#), ► [synapse](#); Mody M et al 2001 Proc Natl Acad Sci USA 98:8862.

Hippopotamus (*Hippopotamus amphibius*): 2n = 36.

HIR: Genes involved in histone and nucleosome assembly at 22q11.2. ► [histones](#); Ray-Gallet D et al 2002 Mol Cell 2002 9:1091.

Hirschsprung's Disease (megacolon): Hirschsprung's disease occurs in several forms involving megacolon (large and dilated terminal section of the intestine), microcephaly (reduced head size), short stature, coloboma of the iris (the iris has two distinct colors) and unequal development of the two sides of the face, obstructed anus (the terminal end of the intestine) and bladder. In Hirschsprung's disease, in case of RET mutations, ganglia are absent from the colon of humans and mice. The symptoms may not all occur in each individual and were attributed most commonly to autosomal recessive endothelin receptor (chromosomal deletion 13q1-q32.1), and less frequently to autosomal dominant mutation (human chromosome 10q11.2) in the RET oncogene (receptor tyrosine kinase), or even to multifactorial inheritance. The RET loss mutation may have a dominant negative effect. A mutation at 9q31 appears to regulate the penetrance of RET. A noncoding element in the first

intron of the RET gene increases the disease risk twenty-fold (Sproat Emison E et al 2005 Nature [Lond] 434:857). Mutations in the glial cell-derived neurotrophic factor (GDNF), encoded in human chromosome 5p13.1-p12 may also have a minor role in the disease. Prevalence is about 1/5000 but among sibs about 1/25. The chance for males to be affected is three to five times higher than in females. Its incidence is high in Down's syndrome (6%) and in piebaldism. This disease also occurs in horses and mice and probably in pigs. Endothelin-3 mutations (20q13.2-q13.3) or defects in the endothelin converting enzyme (1p36.1) may also be responsible factors. In the complex Waardenburg-Hirschsprung disease, Waardenburg-Shah syndrome mutations in the SOX10 gene have been detected. One form is controlled by the Smad-interacting protein (Sip1) encoded at 2q22. The complex Hirschsprung disease may be the outcome of mutations of more than a single gene. ► [eye diseases](#), ► [coloboma](#), ► [stature in humans](#), ► [diabetes mellitus](#), ► [RET oncogene](#), ► [psoriasis](#), ► [hypogammaglobulinemia](#), ► [piebaldism](#), ► [endothelin](#), ► [Shah-Waardenburg syndrome](#), ► [aganglionosis](#), ► [SOX](#), ► [dominant negative](#), ► [Smad](#); Wakamatsu N et al 2001 Nature Genet 27:369; Gabriel SB et al 2002 Nature Genet 31:89.

Hirsh Suppressor: A mutation in *E. coli* tryptophanyl tRNA at G24A (a non-anticodon site) permitted it to pair with the UGA stop codon as well as with the wild type UGG codon and insert tryptophan into the amino acid sequence.

Hirsute: The word means hairy.

HIS Oncogenes (HS2): HIS oncogenes were identified in mouse chromosomes 2 and 19 from leukemia cells. The human homolog was assigned to 2q14-q21. ► [oncogenes](#), ► [leukemias](#)

HIS OPERON: A coordinately regulated gene cluster. In *Salmonella typhimurium*

gene order on the map: *E* (2) *I* (3) *F* (6) *A* (4) *H* (5) *B* (7,9) *C* (8) *D* (10) *G* (1)

and the numbers in parenthesis after each gene indicate the order of the biosynthetic steps the genes mediate. The substrates and products in the pathways are ordered below:

(1) PHOSPHORIBOSYL PYROPHOSPHATE + ATP → (2) PHOSPHORIBOSYL-ATP → (3) PHOSPHORIBOSYL-AMP → (4) PHOSPHORIBOSYL-FORMIMINOAMINOIMIDAZOLE-4-CARBOXAMIDE RIBONUCLEOTIDE + GLUTAMINE → (5) ? → (6) IMIDAZOLE GLYCEROL PHOSPHATE + AMINOIMIDAZOLE-4-CARBOXIAMIDE RIBONUCLEOTIDE → (7) IMIDAZOLEACETOL PHOSPHATE → (8) L-HISTIDINOL PHOSPHATE → (9) L-HISTIDINOL + PHOSPHATE

→ (10) L-HISTIDINE. ► *hut operon*; Alifano P et al 1996 Microbiol Rev 60:44.

Histamine (HA): A decarboxylated histidine (see Fig. H47). A vasodilator (expands blood vessels) mediates the contraction of smooth muscles. It is released in large amounts as part of the allergic response. In allergic persons an immunoglobulin E (IgE)-dependent histamine-releasing factor (HRF) is produced by lymphocytes. HA exerts its effect through four G protein-coupled receptors designated HA receptor H1, H2, H3, and H4. Compared with wild-type animals, mice with a disrupted HA H3 receptor (H3RKO), the expression of which is normally confined to cells of the nervous system, develop more severe disease and neuroinflammation. This effect is associated with dysregulation of blood-brain barrier permeability and increased expression of MIP-2, IP-10, and CXCR3 by peripheral T cells (Teuscher C et al 2007 Proc Natl Acad Sci USA 104:10146). Histamine H3 receptor agonists (imetit) (see Fig. H48) may be effective for treatment of obesity and diabetes (Yoshimoto R et al 2006 Proc Natl Acad Sci USA 103:13866). ► *basophils*, ► *mast cell*, ► *hypersensitive reaction*, ► *allergy*, ► *obesity*, ► *diabetes*, ► *blood-brain barrier*, ► *MIP-1a*, ► *IP³*, ► *CXCR*; Marek J et al 2001 Nature [Lond] 413:420.

Figure H47. Histamine

Figure H48. Imetit

Histidase (histidine ammonia-lyase): ► *histidinemia*

Histidine Kinase: A signal-transducing molecule of two components. One of the components, in response to environmental cues, autophosphorylates a histidine in the catalytic domain. The phosphate is then transferred to an aspartate within the second component, which is a response regulator, binding to another cellular protein to induce a cellular response. The histidine kinase may either be a transmembrane signal receptor or a cytoplasmic protein receiving the signal indirectly from another transmembrane receptor. In yeast, the histidine kinase, SLN1, seems to be a transmembrane protein with the kinase domain in the

NH₂ end region. It is joined to a response regulator domain at the COOH end. It appears that the sensor part is outside the cell and the kinase and the response regulator are within the cytoplasm. In yeast downstream of the histidine kinase (SLN1) the Ssk1 protein, normally phosphorylated by SLN1, is then inactive but when it is not phosphorylated it controls other protein(s) in the signal transduction pathway. Besides Ssk1, the mitogen-activated *HOG1* gene also encodes another SLN1 suppressor. HOG1 appears to be a homolog of MAP (mitogen activated protein kinase) and also Pbs2 which seems similar to the MAP kinase kinase (MAPKK). The ETR1 (ethylene response) histidine kinase gene of the plant *Arabidopsis* is organized after the yeast pattern and this histidine kinase gene is a signal transducer for ethylene. Downstream in the pathway acts the CTR1 (constitutive triple response) gene encoding a serine-threonine kinase negative regulator of ETR1. ► *histidine*, ► *histidine operon*, ► *signal transduction*, ► *ethylene*, ► *phytohormones*, ► *MAP*; West AH, Stock AM 2001 Trends Biochem Sci 26[6]:369.

Histidine Operon: ► *His operon*

Histidinemia: Histidinemia is caused by a deficiency of histidase enzyme (histidine ammonia-lyase) involved in the removal of a NH₃ from histidine. It frequently causes mental retardation and neurological abnormalities. Identification, by enzyme assays, is feasible prenatally. Its pattern of inheritance is not entirely clear. However, an autosomal recessive gene was assigned to human chromosome 12q22-q23. Its prevalence is 1 in 20,000 to 40,000 and in some isolated populations the heterozygote frequency was estimated to be as high as 3%. Histidinemia symptoms may be caused also by nongenetic factors. Histidase alleles were described in chromosome 10 of the mouse. ► *amino acid metabolism*

Histidyl tRNA Synthetase (HARS): Histidyl tRNA synthetase charges tRNA^{His} by histidine. Its gene is in human chromosome 5. ► *aminoacyl-tRNA synthetase*

Histiocytoid Lipidosis (familial cardiac lipidosis): A mitochondrial cardiomyopathy caused by accumulation of lipids in the heart muscle fibers. ► *mitochondrial diseases in humans*, ► *cardiomyopathies*; Reid JD et al 1968 J Pediatr 73:335.

Histiocytosis: A heterogeneous autosomal recessive lethal defect of the immune system, involving uncontrolled activation of the T cells and macrophages, fever, enlargement of the spleen and the liver (hepatosplenomegaly), reduction in the number of blood cells (cytopenia), and neurological disorders. The HPLH1 gene was assigned to 9q21.3-q22 and to

10q21-q22. The erythrophagocytotic lymphohistiocytosis gene was mapped to 11p13 and to 11q25, respectively. The complex disease was described also as familial hemophagocytotic lymphohistiocytosis (FHL, 10q21-q22) and familial histiocytotic reticulosis. The basic problem in FHL appears to be due to deficiency in perforin. ▶perforin; Göransdotter Ericson K et al 2001 Am J Hum Genet 668:590.

Histoblasts: Cell groups that give rise to dorsal epidermis (tergites) and ventral epidermis (sternites), respectively. ▶epidermis

Histochemistry: Histochemistry determines tissue components on the basis of in situ analysis of their chemical reactions by color and/or by specific antibodies. Histochemical techniques are useful tools to study developmental mechanisms (see Fig. H49). ▶Gomori's stain, ▶aequorin

Histocompatibility: ▶HLA, ▶(human leukocyte antigen), ▶leukocytes

Histone Acetylase: ▶histone acetyltransferases

Histone Acetyltransferases (HAT): Histone acetyltransferases are acylate amino acid (lysine, serine) residues in the nucleosomes. They contribute to the remodeling of the nucleosomal structure and facilitate transcription. HAT has a preference for Lys5 and Lys12 or Lys16 (at dosage compensation) in Histone 4. In the active chromatin histone 2a is less acylated than in the inactive one. Acetylated histones permit better DNA access for transcription factors and other proteins modulating gene expression. Histone H3 acetylation of lysine at the entry–exit site of DNA in the nucleosomes facilitates the recruitment of SWI/SNF chromatin remodeling complex (Xu F et al 2005 Cell 121:375). H3 lysine 56 acetylation appears to be needed for the repair of chromosomal DNA damage (Masumoto H et al 2005 Nature [Lond] 436:294). H3K56 acetylation is promoted by yeast protein Rtt109 in cooperation with Asf1 (Driscoll R et al

2007 Science 315:649). Some histones are acetylated at the chromatid location but histone acetylation also takes place in the cytoplasm before entering the nuclei. The RNA polymerase II holoenzyme complex also contains HAT activity. HATs may belong to the GNAT family of proteins (Gcn5-related acetyltransferases) of four conserved motifs. The MYST family (MOZ, Ybf2/Sas3, Sas2, Tip60) shares structural similarity with HATs. HATs may also acetylate several non-histone proteins. HATs play a role in development and in carcinogenesis. ▶GCN5, ▶SAGA, ▶Msl, ▶NuA, ▶p300, ▶CBP, ▶TFII 230/250, ▶PCAF, ▶nucleosomes, ▶promoter, ▶histones, ▶E1A, ▶CAC, ▶chromatin remodeling, ▶bromodomain, ▶dosage compensation, ▶ADA, ▶elongator, ▶acetyltransferases, ▶Asf1, ▶SWI/SNF; Imhof A et al 1997 Curr Biol 7:689; Berger SL 1999 Curr Opin Cell Biol 11:336; Brown CE et al 2000 Trends Biochem Sci 25:15; Roth SY et al 2001 Annu Rev Biochem 70:81; Davie JR et al 1999 Biochem Cell Biol 77:265; An W, Roeder RG 2003 J Biol Chem 278:1504; dynamics of histone acetylation and transcription: Clayton AL et al 2006 Mol Cell 23:289; site-specific acetylation and deacetylation: Shahbazian MD, Grunstein M 2007 Annu Rev Biochem 76:75.

Histone Code: The posttranslational modification of the N-termini of histones H2A, H2B, H3, and H4 may result in altered regulation of genes and altered epigenetic signaling. A study of lysines 5, 8, 12, and 16 substitutions for arginine in the tail of H4 histone, mimicking positively charged, unacetylated lysine states and changes in gene expression detected by microarray analysis, indicated the following. Only lysine 16 mutations had specific consequences for transcription. On the other hand, lysine 5, 8, and 12 affected the transcription in a cumulative manner of about 1,200 genes. Thus, the histone code was specific only for the lysine 16 site in yeast (Dion MF et al 2005 Proc Natl Acad Sci USA 102:5501). ▶histones, ▶epigenetics; He S et al 2003 Proc Natl Acad Sci USA 100:12033; Vu TH et al 2004 Hum Mol Genet 13:2233.

Histone Deacetylases (HDAC): Histone deacetylases are components of the transcriptional suppression system in the inactive chromatin. Both HDAC1 and HDAC2 form a complex with DNA topoisomerase II. There are at least nine HDACs in mammalian cells. The methyl-CpG-binding protein MeCP2 seems to be associated with histone deacetylase activity. Mutations of HDAS2, due to truncation of the protein, reduce its expression and make it more resistant to histone deacetylase inhibitors. Histone deacetylase defects are found in some cancer cells (e.g., nonpolyposis colorectal cancer) and such drugs may not be effective (Ropero S et al 2006 Nature Genet

38:566). The retinoblastoma protein may bind to the E2F transcription factors and the complex then apparently represses the promoters of cell cycle S phase genes. It may activate silenced genes, such as those showing position effect by centromeric or telomeric heterochromatin, and inactive X chromosomes in the mammalian females, imprinting and inactivated tumor suppressor genes. The steroid receptor coactivator (SRC-1) is required for the expression of these enzymes. Protein HDRP (HDAC-related protein) is associated with HDAC4, shares ~50% identity with the non-catalytic NH²-domain of HDAC4 and HDAC5, and seems to be a transcriptional repressor. SMRT (silencing mediator of retinoic acid and thyroid hormone receptor) and NCoR (nuclear receptor corepressor) activate HDAC3. The HDAC3 activation domain (DAD) includes a special motif and a SANT-like (SWI3, ADA2/NCoR/TFIIIB). In addition, it requires a surface exposed lysine residue for activation but not for interaction (Codina A et al 2005 Proc Natl Acad Sci USA 102:6009). Histone deacetylase 7 is expressed in the vascular endothelium and represses matrix metalloproteinase 10 and thereby maintains the integrity of blood vessels (Chang S et al 2006 Cell 126:321). Histone deacetylation and acetylation are not limited to the nucleosomal site including the promoter of a gene but both processes may have somewhat global effects. Blocking histone deacetylation by an antisense construct in *Arabidopsis* resulted in pleiotropic expression of several genes. HDAC inhibitors also inhibit tumors (Bolden JE et al 2006 Nature Rev Drug Discovery 5:769). The inhibition of histone deacetylase (by trichostatin) prevents homologous recombination and survival of cells but does not affect nonhomologous end-joining repair (Yaneva M et al 2005 Nucleic Acids Res 33:5320). ▶DHAC1, ▶HDA1, ▶HOS, ▶RPD, ▶E2F, ▶histone, ▶heterochromatin, ▶nucleosome, ▶chromatin remodeling, ▶ORC, ▶SRC-1, ▶REST, ▶signal transduction, ▶Mad, ▶RAR, ▶nonhomologous end-joining, ▶trichostatin, ▶SAHA, ▶CpG, ▶E1A, ▶NuRD, ▶Sin3/Rpd3, ▶SMRT, ▶N-CoR, ▶DNA methylation, ▶imprinting, ▶lyonization, ▶Xic, ▶Xist, ▶tumor suppressor gene, ▶histone demethylation, ▶topoisomerase, ▶hereditary nonpolyposis cancer; Ahringer J 2000 Trends Genet 16:351; Cress WD, Seto E 2000 J Cell Physiol 184:1; Tanny JC, Moazed D 2001 Proc Natl Acad Sci USA 98:415; Wade PA 2001 Hum Mol Genet 10:6693; Huang X, Kadanaga JT 2001 J Biol Chem 276:12497; Yang W-M et al 2002 J Biol Chem 277:9447.

Histone Demethylation: A lysine-specific demethylase (LSD1), a nuclear homolog amine oxidase removes the methyl group from lysine 3 of the histone H3

N-terminal tail and acts as a transcriptional corepressor. This enzyme cannot demethylate trimethylated lysine 4 of histone 3, the most active form of H3 in transcription. In the process LSD1 generates formaldehyde. The enzyme is present in *Schizosaccharomyces pombe* to humans and apparently plays a general role in gene regulation. Histone H3 lysine 36 demethylation also requires a JHDM1 histone demethylase domain, which in the presence of FeII and α -ketoglutarate demethylates H3-K36 and generates formaldehyde and succinate (Tsukada Y-i et al 2006 Nature [Lond] 439:811). JHDM2A demethylates H3K9 and facilitates transcription activation by the androgen receptor (Yamane K et al 2006 Cell 125:483). JMJD2A (jumoni domain containing) family members demethylate trimethylated and dimethylated lysines of histones (Whetstone JR et al 2006 Cell 125:467). The JMJD2 family protein GASC1 (gene amplified in squamous carcinoma 1) removes tri- and dimethylation of histones and the HP1 protein, and restores function to heterochromatinized DNA and contributes to cancer (Cloos PAC et al 2006 Nature [Lond] 442:307). JMJD2A/JHDM3A demethylates trimethyl H3 histone lysine 9 and lysine 36 and upregulates the expression of human ASCL2 (achaeta-like, 11p15.5) transcription factor involved in trophoblast development (Klose RJ et al 2006 Nature [Lond] 442:312). Human diseases attributed to defects in methylation (colon cancer, leukemias) may have a new therapeutic target. ▶histone deacetylation, ▶histone methyltransferases, ▶epigenesis, ▶COMPASS, ▶androgen, ▶androgen receptor; Shi Y et al 2004 Cell 119:941; Shi Y-J et al 2005 Mol Cell 19:857; Trojer P, Reinberg D 2006 Cell 125:213; crystal structure: Ng SS et al 2007 Nature [Lond] 448:87.

Histone Fold: The core histone octamer is composed of two tetramers (H2A, H2B, H3, H4) which share common motifs of two short α -helices and a long central helix connected by β bridges. Each monomer dimerizes in a head-to-tail arrangement and interacts with the DNA. ▶nucleosome, ▶histones; Selleck W et al 2001 Nature Struct Biol 8[8]:695.

Histone Methyltransferases (HMT): A family of gene-regulatory proteins. They repress gene expression and the cell cycle transition G1→S by chromatin remodeling. Methylation of Histone H3 on lysine 4, 36, and 79 is linked to the activation of genes. Methylation of H3 lysine 9 and 27 and H4 on lysine 20 is found in heterochromatin and in inactive genes in euchromatin (see Fig. H50). In *Arabidopsis*, Histone 3 Lys4 (H3K4me) dimethylation generally marks gene-related sequences and distinguishes them from non-transcribed regions. Trimethylation of H3K4 is a hallmark of the majority of active genes

Figure H50. Proteins binding methylated lysine residues in histones 3 and 4 of the nucleosomes. RNAi also affects methylation through HP1. CHD1 (chromodomain helicase DNA-binding protein 1), HP1 (heterochromatin protein 1), and PC (Polycomb protein) bind by chromodomain. P53HP1 (p53-binding protein) and CRB2 (Cut5-repeat-binding protein 2) bind through the Tudor domain, latter to lysine 20 of Histone 4. (Modified after Bannister AJ, Kouzarides T 2005 Nature [Lond] 436:1103)

(Santos-Rosa H et al 2002 Nature [Lond] 419:407). Demethylation of trimethyl-H3K4 is mediated by the Polycomb-like proteins Ring6a/MBLR and JARID1d that are transcribed at the ENGRAILED 2 gene at human chromosome 7q36 (Lee MG et al 2007 Cell 128:877). H3K27me3 is associated with silent genes that are involved in development. NURF nucleosome remodeling protein and ATP-dependent ISWI proteins are involved in the association with the H4K4me3 tails (Wysocka J et al 2006 Nature [Lond] 441:86). A plant homodomain (PHD) finger of human BPTF (bromodomain and PHD transcription factor) interacts with the H3K4me3 through its antiparallel β -sheets at specific amino acid sites (Li H et al 2006 Nature [Lond] 442:91). The ING2 (inhibitor of growth) subunit (a domain of the lipid-signaling PtdIn[5]P) of the repressive mSin3a-histone deacetylase 1 complex also can bind to trimethylated histones and mediate gene repression (Shi X et al 2006 Nature [Lond] 442:96; Pe-a PV et al 2006 Nature [Lond] 442:100). Lys4, Lys9, and Lys27 methylation in the nucleosomes seem to be regulated differently according to genes, tissues, and development (Alvarez-Venegas R, Avramova Z et al 2005 Nucleic Acids Res 33:5199). H3 lysine 9 may be di- and trimethylated in genetically active regions of mammals. H3 trimethylation at lysine 27 is mediated by EZH2 (enhancer of Zeste); Akt-mediated phosphorylation of EZH2 suppresses the process (Cha T-L et al 2005 Science 310:306). The COMPASS complex is involved in mono-, di-, and trimethylation of H3 K4 (Schneider J et al 2005 Mol Cell 19:849). This methylation is progressive during transcription and rapidly removed upon suppression. Thus, methylation is not a permanent epigenetic state but it may be reversed. Heterochromatin protein 1 γ is also

present during the elongation of the transcript by RNAS polymerase II (Vakoc CR et al 2005 Mol Cell 19:381).

SUV39H1 (Xp11.23, 412 amino acids) is homologous to the *Drosophila* Su(var)3-9 that is a suppressor of variegation. Members of this family are ubiquitous in eukaryotes. SUV39H1 methylates Lys9 in histone H3. It is associated with HP1, which is homologous to the two CBX-like proteins of 185 and 191 amino residues, respectively. HP1 targets the methyltransferase complex to the pericentromeric heterochromatin and to the promoters of genes to be silenced. HP1 α , with the cooperation of Histone H2A.Z, mediates the folding of the chromatin fibers (Fan JY et al 2004 Mol Cell 16:655). SUV39H1 generally occurs in a complex with histone deacetylase, required for methylation.

SUV39H deficiency leads to chromosomal instability, increased risk of tumors and male meiotic anomalies in mice. The retinoblastoma protein is also required for the activity of the complex since it controls the expression of translation elongation factor E2F. G9a is a novel mammalian lysine-preferring HMTase. Like SUV39H1, the first identified lysine-preferring mammalian HMTase, G9a transfers methyl groups to the lysine residues 4, 9 and 27 of histone H3 at a 10- to 20-fold higher efficiency than SUV39H1, which only methylates lysine 9. G9a has an enzymatic nature distinct from SUV39H1 and its homologue H2. G9a was also localized in the nucleus but not in the centromeric domain where the SUV39H1 member of the family is found. Histone-4 methyltransferases (PRMT1) methylates Arg 3 and that is followed by acetylation of the protruding H4 tails by p300. CARM1 and PRMT1 methylate H3 arginine 2, 17 and 26 and activate nuclear

receptors. Histone H3 lysine 4 demethylation in the nucleosomes is mediated by the BHC/LSD1 protein complex containing the REST transcription factor (Lee MG et al 2005 *Nature [Lond]* 437:432). Histone methylation may be preceded by monoubiquitination. A high-resolution map of histone methylation in the human genome is available for 20 histone lysines and arginine, for histone variant H2A.Z, RNA polymerase II and insulator-binding protein CTCF. Promoter, insulator, enhancer, and transcribed region methylation were identified. Mono-methylation of H3K27, H3K9, H4K20, H3K79, and H2BK5 were involved in activation whereas trimethylation of H3K27, H3K9, and H3K79 resulted in repression. H2A.Z is associated with regulatory elements. In T cells cancer breakpoints were associated frequently with H3K4 methylation (Barski A et al 2007 *Cell* 129:823). ▶[chromatin remodeling](#), ▶[NURF](#), ▶[ISWI](#), ▶[bromodomain](#), ▶[phosphoinositides](#), ▶[sin3](#), ▶[histone tail](#), ▶[histone variants](#), ▶[p300](#), ▶[retinoblastoma](#), ▶[E2F](#), ▶[position effect](#), ▶[histone code](#), ▶[methylation of proteins](#); Meisetz Nielsen SJ et al 2001 *Nature [Lond]* 412:561; Tachibana M et al 2001 *J Biol Chem* 276:25309; Wang H et al 2001 *Science* 293:853; Peters AHFM et al 2001 *Cell* 107:323; Kouzarides T 2002 *Current Opin Genet Dev* 12:198; Lachner M, Jenuwein T 2002 *Current Opin Cell Biol* 14:286; enzyme structure: Cheng X et al 2005 *Annu Rev Biophys Biomol Struct* 34:267; Shilatifard A 2006 *Annu Rev Biochem* 75:243.

Histone Phosphorylation: Histone phosphorylation has important roles in chromatin remodeling and initiation of transcription. In addition, C-terminal phosphorylation of H2A histone follows exposure to ionizing radiation. H2A and H2B phosphorylation may signal to caspases and apoptosis. H3 phosphorylation (by Ip11, AIR, NIMA) at Ser/Thr begins at the pericentromeric regions and then spreads along the chromosome arms before mitosis. In the latter cases it actually promotes chromosome condensation although for transcription relaxation of coiling is required and that takes place at chromatin remodeling. ▶[chromatin remodeling](#), ▶[histones](#), ▶[TAF_{II}230–250](#), ▶[Ip11](#), ▶[AIR](#), ▶[NIMA](#), ▶[survivin](#); Jenuwein T, Allis CD 2001 *Science* 293:1074; Nowak SJ, Corces VG 2004 *Trends Genet* 20:214.

Histone Tails: Histone tails are the N- and C-terminal amino acid sequences flanking the histone cores and assuring the coherence of the nucleosome octamer. The tail is frequently modified postranslationally and provides means for chromatin alteration and gene expression. The amino-terminal tail of Histone 3 (H3) and Histone 4 (H4) when methylated hinders gene expression. Proline (P) isomerase Fpr4, a member of the FK506 binding protein family, catalyzes proline

isomerization at sites P30 and P38 alters conformation of the protein. Isomerization of P38 inhibits the ability of Set2 (a methyltransferase) to methylate H3 lysine 36 (H3K36) and thus isomerization is another mechanism of regulating gene expression (Nelson CJ et al 2006 *Cell* 126:905). ▶[nucleosome](#), ▶[isomer](#), ▶[FK506](#), ▶[proline](#), ▶[methyltransferases](#), ▶[histone methyltransferases](#)

Histone Variants: Histone variants may involve only minor or major alterations. Histone 2AX (γ -H2AX) can be phosphorylated and has a role in repair of DNA double-strand break, synapsis, apoptosis, and immunoglobulin gene class switching as well as V(D)J recombination (Fernandez-Capetillo O et al 2004 *DNA Repair* 3:959). Checkpoint control gene MDC1 binds to H2AX and regulates responses to DNA double-strand breaks (Stucki M et al 2005 *Cell* 123:1213). Histone H2A.Z has a role in chromatin remodeling and chromosome segregation (Rangasamy D et al 2004 *Nature Struct Mol Biol* 11:650). H2A.Z in yeast is enriched in the intergenic regions and its presence is inversely proportional to the rate of transcription, not by suppression but by the activation of some genes involved in chromatin remodeling (Li B et al 2005 *Proc Natl Acad Sci USA* 102:18385). MacroH2A has developmental regulatory roles in silencing the mammalian X chromosome and other silencing functions (Chow JC, Brown CJ 2003 *Cell Mol Life Sci* 60:2586). H2A-Bbd has a large primary structure difference from the other H2A molecules and it appears to be a negative regulator of transcription (Bao Y et al 2004 *EMBO J* 23:3314). Methylation of H3 and H4 histones controls epigenetic changes (Grewal SIS et al 2004 *Curr Opin Cell Biol* 16:230). The linker histones of the H1 type display substantial variations among different species and in different tissues of the same individual (Vaquero A et al 2004 *Mol Cell* 16:93). In the germ cells, H3.3A and H3.3B replace most of Histone 3 during the development of spermatids from spermatogonia. In the centromere there is a specific CenH3 histone variant that replaces the canonical H3 histone. The H3.3 histone replaces histones displaced by replication and it serves as a marker for transcribed regions (Henikoff S et al 2004 *Trends Genet* 20:320). A single protein chaperone RbAp48 complex containing CenH3 and H4 assists in assembling, modifying, and remodeling of the chromatin. This complex is different from the H3 and H3.3 assembly complex (Furuyama T et al 2006 *Proc Natl Acad Sci USA* 103:6172).

These histones are very similar in amino acid composition although their coding sequence varies (Bramlage B et al 1997 *Differentiation* 62:13). Histone H3 is the only histone with one or two cysteine residues. Histone H3.3 replaces H3 in

transcriptionally active chromatin (Mito Y et al 2005 Nature Genet 37:1090). CENP-A (centromeric protein) is also a variant of H3. TH2B is a testis-specific variant of H2B displaying additional phosphorylation sites and is present in octamers very similarly to somatic histones (Li A et al 2005 Biochemistry 44:2529). H1 has different variants (Kimmins S, Sassone-Corsi P 2005 Nature [Lond] 434:583) that are present during gametogenesis: H1t (in pachytene to elongating spermatids), H1t2 (in round and elongated spermatids), HILS1 (with shorter C terminus in elongated spermatids), and H1Foo (with elongated C terminus in oocytes). Histone B4 occurs in early development of the embryo and changes into H1 later. HB4 makes chromatin more accessible (Saeki H et al 2005 Proc Natl Acad Sci USA 102:5697). ►histones, ►epigenesis, ►transcription, ►double-strand breaks, ►sister chromatid exchange, ►spermiogenesis, ►centromere; He H, Lehming N 2003 Briefings Funct Genom Proteom 2:234; Sarma K, Reinberg D 2005 Nature Rev Mol Cell Biol 6:139; H3 variants and H3 barcode hypothesis: Hake SB, Allis CD 2006 Proc Natl Acad Sci USA 103.

Histones: Histones are five basic (rich in arginine and lysine) DNA-binding proteins. H2A, H2B, H3, and H4 are parts of the nucleosome core and H1 (H5 in birds) is generally a linker between nucleosomes. In mammals H1 has several isoforms, which may regulate gene expression. H1 deficiency may cause changes in the methylation pattern of DNA and developmental alterations in *Arabidopsis* (Wierzbiczki AT, Jerzmanowski A 2005 Genetics 169:997). Reduction of H1 alters chromatin structure but it influences the expression of only a few genes. It primarily affects imprinted and X-chromosomal genes (Fan Y et al 2005 Cell 123:1199). H2AX may be a modified C-terminal phosphorylated histone (γ -H2AX) that may be present in 15% of H2A. H2AX seems to protect chromatin against the consequences of double-strand breaks of the DNA and against cancer, especially in the presence of active p53 (Bassing CH et al 2003 Cell 114:359; Celeste A et al 2003 Cell 114:371). The histone genes were highly conserved during evolution. The N-terminal domains of the core histones and the C-terminal domain of H2A protrude from the nucleosomes and provide means for interacting with other proteins involved in genetic regulation and repair. The macroH2A variant is involved in the inactivation of the inactive X chromosome (lyonization). Phosphorylation of serine and acetylation of lysine residues in the N-terminal domain of core histones (H3, H4) contributes to modulation of transcription by the nucleosomal structure. H3 arginine methylation occurs in active transcription. This process is facilitated by

CARM1/PRMT4 (coactivator-associated arginine methyltransferase). Deimination of arginine by PADI4 (peptidyl arginine deiminase) produces citrulline from arginine and antagonizes transcriptional induction (Cuthbert GL et al 2004 Cell 118:545). Acetylation/deacetylation, phosphorylation, and methylation mediate the modulation. Methylation of tail lysines and arginines may result in activation or repression depending on the residue modified. Lys4 methylation prevents the recruitment of histone deacetylase to the active coding region and protein Set1 protects against the deacetylase (Bernstein BE et al 2002 Proc Natl Acad Sci USA 99:8695). Subsequently, a combination of proteins is attracted to the N end. There are 17 lysine and 7 arginine residues that can potentially be methylated, and considering other sites of methylation the combinatorial chance is about 3×10^{11} (Bannister AJ, Kouzarides T 2005 Nature [Lond] 436:1103). It is assumed that these accessory proteins represent a “histone code” for the regulation of chromatin remodeling and transcription (Turner BM 2002 Cell 111:285). The H2A tail contains a leucine zipper, which may be involved in interaction with the TATA box-associated proteins. The “deviant” histones may associate with the nucleosomal structure and exercise regulatory roles. The centromeric nucleosomes bind specific proteins (CENP-A, CENP-B, CENP-C) that are essential for proper chromosome segregation. The H1 and H5 linker histone in the nucleosomal structure contain a “winged helix”, a bundle of three α -helices attached to a three-stranded antiparallel β -sheet. The absence of H1 may slightly decrease the expression of some yeast genes (Hellauer K et al 2001 J Biol Chem 276:13587). This structure is found in sequence-specific regulator proteins like the catabolite activator protein and the hepatocyte-activating factor HNF3. The HNF3 protein replaces the H1 linker within chromatin containing the serum albumin enhancer. Similarly, H3 may be replaced by CENP-A at the centromere. Histones also regulate telomeric sites and the silent mating type locus. The yeast nucleosomes are compact and may not have H1 although a H1 gene was discovered in chromosome XVI. In *Tetrahymena*, H1 may act as specific positive or negative regulator for some genes but does not have a general regulatory role in transcription although it is believed that H1 stabilizes the higher order of chromatin structure. These pieces of information indicate the special role of histones and nucleosomes in gene regulation through chromatin structure. The histone genes lack introns; their mRNA is not polyadenylated. In the mammalian spermatozoa, protamines and transition proteins replace the somatic histones during maturation. The histone level may be controlled by ubiquitination. Histone2B (but not H2A) is specifically deubiquitinated by the USP7-GMPS complex (van der Knaap J

et al 2005 Mol Cell 17:695). Histone H2A ubiquitination is associated with the E3 ubiquitin ligase complex. The complex is composed of several Polycomb-group proteins (Wang H et al 2004 Nature [Lond] 431:873). ►nucleosome, ►H1TF2, ►HU, ►HiNF, ►CCE, ►chromatin, ►spermiogenesis, ►RPD, ►lyonization, ►histone acetyltransferase, ►histone deacetylase, ►LCR, ►promoter, ►chromatin remodeling, ►CARM1, ►ubiquitin, ►histone variants, ►Polycomb, ►parental histone segregation; Santisteban MS et al 2000 Cell 103:411; Nakayama J-i et al 2001 Science 292:110; Faast R et al 2001 Curr Biol 11:1183; Marmorstein R 2001 Nature Rev Mol Cell Biol 2:422; Jenuwein T, Allis CD 2001 Science 293:1074; Celeste A et al 2002 Science 296:922; Ahmad K, Henikoff S 2002 Mol Cell 9:1191; Nishioka K et al 2002 Mol Cell 9:1201; Peterson CL, Laniel M-A 2004 Current Biol 14:R546; Johnson L et al 2004 Nucleic Acids Res 32:6511; histone modifications and gene expression: Shilatifard A 2006 Annu Rev Biochem 75:243; proteomics approach for the analysis of modification: Macek B et al 2006 Mol Cell Proteomics 5:949; <http://genome.nhgri.nih.gov/histones/>.

Historical Control: The concurrent controls are run along the experimental series. In some instances this is impossible to use (e.g., some epidemiological studies, effects of environmental pollution, etc.) because there are no means to exempt the control from the overall consequences of the factors studied. For example, if we want to assess the effect of a particular compulsive vaccination system there is no contemporaneous non-vaccinated cohort group for the comparison. In such cases, similar data preceding the experiment or control data collected elsewhere under similar conditions are used as standard for the comparisons. ►control, ►concurrent control, ►cohort

Histotope: The site of the MHC molecule recognized by the T cell receptor. ►MHC, ►TCR, ►agretope, ►desetope, ►epitope

Hit and Run Technique: This technique is expected to target the mutation or replacement of only a single nucleotide or a very minute segment of a gene. The causative agent is not permanently required for the altered state. ►targeting genes; Skinner GG 1976 Br J Exp Pathol 57[4]:361.

Hitchhiking: Non-advantageous genes may be maintained in a population because of their close linkage to genes of selective advantage. The effect of hitchhiking is inversely proportional to the frequency of recombination. Directional hitchhiking models assume that linked polymorphism is periodically eliminated from the population, yet it is replenished by mutation and genetic drift. ►linkage drag,

►genetic load, ►Hill-Robertson effect, ►linkage disequilibrium, ►Muller's ratchet, ►evolvability, ►background selection, ►pseudo-hitchhiking, ►H test; Maynard-Smith J, Haigh J 1974 Genet Res 23:23; Barton NH 2000 Philos Trans R Soc London B Biol Sci 355:1553; Fu YX 1997 Genetics 147:915.

Hit Theory: ►target theory

HIV-1, HIV-2: HIV-1 and HIV-2 are lentiviruses and causative agents of acquired immunodeficiency disease which suddenly erupted in the 1950s. These two different yet related viruses evolved from the related Simian viruses (SIV) long present in about 26 African primate species. Generally, in the wild primates SIV infection does not lead to a devastating disease like in humans. The HIV-1 is supposedly originated from chimpanzees while HIV-2 from the sooty mangabeys although the transmission from nonhuman primates to humans has taken place repeatedly from the 1930s on. ►acquired immunodeficiency (AIDS), ►viral vectors, ►lentivirus, ►SIV, Hahn BH et al 2000 Science 287:607; <http://www.hiv.lanl.gov/content/index>; HIV Protein Interaction Database: <http://www.ncbi.nlm.nih.gov/RefSeq/HIVInteractions/index.html>; recombination server: <http://jphmm.gobics.de/>.

Hix: An invertase. ►invertases
